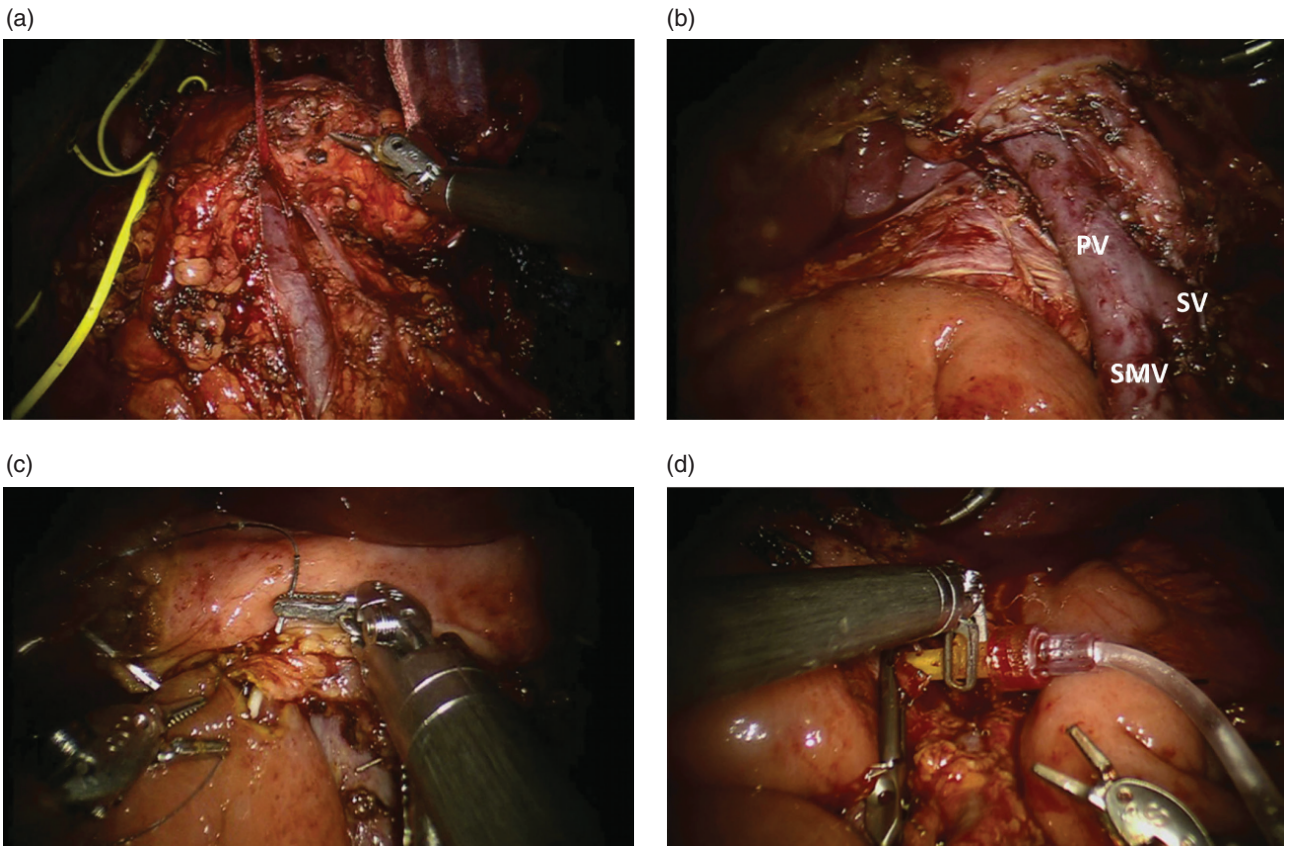

**Figure 60.1** Robotic-assisted total pancreatectomy with auto-islet transplantation. (a) Pancreatic neck is freed from the superior mesenteric vein (SMV), splenic vein (SV), and portal vein (PV). (b) Resection of entire pancreas from the retroperitoneum. (c) Creation of hepaticojejunostomy over a stent. (d) Angiocatheter introduced through the SV stump for islet cell infusion.

patients with chronic pancreatitis underwent AIT; seven patients had concomitant splenectomy while two were spleen-preserving. Median operative time was 560 minutes and median EBL was 650 mL. There was no 90-day mortality, and two Clavien–Dingo grade III complications were reported in two patients, including pleural effusion and fascial dehiscence. The median length of stay (LOS) was 10 days. These results are comparable to a recently published series of 12 TPIAT through an open approach [20].

## Pancreaticoduodenectomy (Whipple)

The last 10 years have witnessed an increasing number of single-institution reports of minimally invasive pancreaticoduodenectomy, but the efficacy of either laparoscopic or robotic pancreaticoduodenectomy for chronic pancreatitis still requires larger series and a more robust assessment of outcomes. It can be inferred from these studies that include benign and malignant indications that the minimally invasive pancreaticoduodenectomy is a safe and feasible procedure for select cases at high-volume centers. A recent systematic review, for example, comparing laparoscopic and open pancreaticoduodenectomy (17.5% for benign disease) found similar rates of postoperative morbidity [7]. The study included 25 articles encompassing 746 cases of laparoscopic pancreaticoduodenectomies: 386 (52%) were pure laparoscopy, 121 (16%) with laparoscopic assistance, 231 (31%) with robotic assistance, and 5 (1%) with hand assistance. Overall, open conversion was necessary in 9.1% of all cases. Mean operative time was 464 minutes and EBL 321 mL. The morbidity rate was 41%, including 22% patients developing pancreatic fistula, and mortality 1.9%. Mean LOS was 13.6 days. Pure laparoscopy was associated with shorter operative times, less blood loss, and lower rates of pancreatic fistula. Laparoscopic assistance had shorter operative times than robotic assistance, but higher rates of blood loss and pancreatic fistulas. The largest available single-institution review of robotic pancreaticoduodenectomy (132 cases) performed for various indications reported outcomes comparable to open historic controls [6].

## Distal Pancreatectomy

Similar to pancreatic head resections, the majority of studies comparing laparoscopic with open distal pancreatectomy do not stratify between benign and malignant indications. Specifically, data on minimally invasive

distal pancreatectomy for chronic pancreatitis are lacking and limited to a handful of small series such as that by Fernandez-Cruz et al., who reported a series of five chronic pancreatitis patients who underwent LDP with spleen preservation, compared to 41 open pancreaticoduodenectomies with or without splenectomy [8]. This early study suggested that LDP for chronic pancreatitis was feasible with acceptable outcomes.

LDP appears to be a safe and feasible approach for the treatment of left-sided pancreatic pathology. A systematic review of 18 studies by Venkat et al. (1814 patients) comparing laparoscopic (43%) and open (57%) distal pancreatectomies for all indications found that the laparoscopic technique was associated with decreased intraoperative blood loss by 355 mL, surgical site infections (3% vs. 8%), postoperative complications (34% vs. 44%), and decreased length of hospital stay by 4 days [9], with no differences in operative time, postoperative pancreatic fistula, or mortality. In addition, two single-institution retrospective series also suggest the robotic approach to distal pancreatectomy may have lower rates of open conversion, and higher rates of splenic preservation compared to conventional laparoscopy [21,22]; this latter benefit, however, may not be translatable in the setting of adhesive chronic pancreatitis.

## Drainage Procedures

### Lateral Pancreaticojejunostomy (Puestow)

The conventional open lateral pancreaticojejunostomy (LPJ) can be associated with high morbidity rates of up to 25% and a morality <5% [10]. Limited case reports of laparoscopic LPJ have shown it to be feasible, safe, and effective [10,12]. In 2014, Khaled et al. described five laparoscopic LPJ for chronic pancreatitis with a median operative time of 278 minutes and EBL of 150 mL with no mortality and 5 day LOS. At a follow-up of 14 months, four out of the five patients were pain free [12]. These results are comparable to a recent literature review of 37 laparoscopic LPJs that reports a mean operative time of 218 minutes, 0% mortality, and mean 5.5 day LOS. There was a 13.5% rate of open conversion and 13.5% complication rate. Importantly, at variable rates of follow-up between 5 and 84 months, 89% of patients were pain free [10].

A single-case report of a robotic-assisted LPJ in a 14-year-old child with idiopathic chronic pancreatitis was recently reported. Reported operative time and EBL were 390 minutes 8 days, and the patient remained asymptomatic and pain free at 2 years postoperatively [11].

### Cyst Gastrostomy

Complications of pancreatitis such as pseudocyst, walled-off necrosis (WON), and infected WON are increasingly being managed by minimally invasive techniques. Although WON have been traditionally treated with open cyst gastrostomy (or cyst jejunostomy if the WON is not retrogastric in location) and necrosectomy, the associated operative morbidity of this approach has spawned the application of endoscopic and minimally invasive surgical alternatives (Fig. 60.2) [13,15].

Deciding between an endoscopic versus minimally invasive approach to cyst gastrostomy and necrosectomy should take several factors into consideration. Endoscopic and laparoscopic cyst gastrostomy have been shown to have comparable mortality and morbidity, but the reintervention rate is usually higher using the endoscopic route [15]. Khreiss et al. compared 20 patients with sterile WON undergoing minimally invasive surgical drainage with 20 patients undergoing endoscopic drainage. In the laparoscopic group, the median operating room time was 167 minutes with 30 mL EBL. There were no open conversions, reoperations, or periprocedural mortality, and both groups had equal complication rates (20%). However 45% of the endoscopic patients required a reintervention for residual WON, compared to 15% in the minimally invasive surgical group. Despite a shorter LOS in the endoscopic group (2 days vs. 7 days), surgical patients had a faster time to resolution (mean 0.42 months vs. 3.6 months). The authors concluded that minimally invasive cystgastrostomy and debridement for WON can be advantageous, especially if a concomitant cholecystectomy is needed at the time of the WON drainage. A similar retrospective review of 21 patients with pancreatic necrosis (14/21 with sterile necrosis) by Worhunsky et al. reported that 19 of 21 patients (90%) were successfully debrided in a single operation without requiring additional interventions [14].

### Video-Assisted Laparoscopic Retroperitoneal Debridement

Video-assisted retroperitoneal debridement (VARD) is a minimally invasive technique that allows debridement of WON via a retroperitoneal route. The presence of a retroperitoneal drain—especially on the left side—is a requirement for a VARD procedure, since it provides a direct unimpeded route to the necrosum, thereby avoiding associated peritoneal inflammation and adhesions. Briefly, the procedure entails placing a laparoscopic port into the retroperitoneal cavity with the guidance of a percutaneous drain. Irrigation, suction, and direct debridement are gently conducted under direct visualization. A large sump drain is left in the cavity at the conclusion of the operation. Postoperatively, scheduled lavage using normal saline or dilute hydrogen peroxide is repeated until the effluent is clear.

Horvath et al. analyzed 40 patients with pancreatic necrosis across six tertiary care centers; 9 of whom were treated with drains alone, 25 with VARD, and 6 with

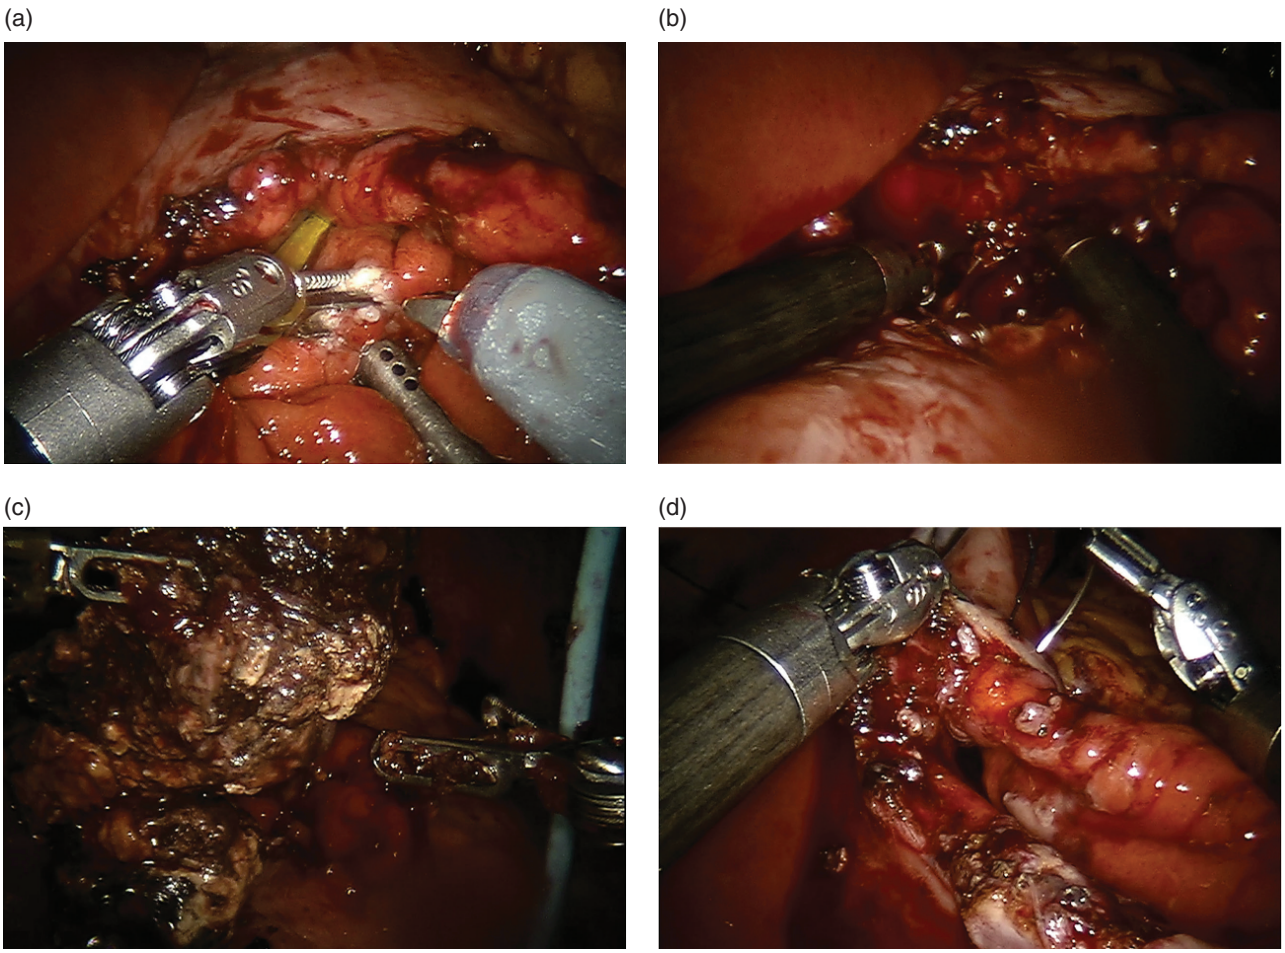

**Figure 60.2** Robotic-assisted laparoscopic cyst gastrostomy. (a) Anterior cyst gastrostomy. (b) Posterior cyst gastrostomy. (c) Pancreatic debridement. (d) Gastrostomy closure.

planned open surgery [16]. Patients already treated with a percutaneous drain were enrolled, and received an additional retroperitoneal drain (within 48 hours of enrollment) that was upsized every 3–4 days until a 20 F catheter was reached. Patients underwent a computed tomography (CT) scan on postdrain day 10–14; those exhibiting >75% reductions in collection size were treated with drains alone. Out of 25 patients requiring VARD, 10 (40%) required an open conversion and 19% required a second VARD. The most common cause of open conversion was a centromedial collection with extension into the mesenteric root that was not accessible from the flank. The mean operative time was 135 minutes. There were 4 (16%) primary VARD-related complications including bleeding and enteric fistula, and 9 secondary complications (pneumonia, deep vein thrombosis, respiratory failure, bacteremia, pseudocyst, pancreatic fistula). The median LOS was 64 days, and there were no 30-day mortalities, though there was 1 death (4%) between 3–6 months following discharge.

Overall, low reported rates of morbidity and mortality for VARD compare favorably to open necrosectomy. As 23% of 40 patients in the Horvath study were successfully treated with percutaneous drainage alone, and in accordance with the "step-up approach" [23], it is reasonable to begin with percutaneous or endoscopic drainage. Of note, 75% size reduction of the necrotic collection at 10–14 days on CT scan in the Horvath study predicted success of percutaneous drains alone with 100% accuracy. If patients fail to progress clinically, treatment may be escalated to additional drains, or a VARD.

## Combination Procedures (Resection and Drainage)

### Frey Procedure

The surgical tenets of the laparoscopic Frey procedure are closely modeled after the open technique, as depicted in Fig. 60.3. However, data from Europe and the United States on outcomes following laparoscopic Frey procedure for chronic pancreatitis are limited to case reports [18].

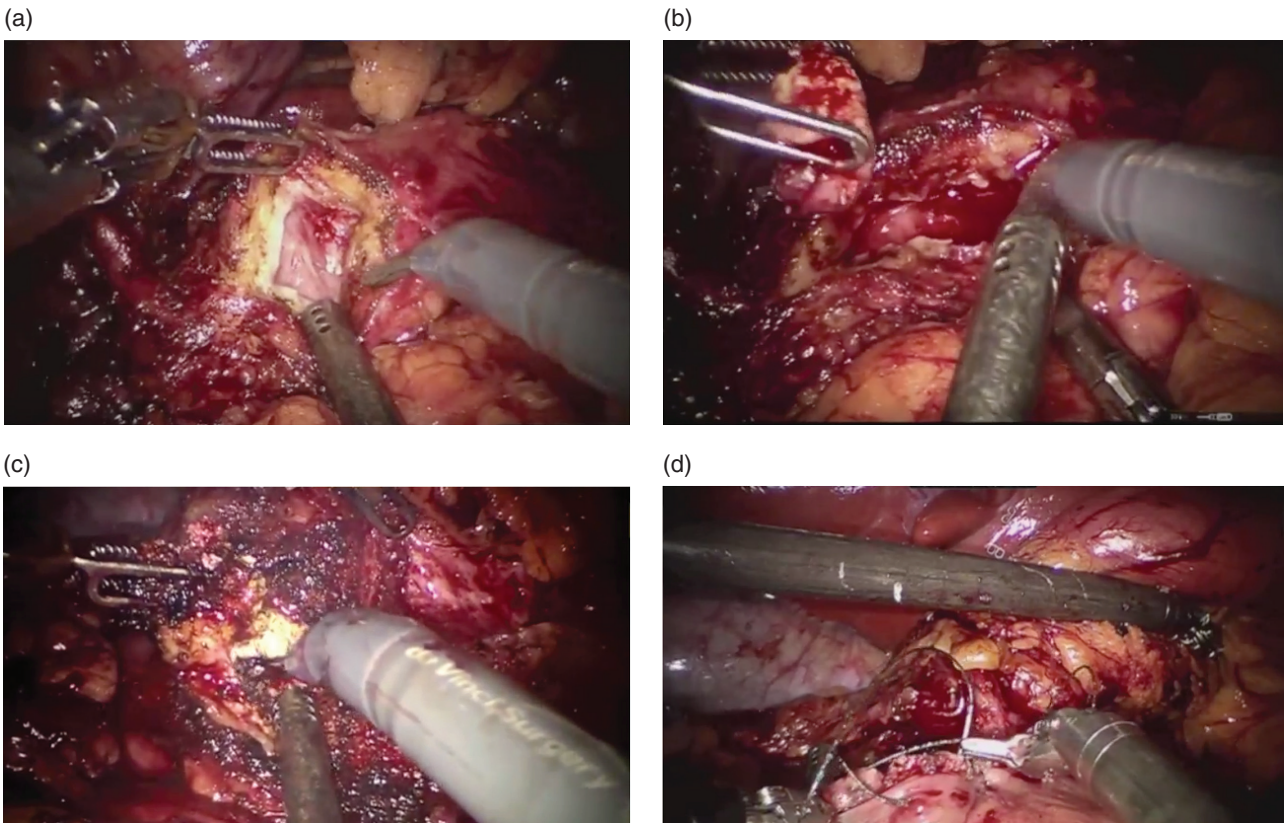

**Figure 60.3** Robotic-assisted Frey procedure. (a) Opening of pancreatic duct. (b) Removal of pancreatic duct stones. (c) Enucleation of pancreatic head. (d) Lateral pancreaticojejunostomy.

A single-institution experience in China described 9 laparoscopic and 37 open Frey procedures for chronic pancreatitis [19]. In 2 (22%) laparoscopic cases, open conversion was necessary due to inability to locate the pancreatic duct. In the 7 laparoscopic completions, mean operating room time was 323 minutes with 57 mL of blood loss. There was 1 postoperative complication of postpancreatectomy hemorrhage, with no mortality. Average LOS was 7 days. At 3-month follow-up, all seven patients had significantly decreased visual analog scale (VAS) scores for pain. Outcomes were comparable to the open cohort. The authors recommended a minimum pancreatic duct width of >8 mm for successful laparoscopic intervention.

### Beger Procedure

Available data on the laparoscopic Beger procedure is scarce. A case report of a laparoscopic Beger procedure with "Berne modification" in a patient with an inflammatory head mass causing an intrapancreatic common bile duct stricture documented [12] an operative time of 285 minutes. The patient was discharged after 5 days without complications and at 16-month follow-up reported mild pain, controlled with one-third of the preoperative oral opioid dose.

## Patient Selection

Laparoscopic pancreatic resection, drainage, or combination procedures offer the advantages of minimally invasive surgery to appropriately selected patients. For example, young adults with hereditary pancreatitis may benefit from less pain and psychological trauma that is associated with a laparotomy scar. The specific procedure of choice will depend on patient factors, as well as anatomic considerations such as the presence of a pancreatic head mass, peripancreatic fluid collection, dilated pancreatic duct, etc. Patient-related factors including age, comorbidities, body habitus, ability to tolerate pneumoperitoneum, prior pancreatic interventions, and abdominal surgeries are also important to consider when deciding on minimally invasive approaches to chronic pancreatitis. Importantly, given the infrequent indication for surgical interventions in chronic pancreatitis, minimally invasive pancreatic operations for chronic pancreatitis are best delivered at high-volume tertiary centers, by experienced pancreatic surgeons, in the context of multidisciplinary assessment. The operative approach to such patients (open, laparoscopic or robotic assisted) must be dictated by surgeon experience and comfort level.

## Conclusion

Although limited by small retrospective studies and case reports, laparoscopic approaches for chronic pancreatitis are safe and feasible in highly specialized centers. Analogous to the open approach, a myriad of resection, drainage, and combination type procedures can be performed. Further comparative studies on the efficacy of minimally invasive approaches and their impact on the quality of life of this patient subset are needed.

# Management of Diabetes and Long-Term Outcome of Chronic Pancreatitis

## 61

## Chronic Pancreatitis: Long-Term Outcome After Medical and Surgical Treatment

*Volker Aßfalg, Norbert Hüser, and Helmut Friess*

*Technical University of Munich, School of Medicine, Klinikum rechts der Isar, Department of Surgery, Munich, Germany*

## Introduction

Both interventional and surgical approaches can be used to treat outflow disorders of the pancreatic duct or the common bile duct and pseudocysts due to chronic pancreatitis. The best procedure for symptom-oriented therapy has to be decided on according to the clinical appearance of the patient and the varying disease patterns on the one hand and the long-term outcome on the other hand. A primary aim is the provision of adequate pain therapy. Whereas Chapters 55–60 focus on interventional and surgical procedures for pseudocysts, pain due to chronic pancreatitis, and biliary and pancreatic duct obstructions, this chapter reports on long-term results and discusses the significance within the context of complex treatment of chronic pancreatitis.

## Outcomes of Interventional and Surgical Therapy for Pancreatic Pseudocysts

### Results of Interventional Therapy for Pseudocysts

The etiology of pseudocysts has to be considered during therapy planning. Internal drainage techniques have increasingly replaced percutaneous methods. Today, computed tomography (CT)- or ultrasound-guided percutaneous puncture and drainage is almost always restricted to emergency relief of infected or necrotic cysts. The reason for this development is the observation of recurrence in as many as 70% of patients and cutaneous fistulas in up to 20% of patients. An analysis in terms of the effectiveness of percutanously drained pseudocysts remains difficult because of inconsistencies in the nomenclature of pseudocysts in different studies. Moreover, there are no data on long-term surveillance.

Pancreatic pseudocysts can be drained safely by transgastric, transduodenal, or transpapillary routes using an endoscopic approach with placement of stents in the cyst cavity. However, there are no prospective data concerning the best time point for changing the stents and the duration of stent therapy. In the case of a transmural drainage of cysts the distance between cyst cavity and the wall of the hollow organ should be as small as possible to reduce the risk of stent dislocation. Endoscopic ultrasound (EUS)-guided puncture and drainage of a cyst is technically superior to the non-ultrasound-guided transmural drainage (success rate 94% vs. 72%), whereas no differences exist with regard to complication rate and short-term treatment outcome [1]. The long-term results from endoscopically inserted stent therapy are difficult to determine because of an inconsistent nomenclature and consideration of the etiology (acute vs. chronic) of the pseudocysts. Recent studies report symptom resolution, and therefore therapeutic effectiveness, of up to 91% and mortality of less than 1%, on the one hand, and a maximum recurrence rate of 18% in long-term follow-up (median 6–43 months), on the other hand [2–4].

### Results of Surgical Therapy for Pseudocysts

The aim of surgery is the eradication of the cyst. However, surgical therapy increasingly comes up against the complex pseudocysts frequently associated with chronic pancreatitis. These include huge pseudocysts, multiple pseudocysts, or those with simultaneous stone- or stricture-associated changes and truncation of the pancreatic duct [5]. The so-called internal and external drainage procedures can be expanded by a partial resection of the pancreas.

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

External drainage surgery has no noteworthy status in the therapy of chronic pancreatitis. The long-term prospect of success is too low and these procedures are therefore at most performed to relieve infected pseudocysts in acute pancreatitis. There are no data on the long-term outcome of these procedures in chronic pancreatitis.

Internal drainage procedures include pseudocyst gastrostomy, pseudocyst duodenostomy, and pseudocyst jejunostomy. If possible, the anastomosis should be placed at the lowest part of the cysts to guarantee longstanding complete emptying. Depending on the localization of the pseudocysts and the underlying disease the technical feasibility ranges between 90% and 100%, with an average rate of recurrence of 12% in long-term follow-up. The procedure-associated mortality is 2.5% and the morbidity is approximately 16% [5]. Although there are no randomized trials, a center-specific overview suggests that pseudocyst jejunostomy is the preferred surgical procedure compared to pseudocyst gastrostomy.

Surgical procedures for drainage of pseudocysts have slightly higher success rates but also have a higher morbidity compared to endoscopic pseudocyst drainage into the duodenum or the stomach. Surgical resection procedures are mainly performed in cases of obstruction of the pancreatic duct or of the bile duct in the course of chronic pancreatitis.

Unfortunately, there are currently no randomized trials comparing surgical and endoscopic and interventional drainage procedures for pseudocysts. Comparison and evaluation of operative, interventional, and endoscopic drainage procedures is difficult because of the different accompanying morbidities in what is a very heterogeneous patient group.

Laparoscopic surgery has been established for pseudocyst jejunostomy, a combined laparo-endoscopic intragastric pancreatic pseudocyst gastrostomy, and pseudocyst gastrostomy via an anterior approach. Hitherto, the significance of the different procedures has not been finally classified because there are no prospective randomized trails. The perioperative complication rate is less than 10% and the long-term follow-up of some studies is longer than 6 years [6]. Thanks to a recurrence rate between 0% and 13% [7], the effectiveness and safety of the laparoscopic procedures can be compared with open surgery. Both the comorbidities of the patients and the nature and localization of the pseudocysts are very heterogeneous. All these aspects impact on the short-term course, but also have a particular effect on the long-term outcome of interventional, endoscopic, and surgical treatments of pseudocysts. Needless to say, the experience and expertise of the treating endoscopist, interventional radiologist, or surgeon play important roles. To achieve reliable statements in terms of therapeutic procedures and follow-up there is a need for clear definitions of pseudocysts and comprehensive consideration of the etiology of pancreatitis [8].

## Outcome of Pain Management in Chronic Pancreatitis

The morphologic correlates of recurrent pain in chronic pancreatitis are inflammatory cellular infiltration of the parenchyma and nerve sheaths, often associated with inflammatory pancreatic head enlargement or obliterating stones in the main pancreatic duct. The primary therapeutic step is the avoidance of triggering factors—most frequently a complete abstinence from alcohol and smoking—and adequate analgesia. In the case of persistent pain despite medical treatment, multidisciplinary therapy needs to be escalated by interventional or surgical methods [9]. This section focuses on the outcome of the therapeutic procedures presented in Chapters 51–54.

### Results of Medical Treatment for Chronic Pain

According to the World Health Organization (WHO) scheme for pain therapy and as explained in Chapters 41 and 51, peripherally acting analgesics are combined with tricyclic antidepressants, anticonvulsive agents, or opioids to achieve a positive effect in the therapy of chronic pain due to chronic pancreatitis [10]. In the next step, more potent opioids can be applied with close attention to both the patient's pain symptoms and the efficacy profile of the drug.

There are no reliable long-term results from well-designed randomized controlled trials that identify any opioid as being better than others with regard to both pain relief and side-effects [11]. With regard to the genesis of neuropathic pain in chronic pancreatitis, pregabalin has been tested for its potency in pain relief and was found to be significantly suited [10], although long-term results on both persistent pain relief and late drug-related side-effects in chronic pancreatitis are still not available.

### Results of Interventional Treatment Options for Chronic Pain

The so-called celiac plexus blockade can be performed endoscopically or under CT guidance. The aim is to interrupt pain sensations in sensory nerval fibers of the celiac ganglion region by either a mix of steroids and anesthetics (nerve block) or concentrated alcohol (50–90%) or phenol (neurolysis). In the short term, a

significant improvement should be found in the overall pain score. EUS-guided techniques seem to be safer, more effective, and more enduring compared to fluoroscopy-guided or CT-guided techniques [12–14]. The success rate of EUS-guided plexus blockade in terms of sufficient pain reduction was reported to be between 50% and 60% in two meta-analyses [12,13]. However, long-term data are rather sparse and the effect is only transient in most cases, as only 10% of the patients treated still enjoy persistent pain relief after 24 weeks [15].

Pain therapy includes treatment for pancreatic duct strictures and impacted stones, so lithotripsy, sphincterotomy, dilatation, or stenting of the pancreatic duct may become necessary. Pancreatic duct drainage hypothetically initiates decompression of the duct and reduced pressure in the segments behind, which consecutively leads to pain reduction or even freedom from pain. Nevertheless, it remains difficult to evaluate the individual impact of the changes on the character of pain. The clinical guideline of the European Society of Gastrointestinal Endoscopy (ESGE) recommends extracorporeal shock wave lithotripsy (ESWL) for first-line therapy in uncomplicated, painful chronic pancreatitis and (head)stones larger than 5 mm which obstruct the main pancreatic duct, followed by endoscopic removal of the fragments [16]. During a follow-up period of up to 77 months after this procedure, complete freedom from pain and partial freedom from pain were reported in 48% and 91% of patients, respectively [17]. However, only one randomized controlled trial exists comparing ESWL versus ESWL plus endoscopy in patients with obstructive chronic pancreatitis. Interestingly, both intensity and number of pain relapses were similar during a 2-year follow-up [18].

Evidence-based recommendations for endoscopic therapy of pancreatic duct strictures are lacking. Overall, the long-term pain relief of different studies varies between 52% and 90% over 14–69 months [19]. Multiple stenting was found to be successful in terms of freedom of pain and symptoms in more than 80% of the patients treated in an interval of 38 months [20]. However, prospective studies are necessary to investigate this therapeutic approach because single versus multiple stenting have not been compared to date.

## Results of Surgical Therapy for Chronic Pain

Direct comparison of surgical therapy (80% resections, 20% draining procedures) and endoscopic therapy with and without stenting revealed the superiority of the surgical approach for long-term pain and weight control in a prospective, controlled, randomized study. The results in terms of at least partial pain relief were still comparable (more than 90%) in both groups after 1 year. However, surgery aiming for freedom from pain turned out to be significantly advantageous in chronic obstructive pancreatitis after 3 and 5 years (surgery: 41% vs. endoscopic: 11% and surgery: 37% vs. endoscopic 14%, respectively) during further observation. In addition, the percentage of so-called "non-responders" (failure) was significantly higher in the interventionally treated group of patients. The monitoring of the course of the body weight of patients who received either surgery or intervention revealed similar results of superiority of the surgery group with an increase of body weight (surgery vs. endoscopy: 60% vs. 66% after 1 year but more than 50% and 27% after 5 years) [21].

Another prospective, randomized controlled study investigated approaches for refractory pain and compared endoscopical stenting and operative lateral pancreaticojejunostomy [22]. Patients from the surgical group reported partial or complete freedom of pain in 75% whereas only 32% of the patients of the interventionally treated group showed this improvement. The study had to be stopped prematurely because the advantage of the operative strategy was obvious and therefore continuing patient recruitment for study completion was ethically unacceptable. During the long-term follow-up of 79 months, another important finding was that patients who initially received surgical drainage reported markedly less pain and less frequently required additional therapy, either endoscopic or operative. However, surgical or interventional reintervention was required in almost 50% of the primarily endoscopically treated patients [23]. Moreover, physicians should bear in mind that early surgical therapy within the first 3 years after diagnosis apparently results in the best outcome in terms of pain reduction [24].

In a multicenter randomized trial initiated by the Dutch Pancreatitis Study Group the best time point for operative therapy after diagnosis is currently being investigated. The aim of this trial is to clarify whether early surgical intervention is better in terms of pain control and organ function compared to the step-up model of medical, endoscopic, and surgical treatment [25].

However, there are data indicating increased morbidity of salvage surgery after failed endoscopic treatment of pancreatic disease [26].

Taken together, the results of two randomized controlled clinical trials reveal the superiority of surgery compared to interventional endoscopy in the treatment of chronic pancreatitis. In addition to local pancreatic surgery, the efficacy of bilateral thoracoscopic transection of the splanchnic nerves has been shown to have long-lasting or even permanent positive effects in terms of pain control and quality-of-life improvement in chronic pancreatitis [27–29].

## Outcome of Therapeutic Options for Biliary and Pancreatic Ductal Stenoses

In association with inflammatory reactions and advancing glandular remodeling, stenoses of the pancreatic duct and the intrapancreatic biliary duct may develop. In addition to endoscopic methods, resective and operative drainage procedures must be evaluated. However, it should be remembered that the possibility of malignant lesions in the pancreatic tissue should be considered. After all, the cumulative risk for pancreatic cancer is considerably increased with an incidence of 4.6% after 5 years and 14% after 25 years in patients with chronic pancreatitis compared to disease-free controls [30].

### Results of Endoscopic Therapy for Ductal Stenoses

Different factors have relevant impacts on the success of endoscopically treated pancreatic duct strictures and stenoses. These are, for example, the number of impacted stones and/or strictures, the length of the latter, and the dilatation of the distal duct segment. Endoscopic therapy has been shown to be particularly effective in treating dominant strictures and dilatation of the pancreatic duct. In an overview including approximately 1500 patients, pain relief was reported in 31–100% during an observation time of 8–72 months [31]. A multicenter study concentrated on the long-term course after decompression of the pancreatic duct including strictures, stones, and the combination of both in more than 1000 individuals. During the follow-up period of up to 12 years, pain reduction, independently from the localization of the stricture and stone impaction, was achieved in 86% and in 65% in an intention-to-treat analysis. Over the long term (2–12 years; mean 4.9 years), surgical intervention was inevitable in a quarter of the patients [32]. Previous stent application was not rated as an obstacle during the subsequent operation.

The incidence of bile duct strictures in the context of chronic pancreatitis ranges between <5% and approximately 50% [33]. Both plastic and metal stents can be placed endoscopically. During a follow-up of nearly 5 years the disappearance of strictures was reported in 10–38% only [34]. Multiple stenting over 4 years resulted in a long-term resolution rate of 44% [35]. These results appear rather unsatisfactory with regard to effective treatment of bile duct obstructions in patients with chronic pancreatitis. Therefore, surgical options should be taken into consideration whenever other chronic pancreatitis-related complications such as duodenal stenosis or pain exist.

### Late Outcome of Resective Versus Draining Procedures

Operative strategies for chronic pancreatitis for both draining and resection should consider pathophysiology and the underlying morphologic changes. Details of the various surgical procedures mentioned in the next paragraph can be found in Chapters 56–60.

In brief, surgical drainage procedures are performed if the pancreatic head is not enlarged but the pancreatic duct shows congestion. The most common surgical technique is longitudinal pancreaticojejunostomy, according to Partington–Rochelle. In addition to a low morbidity of 21% and a mortality of less than 1%, sufficient and lasting pain-release has been reported in 80% for an observation period of 15–110 months [24,36].

The rationale behind a (limited) pancreatic head resection is the hypothesis that pain persists due to incomplete decompression of the duct in the pancreatic head by a drainage-only procedure. For long time classical pancreatoduodenectomy (Kausch–Whipple) was the first choice in surgical therapy of chronic pancreatitis with head-related complications. However, despite a low mortality (less than 5% in high-volume centers) more than half of the patients showed long-term gastrointestinal problems such as dumping, diarrhea, peptic ulcers, delayed gastric emptying, and diabetes. Alternatively, the pylorus-preserving modification according to Traverso was developed, but this modification was found to be no better than the classical Kausch–Whipple procedure with regard to morbidity, mortality, and adverse side-effects.

In patients with inflammatory enlargement of the pancreatic head and pancreatic duct dilatation a combination of both resection and drainage has been suggested. Several techniques have been developed, including the duodenum-preserving pancreatic head resection pioneered by Hans Beger from the early 1970s. The encouraging long-term outcome of this technique performed in 504 patients revealed 91% freedom from pain, 69% professional rehabilitation, and 72% of the patients had a Karnofsky index of 90–100% whereas only 9% had a recurrence of pancreatitis during up to 14-year follow-up [37].

Beger's original idea of performing organ-preserving surgery for chronic pancreatitis-related complications was subsequently modified by Frey, Büchler/Bern, and Farkas in the following years. Recently, the results from a randomized controlled trial comparing the Beger procedure and the Bern modification showed no difference in patient-relevant long-term outcome during a median 129 months follow-up [38].

In a first randomized trial investigating both short- and long-term outcomes, the superiority of duodenum-preserving pancreatic head resection compared to the classical Kausch–Whipple procedure was demonstrated

with regard to pain relief, gain of body weight, and time of hospital stay [39]. In addition to comparable results concerning morbidity, course of pain intensity, and endocrine function, a meta-analysis showed advantages of the duodenum-preserving procedures (Beger, Frey, Büchler/Bern procedures) concerning hospital stay, exocrine function, and quality of life [40]. However, especially with regard to effective long-term absence of pain and quality of life these results have to be treated with caution because a meta-analysis could not find a significant superiority [41]. In 2008 the long-term results (14-year follow-up) from a randomized clinical trial comparing pylorus-preserving resection and Beger procedure demonstrated no presence of the early advantages of the latter [42]. The results from the ongoing randomized multicenter study (ChroPac) comparing duodenum-preserving pancreatic head resection and classical pylorus-preserving duodenopancreatectomy with regard to the primary end-point "quality of life" 2 years after surgery will be available within the next few years. In 2013, the 15-year follow-up data from a randomized controlled trial on pylorus-preserving pancreatoduodenectomy versus Frey procedure in chronic pancreatitis was published [43]. Whereas pain control was comparable between both groups in the long-term follow-up, the authors reported better quality of life after Frey procedure and an increased long-term mortality after pylorus-preserving duodenopancreatectomy [43]. Furthermore, no correlation between endocrine and exocrine pancreatic function and pain could be identified. Taken together, this study clearly recommends duodenum-preserving pancreatic head resection in chronic pancreatitis whenever possible.

Another study investigated the differences between the Beger procedure and the Frey procedure but could not identify any superiority with regard to morbidity, quality of life, pain relief, and endocrine or exocrine function [44]. Recently, the data from a 16-year follow-up analysis after Beger and Frey procedure agreed with these findings [45]. Comparison of the two duodenum-preserving resections—"Beger procedure" and "Büchler/Bern procedure"—revealed a shorter operation time and a shorter hospital stay for the latter [38,46] but no differences with regard to quality of life, pain control, occupational disability, exocrine and endocrine pancreatic function, endoscopic interventions, and reoperations during the 10-year follow-up [38]. Finally, there are no published studies in the literature comparing the "Büchler/Bern procedure" and the "Frey procedure."

## Conclusion

Currently, surgeons and gastroenterologist do not always agree in terms of the right time point and indications for interventional or surgical therapy in patients with obstructive chronic pancreatitis. Even among surgeons there are different opinions concerning the respective operative procedures. Both individual experience and local or interdisciplinary expertise have crucial impacts on decision making. This inhomogeneity is caused by the weak evidence of existing analyses, which are small and underpowered in most cases. New comprehensive, randomized controlled trials should clearly be initiated to support or refute these data. Complex cases have to be discussed and planned in an interdisciplinary approach. Nevertheless, in the light of the currently existing data there should be some change in decision making in favor of earlier initiation of a surgical approach, because studies report better and more long-lasting pain control and maximum possible preservation of function after organ-sparing operations. Early surgery can also prevent damage to the parenchyma which leads to better postoperative function of the remaining pancreatic tissue and reduces the risk of malignant transformation.

# Management of Pancreatic Diabetes Secondary to Chronic Pancreatitis

*Keiko Shiratori*

*Departments of Internal Medicine and Gastroenterology, Tokyo Women's Medical University School of Medicine, Tokyo, Japan*

## Introduction

Because of the close anatomic and functional links between the exocrine and endocrine pancreas, any pancreatic disease that involves one will inevitably affect the other. Chronic pancreatitis is characterized by pancreatic inflammatory and fibrotic injury that results in loss of pancreatic structure and both exocrine and endocrine functions, often leading to complications such as glucose intolerance and diabetes mellitus [1–5]. Diabetes secondary to pancreatic diseases is classified as pancreatic diabetes or type 3c diabetes in the current classification of diabetes [6]. Diabetes secondary to chronic pancreatitis differs both metabolically and clinically from other forms of diabetes, and usually occurs late in the course of chronic pancreatitis. Since the reduction in β-cell mass caused by chronic inflammation of the pancreas plays a major role, pancreatic diabetes is characterized by marked impairment of insulin secretion in response to ingestion of a meal. Secretion of counterregulatory hormones including glucagon and pancreatic polypeptide (PP) is simultaneously impaired. Managements of hyperglycemia with glucose-lowering agents and improvement of malnutrition status are very important.

## Definition and Prevalence of Pancreatic Diabetes

Type 3c diabetes is a complication of exocrine pancreatic disease, including pancreatitis of any etiology, pancreatic trauma, pancreatectomy, neoplasia, cystic fibrosis, hemochromatosis, and fibrocalculous pancreatopathy [6,7]. Type 3c diabetes accounts for 5–10% of all cases of diabetes in Western populations [4], but most of the cases have been misclassified as type 2 diabetes [8,9]. Distribution of those pancreatic diabetes based on 1922 hospitalized patients with diabetes consisted of chronic pancreatitis (76%), pancreatic neoplasia (9%), hemochromatosis (8%), cystic fibrosis (4%), and post-pancreatic resection (3%) [8]. Ewald et al. [10,11] showed that 9.2% of all patients with diabetes were classified as having type 3c diabetes, and in 78.5% of the patients with type 3c diabetes chronic pancreatitis was the underlying disease.

## Incidence of Diabetes in Chronic Pancreatitis

The reported incidences of diabetes in chronic pancreatitis have been in the approximately 40–60% range [1]. Several studies of large series of patients with chronic pancreatitis have been conducted in various countries [1,3,12–15]. The results of a recent national survey in Japan showed that 46.3% of patients with chronic pancreatitis had diabetes [16], and an Italian survey reported that 31% of patients with chronic pancreatitis had endocrine insufficiency [17].

There is a strong positive correlation between the duration of chronic pancreatitis and the incidence of pancreatic diabetes. In Italy, 41.5% of patients with chronic pancreatitis were found to have diabetes at the 15-year follow-up examination [13]; 23.6% were on insulin therapy and 17.9% were being treated with oral antidiabetic agents [13]. Ammann et al. [14] conducted a long-term study of 207 patients with alcoholic chronic pancreatitis and found that overt diabetes requiring treatment with oral hypoglycemic agents or insulin was present in approximately 20% at 6 years after the onset of chronic pancreatitis, and in nearly 50% 10 years after

Companion website: www.wiley.com/go/beger/thepancreas

onset. A prospective cohort study of 500 patients with chronic pancreatitis revealed a cumulative rate of complication by diabetes of 83% at 25 years after the clinical onset of chronic pancreatitis, and 54% of the patients with diabetes required insulin [1]. Wang et al. [3] monitored patients with chronic pancreatitis for the development of diabetes over a 20-year period and reported cumulative rates of diabetes of 3.6% at 0 year, 7.5% at 1 year, 24.2% at 10 years, and 51.5% at 20 years after the clinical onset of chronic pancreatitis.

Autoimmune pancreatitis is a particular type of pancreatitis [18,19], and 83.3% of the patients have diabetes [20]. Steroid therapy has been reported to ameliorate both diabetes and exocrine dysfunction in patients with autoimmune pancreatitis complicated by diabetes [21,22].

## Risk Factors for Pancreatic Diabetes in Chronic Pancreatitis

### Alcohol Abuse

Alcohol abuse is a factor of chronic pancreatitis in the progression as well as in its etiology. Endocrine function is more impaired in alcoholic chronic pancreatitis than in nonalcoholic chronic pancreatitis. Koizumi et al. [12] reported an incidence of pancreatic diabetes in nonalcoholic and alcoholic cases of 36.1% and 53.7%, respectively. In a recent nationwide study in Japan, the largest causal factor of chronic pancreatitis with pancreatic diabetes was alcoholic consumption (77.3%) [16].

### Pancreatic Calcification

Pancreatic calcification is an indicator of longstanding and advanced chronic pancreatitis, and correlates well with pancreatic tissue loss. Both secretion of insulin and glucagon have been reported to be more severely impaired in calcified chronic pancreatitis than in noncalcified chronic pancreatitis [23]. There is a close correlation between the presence of pancreatic calcification and the development of pancreatic endocrine insufficiency [1,13]. In a prospective study by Malka et al. [1], the presence of pancreatic calcification was the clinical factor significantly associated with the risk of diabetes, and once calcification had developed, the risk of diabetes and insulin requirement increased by more than threefold. Ito et al. [24] reported findings that the risk of diabetes increased 1.32-fold after the onset of calcification. A recent report from China also identified pancreatic calcification as a risk factor for diabetes (HR 2.326) [3]. Kawabe et al. [25] reported findings that patients with pancreatic diabetes were more common in a calcified chronic pancreatitis group (74.4%) than in a noncalcified group (21.3%).

### Smoking

Smoking is known to increase the risk of pancreatic diabetes in chronic pancreatitis patients. Maisonneuve et al. [26,27] found that heavy smoking (>20 cigarettes/day) was associated with the development of diabetes (HR 2.3) in patients with alcoholic chronic pancreatitis. Wang et al. [3] identified smoking as an independent risk factor for diabetes (HR 2.859) in chronic pancreatitis in Chinese patients before any invasive therapy.

## Pathogenesis of Pancreatic Diabetes

### Pancreatic Histology and β-Cell Dysfunction

Histologically, in the advanced stages of chronic pancreatitis, the exocrine parenchyma is almost completely replaced by fibrosis. Alterations of the endocrine islets are rather modest in the early stages of chronic pancreatitis, and even in the advanced stages of the disease. Although histologic examination of the pancreas in advanced chronic pancreatitis shows that the pancreatic islets are embedded in fibrous tissue, they are relatively well preserved in comparison with the degree of acinar cell destruction. Many studies have shown that even though a decrease in the number of islets is observed in chronic pancreatitis patients, the residual islets are often enlarged because the islet cells have undergone hyperplasia [28–30].

The relation between pancreatic β-cell area and the clinical manifestation of pancreatic diabetes in chronic pancreatitis patients has been investigated [31,32]. Meier et al. [32] conducted a study of 82 patients who underwent pancreatic surgery. They found that the relative β-cell deficits at the onset of diabetes and impaired glucose tolerance were 64% and 21%, respectively, based on 2-hour glucose levels, and concluded that pancreatic diabetes probably develops after a reduction in β-cell area of ~65%. Islet morphology and physiology may be altered by inflammation and cytokine release [33,34], which led to islet dysfunction, and the subsequent development of fibrosis and sclerosis may impair pancreatic capillary circulation and diminish islet perfusion, and ultimately leads to islet destruction. Cyclooxygenase has also been found to play a major role in islet inflammation and in the pathogenesis of diabetes [35].

### Dysfunction of Other Hormones

#### Glucagon

Beta-cell dysfunction develops first in chronic pancreatitis patients, and is followed by impairment of α-cell function. Alpha cells appear to be more resistant to the effects of chronic inflammation. Basal glucagon levels have been

reported to be maintained in chronic pancreatitis patients, but their response to stimulation is weaker [36]. Another study showed lower basal glucagon levels in patients with calcific chronic pancreatitis than in patients with primary diabetes or healthy controls [23].

### Pancreatic Polypeptide

The number of PP cells is also decreased in chronic pancreatitis. Since the fasting and postprandial increases in PP have been shown to be much lower in patients with chronic pancreatitis [7,30,36], a diminished PP response can be used as an early marker of the development of endocrine insufficiency [37]. A recent consensus statement has proposed a weak or absent PP response to meal testing as a specific sign of pancreatic diabetes [38]. The impaired expression of hepatic insulin receptor that occurs in association with chronic pancreatitis may be caused by PP deficiency, because PP has been shown to have an effect on hepatic sensitivity to insulin [4,7,36,39]. Andersen [39] has demonstrated reversal of the decrease in hepatic insulin receptor in patients with chronic pancreatitis in response to PP administration, and a randomized placebo-controlled study has shown that PP administration enhanced insulin sensitivity and lowered the insulin requirements of the patients with type 1 and type 3c diabetes [40].

### Incretins

Glucose-dependent insulinotropic polypeptide and glucagon-like peptide 1 (GLP-1) are insulinotropic intestinal peptide hormones, also known as "incretin hormones." Incretins are responsible for up to 70% of the insulin secretion after glucose ingestion. Because incretin secretion is stimulated by nutrient digestion and absorption in the small intestine, pancreatic exocrine insufficiency results in decreased incretin release [41]. In fact, the incretin effect is strongly reduced in chronic pancreatitis patients with diabetes, suggesting that the incretin defect is a consequence of the diabetic state [42–44]. Several studies have shown that pancreatic enzyme supplementation increases the postprandial incretin response in patients with pancreatic exocrine insufficiency [42–44].

## Diagnosis of Type 3c Diabetes

The initial diagnostic evaluation of diabetes in patients with chronic pancreatitis is a fasting blood glucose and $HbA_{1c}$ analysis. A fasting blood glucose level >126 mg/dL or $HbA_{1c}$ value >6.5% may indicate the presence of diabetes based on the most widely used diagnostic criteria for diabetes [6,38]. Type 3c diabetes is more common than generally thought [10,11]. It is very important to recognize this type because failure to make the diagnosis would result in failure to implement appropriate therapy [8,45]. Ewald et al. [11,45] recently proposed new criteria for diagnosing type 3c diabetes (Box 62.1), but there is a degree of overlap between type 3c diabetes and other forms of diabetes, because longstanding type 1 and type 2 diabetes are also often associated with exocrine pancreatic failure. An absent PP response to a mixed-nutrient test meal appears to be the most reliable and specific indicator of type 3c diabetes (Table 62.1) [7,38].

**Box 62.1 Proposed diagnostic criteria for type 3c diabetes mellitus**

**Major criteria (must be present)**

- Presence of exocrine pancreatic insufficiency (monoclonal fecal elastase-1 test or direct function tests)
- Pathological pancreatic imaging (endoscopic ultrasound, MRI, CT)
- Absence of type 1 diabetes mellitus associated autoimmune markers

**Minor criteria**

- Absent pancreatic polypeptide secretion
- Impaired incretin secretion (e.g., GLP-1)
- No excessive insulin resistance (e.g., HOMA-IR)
- Impaired β-cell function (e.g., HOMA-B, C-peptide/glucose ratio)
- Low serum levels of lipid soluble vitamins (A, D, E, and K)

*Source:* Ewald, Hardt 2013 [11], Table 2. 

## Clinical Characteristics of Pancreatic Diabetes

The most common symptoms of pancreatic diabetes are the same as those of any other type of diabetes, but the alterations in glucose metabolism range from only mild impairment to a severe form characterized by frequent episodes of hypoglycemia, particularly after insulin administration, commonly referred to as "brittle diabetes." Glycemic control in type 3c diabetes is unstable because of the loss of the glucagon response to hypoglycemia, carbohydrate malabsorption, and/or inconsistent eating patterns as a result of concomitant pain and/or nausea or chronic alcohol abuse [11]. Unlike hypoglycemia, diabetic coma and diabetic ketoacidosis are relatively rare in pancreatic diabetes.

**Table 62.1** Islet cell hormonal response to mixed-nutrient meal testing.

| | Type 1 diabetes | Type 2 diabetes | Type 3c diabetes |
|---|---|---|---|
| C-peptide | Normal[a], low or absent | Elevated[b] or normal[a] | Normal[a], low or absent |
| Insulin | Normal[a], low or absent | Elevated[b] or normal[a] | Normal[a], low or absent |
| Glucagon | Normal[a] or elevated | Normal[a] or elevated | Normal[a], low or absent |
| Pancreatic polypeptide | Normal or low | Normal or elevated | Low or absent |

*Source:* Rickels et al. 2013 [38], Table 3. Reproduced with permission of Elsevier.
[a] Values in the normal range are inappropriate in the context of elevated glucose and indicate an impairment in β-cell mass or function.
[b] Elevated levels were calculated by comparing area under the curve for serum C-peptide and insulin responses to a liquid test meal for cases and controls.

## Complications of Pancreatic Diabetes

Prolonged hyperglycemia puts diabetes patients at increased risk of micro- and macrovascular complications, which cause high morbidity and mortality. The development of early microvascular complications in pancreatic diabetes is similar to that in other types of diabetes. Nakamura et al. [46] reported a high incidence (40%) of retinopathy in calcified chronic pancreatitis. The peripheral nerves in patients with alcoholic chronic pancreatitis have already been damaged as a result of long-term alcohol abuse, malnutrition, and vitamin malabsorption due to pancreatic exocrine insufficiency. A prevalence of neuropathy of 30% has been reported in patients with pancreatic diabetes, which is comparable to its prevalence in idiopathic diabetes [46]. A higher prevalence of peripheral neuropathy has been reported in patients with chronic pancreatitis due to alcohol abuse (44%) and in patients with pancreatic diabetes treated with insulin (79%) [12].

## Therapy of Pancreatic Diabetes

Management that maintains good glycemic control and good nutritional status is most important, because it can prevent long-term complications of diabetes in patients with pancreatic diabetes. The initial treatment of all patients with type 3c diabetes should begin with a concentrated effort to correct lifestyle factors, including weight control, abstinence from alcohol, and smoking cessation. The goal of treatment in pancreatic diabetes is to achieve an $HbA_{1c}$ level as close to normal as possible, while avoiding life-threatening hypoglycemia. Whether to choose insulin or noninsulin therapy for the initial treatment of pancreatic diabetes depends on the clinical presentation of the patient [4].

### Insulin Therapy

Insulin replacement therapy is the only effective treatment option for patients with advanced pancreatic diabetes who are markedly hyperglycemic (fasting glucose >10 mmol/L or 180 mg/dL, and $HbA_{1c}$ level >8.5%). Insulin therapy is often used as the treatment of first choice for patients with severe malnutrition and weight loss because the desired anabolic effects in such patients. Although patients with type 3c diabetes should be treated based on the general insulin dosing and regimen guidelines for type 1 and type 2 diabetes [47,48], the dose of insulin required to achieve and maintain glycemic control in type 3c diabetes may be significantly lower than in other types of insulin-dependent diabetes.

Insulin therapy for patients with type 3c diabetes is started with a bedtime 10 U or 0.2 U/kg dose of an intermediate-acting insulin or with a bedtime or monitoring dose of a long-acting insulin, with progressive dose increases based on the results of fasting and postprandial blood glucose determinations [4,47]. Intensive insulin therapy in combination with a preprandial dose of short- or ultra-short-acting insulin for postprandial hyperglycemia and a dose of long-acting insulin at bedtime for basal requirement is also recommended (Fig. 62.1) [25]. Since the long-acting insulin analogs are characterized by the absence of pronounced peaks and a 24-hour time–action profile, nocturnal hypoglycemia can be avoided.

Patients with pancreatic diabetes lack counterregulatory hormones, such as glucagon and PP, and thus are susceptible to hypoglycemia and other metabolic dysfunctions. Because of the lack of pancreatic enzymes and significant delay in digestion, there may be asynchrony between meal ingestion, delivery of exogenous insulin, and nutrient absorption.

### Therapy with Other Hypoglycemic Agents

The hypoglycemic agents typically used to treat type 3c diabetes are the same as used to treat type 2 diabetes [30,47,48]. They may be tried as a valid approach in patients with pancreatic diabetes with mild hyperglycemia and relatively early in the course of the disease [38].

When the hyperglycemia in pancreatic diabetes secondary to chronic pancreatitis is mild ($HbA_{1c}$ <8.0%) and concomitant insulin resistance is suspected, metformin is the preferred initial drug of choice for oral antidiabetic therapy because of improvement of insulin resistance

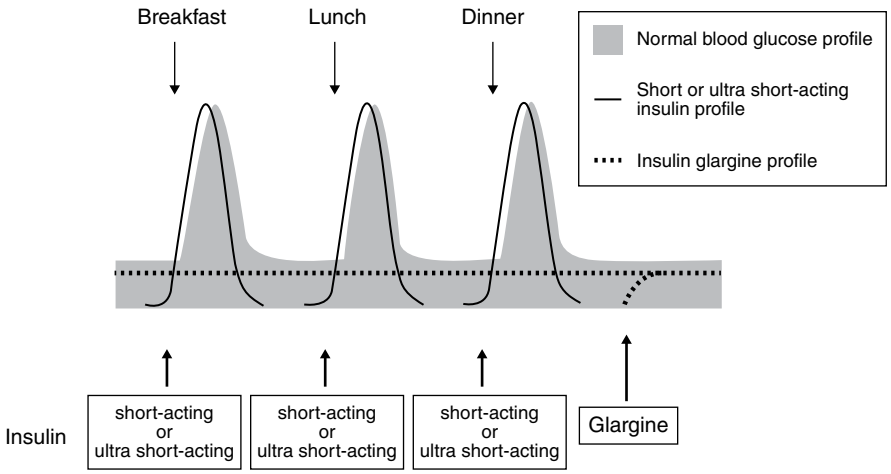

**Figure 62.1** Intensive insulin therapy in combination with pre-meal short- or ultra-short-acting insulin and long-acting insulin glargine for basal requirement. *Source:* Kawabe et al. 2009 [25], Fig. 6. Reproduced with permission of Springer.

and reduction in risk of malignancy in patients with chronic pancreatitis [38]. Insulin and insulin secretagogues therapy may increase the risk of malignancy in patients with chronic pancreatitis [49], whereas metformin therapy has been shown to reduce the risk of pancreatic cancer by as much as 70% [50]. Metformin should be continued if insulin therapy must be added to achieve adequate glycemic control [4,7,11].

Therapy with insulin secretagogues (sulfonylureas and glinides) may also be considered in patients with pancreatic diabetes in the early stages ($HbA_{1c}$ <8.0%) [38]. However, because the risk of hypoglycemia with these drugs may be greater in patients with impaired glucagon secretion, short-acting agents are preferable when meal ingestion is inconsistent. Sulfonylureas may increase the risk of severe and prolonged hypoglycemia.

Incretin-based therapies with GLP-1 analogs and dipeptidyl-peptidase-4 (DPP-4) inhibitors may be ineffective in pancreatic diabetes because natural incretin levels may already be high [41,42]. Moreover, the possible induction of pancreatitis and pancreatic cancer by incretin-based therapies has been widely debated [51], although a recent study reported a low incidence of pancreatitis among patients being treated with incretins and that the drugs do not increase the risk of pancreatitis [52]. It might be better to avoid their use in pancreatic diabetes patients until their safety is clearly confirmed.

Glitazones improve peripheral insulin resistance sensitivity, but are known to associate increased risk of fluid retention, congestive heart failure, and bone fracture. Fractures are a particular concern, because chronic pancreatitis patients are already at increased risk of osteoporosis. Alpha-glucosidase inhibitors (α-GI) specifically lower postprandial glucose excursions, but may aggravate diarrhea, bloating, and intestinal malnutrition. Such adverse effects may further impair intestinal digestion and absorption in patients with pancreatic exocrine dysfunction. The actions of sodium–glucose cotransporter-2 (SGLT-2) inhibitors are independent of insulin, but the weight loss should be considered, especially in patients with malnutrition. Thus, therapeutic effects of glitazones, α-GI, and SGLT-2 inhibitors on pancreatic diabetes have not been confirmed, and their use should generally be avoided [38].

## Pancreatic Enzyme Replacement Therapy

Many patients with chronic pancreatitis manifest some degree of fat malabsorption, regardless of the presence of symptoms. Since clinically apparent protein and fat malabsorption does not occur until over 90% of pancreatic exocrine function is lost, exocrine pancreatic insufficiency and maldigestion may remain undetected by patients and their physicians. Impaired absorption of fat-soluble vitamins (A, D, E, and K) should be a concern in patients with even mild fat absorption. A decrease in serum 25-hydroxyvitamin D level has been observed in >90% of patients with pancreatic diseases [53]. Oral pancreatic enzyme replacement protects against the failure to absorb of fat-soluble vitamins and prevents metabolic bone diseases [39].

Several studies have shown improvement in the incretin response to ingestion of nutrients after pancreatic enzyme replacement in patients with pancreatic exocrine insufficiency due to chronic pancreatitis [44,45] and cystic fibrosis [46]. Adequate oral pancreatic enzyme replacement therapy should therefore be added to glycemic control therapy to improve clinical symptoms of steatorrhea and prevent qualitative malnutrition and metabolic complications. Diabetes and malabsorption may impair the metabolism of trace elements and decrease plasma concentrations of zinc and selenium.

### Total Pancreatectomy with Islet Autotransplantation

Total pancreatectomy with islet autotransplantation (TPIAT) is a potential treatment option for select patients with severe painful chronic or recurrent acute pancreatitis. Bellin et al. [54] reported being able to isolate significant islet mass in 27 patients with chronic pancreatitis and diabetes who underwent TPIAT. Recommendations for TPIAT in chronic pancreatitis have recently been published by the PancreasFest working group [55]. Numerous areas of potential future research in regard to TPIAT remain.

## Prognosis of Pancreatic Diabetes

A long-term follow-up study of patients with chronic pancreatitis showed that 5.6% of them had died of diabetes [13]. The cause of death in half of the cases was hypoglycemia, and in the other half it was hyperglycemia. Another study reported finding that the major causes of death at an average of 5.5 years after the onset of diabetes were diabetic complications (about 48%), including cardiovascular and cerebrovascular diseases [12]. Ammann et al. (14) reported that the death rate in chronic pancreatitis was almost three times higher in a group that continued to abuse alcohol than in a group that decreased or ceased alcohol intake. An epidemiologic survey conducted in Japan revealed a mortality rate 2.3%, that hypoglycemia was the most frequent cause of death, and that many of the deceased patients had been treated with insulin but continued to consume alcohol [16]. Cessation of drinking and smoking may decrease the mortality rate from pancreatic diabetes.

Chronic pancreatitis, longstanding diabetes, and insulin therapy are known risk factors for pancreatic cancer [5,7,49]. Patients with diabetes secondary to chronic pancreatitis on insulin therapy are at very high risk of developing pancreatic cancer [4].

## Introduction

There are two histologic types of autoimmune pancreatitis (AIP): (i) lymphoplasmacytic sclerosing pancreatitis (LPSP), which is called type 1 AIP, and (ii) idiopathic duct-centric pancreatitis (IDCP), which is called type 2 AIP. Type 1 AIP has come to be recognized as a pancreatic manifestation of IgG4-related disease [1]. Since 2002, several sets of diagnostic criteria for AIP have been developed worldwide and international consensus diagnostic criteria (ICDC) were created to incorporate the diagnostic strategies used in the different criteria [2].

There have been three nationwide epidemiologic surveys of AIP in Japan [3–5], as well as three international multicenter surveys of AIP [6–8]. In this chapter, the epidemiology of AIP is described based on the findings of these surveys.

## Nationwide Survey of Autoimmune Pancreatitis in Japan

The first nationwide survey of AIP was conducted in Japan in 2002, and the estimated number of AIP patients was 900 [3]. This number increased 3.1 times to 2,790 in 2007 in the second Japanese nationwide survey [4]. This rapid increase in the number of AIP patients might be explained by the following: the focal type of AIP could not be diagnosed using the Japanese diagnostic criteria of 2002, and recognition of AIP increased in Japan.

The third nationwide survey in Japan was conducted in 2011 [5] using the Japanese diagnostic criteria of 2011 [9]. At that time, there were an estimated 5,745 AIP patients, and the overall prevalence rate was 4.6 per 100,000 population. The number of newly diagnosed AIP patients was estimated to be 1,808, and the annual incidence rate was 1.4 per 100,000 population. The male to female ratio was 3.2, and the patients' mean age was 66.3 years. Of the 936 patients, 86.4% presented with high serum IgG4 levels (≥ 135 mg/dL), while almost 50% of patients were found to have localized pancreatic enlargement. Pancreatic tissue was obtained in 45.4% of cases, and tissue samples were obtained by endoscopic ultrasound-guided fine needle aspiration (EUS-FNA) in 63.8%. A total of 532 (57.9%) patients had extrapancreatic lesions: 153 had sialadenitis/dacryoadenitis, 95 hilar sclerosing cholangitis, 76 retroperitoneal fibrosis, and others. Steroid treatment was given to 761 (82.3%) patients and it was effective in 96.3%. Maintenance steroid treatment was given to 84.6% and the relapse rate was 22.2%. Overall, 109 (11.8%) patients had malignant tumors, including 7 patients with pancreatic cancer.

## First International Survey of Autoimmune Pancreatitis

The first international multicenter survey of AIP in 2009 involved 10 centers in 5 Asian countries (Japan, Korea, Taiwan, China, and India) [6]. A total of 327 AIP patients (258 males, 69 females; average age 60.0 years) who were diagnosed according to the Asian diagnostic criteria [10] were enrolled.

Obstructive jaundice was the most common initial symptom, followed by weight loss and abdominal pain. Diffuse swelling of the pancreas was common in Japan (64%) and Korea (81%), whereas segmental swelling of the pancreas was more commonly seen in Taiwan (70%)

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

and China (72%) ($P < 0.01$). In Japan, Korea, and Taiwan, 58–100% of patients had increased serum IgG4 levels. Pathologically, almost all Asian AIP patients were diagnosed with LPSP. Steroid therapy was the major therapeutic strategy and it was effective, although the rate of resection or bypass surgery was higher in Taiwan and China ($P < 0.01$).

Due to their geographic proximity, the populations of Japan, Korea, Taiwan, and China appear to share a common genetic background. AIP patients had fundamentally similar characteristics, with most being type 1 AIP in these countries. Differences in the rates of recognition of this disease might account for the differences in the clinical and pathophysiological characteristics of AIP in these countries.

## Second International Survey of Autoimmune Pancreatitis

The second international, multicenter survey of AIP in 2010 involved 15 institutes from 8 countries (Japan, Korea, Taiwan, India, the United States, Germany, Italy, and the United Kingdom) [7]. A total of 731 AIP patients were enrolled; 204 cases were confirmed histologically to be LPSP, and 64 cases were confirmed to be IDCP. Various diagnostic criteria were used to diagnose AIP.

LPSP patients were approximately 16 years older than IDCP patients (61.6 years vs. 44.8 years), and there was no sex difference between the two groups. With respect to the initial presentation, obstructive jaundice was more common in LPSP than in IDCP (75% vs. 47%, $P < 0.01$), whereas abdominal pain (41% vs. 68%, $P < 0.01$) and acute pancreatitis (5% vs. 34%, $P < 0.01$) were more common in IDCP patients. LPSP patients were more likely than IDCP patients to have diffuse pancreatic swelling (40% vs. 25%, $P < 0.05$), increased serum IgG4 levels (63% vs. 23%, $P < 0.01$), retroperitoneal fibrosis (7% vs. 0%, $P < 0.05$), and salivary gland swelling (12% vs. 0%, $P < 0.01$), while they were less likely to have ulcerative colitis (1% vs. 16%, $P < 0.01$). Surgery was more commonly performed for IDCP patients (60% vs. 78%, $P = 0.01$). Both groups showed good therapeutic responses to steroid treatment, though the relapse rate was significantly lower in IDCP patients (36% vs. 5%, $P < 0.01$).

Among AIP patients whose diagnosis was not confirmed histologically, obstructive jaundice was the most frequent initial symptom in six countries, but it was less frequent in Italy (44%) and Germany (13%), while abdominal pain was the most frequent initial symptom in India (86%) and Germany (63%). Acute pancreatitis was common in Germany (66%) and Italy (32%). Overall, 85–100% of AIP patients had increased serum IgG4 levels in Japan, Taiwan, India, and the United States, while only 50–61% had increased serum IgG4 levels in other countries. Italian AIP patients often had ulcerative colitis (30%). Steroid treatment was given to 69–100% of AIP patients, with the initial prednisolone dose being 1 mg/kg/day in three countries, 0.6 mg/kg/day in two countries, and 30–40 mg/day in the remaining three countries. This dose was then tapered by 5 mg every 1–2 weeks. The time from initiation to cessation of steroid therapy ranged from 3 months to 2 years, and all patients responded well to steroid therapy, with a relapse rate of 15% to 64% in steroid-treated patients (Table 63.1).

The clinical profiles of patients in six countries were similar to those of LPSP patients. However, different clinical profiles that appeared to include a mixture of LPSP and IDCP were observed in Italian and German AIP patients.

## Third International Survey of Autoimmune Pancreatitis

The third international, multicenter survey of AIP in 2012 involved 23 institutes in 10 countries (Japan, Korea, Taiwan, the United States, Germany, Italy, the United Kingdom, Hungary, Sweden, and France) [8]. The patients were diagnosed using the ICDC [2], and the survey focused on long-term outcomes, including organ involvement, treatments, relapse frequency, and long-term sequelae.

The survey included 1,064 patients meeting the ICDC [2] for type 1 ($n = 978$) or type 2 ($n = 86$). The average ages of type 1 and type 2 patients were 61.4 and 39.9 years, respectively, and 77% of type 1 patients and 55% of type 2 patients ($P < 0.01$) were males. The proportion of patients diagnosed with type 2 AIP was lower in Asia (3.7%) than in both Europe (12.9%, $P < 0.01$) and North America (13.7%, $P < 0.01$) (Fig. 63.1).

In type 1 patients, jaundice was the most common presentation in 63%, followed by abdominal pain, but abdominal pain and inflammatory bowel disease were the most common in type 2 AIP. Most (74%) type 1 patients were initially treated with steroids, while only 62% of type 2 patients were treated with steroids ($P = 0.01$).

Almost all type 1 and 2 AIP patients achieved remission, while 302 (31%) type 1 patients had at least one disease relapse, compared to 8 (9%, $P < 0.01$) of type 2 patients. Most relapses in type 1 patients involved the biliary system or pancreas, while all relapses in type 2

patients involved the pancreas. Several relapses occurred in type 1 AIP, but only one relapse occurred in type 2 AIP (Table 63.2). With or without alternative treatment, such as azathioprine, steroid retreatment remained effective for inducing remission.

## Conclusions

With increased recognition of the concept of AIP and the development of diagnostic criteria, the number of AIP patients has increased rapidly in Japan. The recent nationwide survey in Japan estimated that there were 5,745 AIP patients, with an overall prevalence rate of 4.6 per 100,000 population.

The international surveys of AIP highlighted regional and ethnic differences in the pathologic and clinical features of AIP, as well as the quite different profiles of type 1 and type 2 AIP patients. Further multinational collaborations are required to improve our understanding of this disease. Whether or not the prevalence of type 2 AIP, for which no blood test is currently available, is being underestimated and whether AIP in general is a risk factor for pancreatic cancer or merely a common differential diagnosis will also have be determined by careful epidemiologic surveys.

**Table 63.2** Initial treatment strategies and relapse in type 1 and type 2 AIP patients in the third international survey.

# Pathogenesis of Autoimmune Pancreatitis

*Yoh Zen*

*Department of Diagnostic Pathology, Kobe University, Kobe, Japan*

## Introduction

Similar to many other immune-mediated conditions, a likely pathogenetic mechanism for autoimmune pancreatitis (AIP) is the exposure of genetically susceptible individuals to environmental or intrinsic factors that results in orchestral immune reactions. Among the two distinct subtypes of AIP, type 1 has been the main target of pathogenetic studies [1]. Therefore, this chapter focuses on the prototypic type of immune-mediated pancreatitis. Although the molecular features of type 2 AIP are currently unclear, recently obtained findings on the less common form of AIP are also briefly introduced in the last section.

## Type 1 Autoimmune Pancreatitis

### Genetic Predisposition

The strongest genetic risk is related to human leukocyte antigens (HLA), with the subtypes DRB1*0405 and DQB1*0401 known to increase the susceptibility of Japanese populations to type 1 AIP [2]. The absence of aspartic acid at HLA DQβ1 57 has also been correlated with disease relapse in Koreans [3]. Other potential disease-susceptible genes encode cytotoxic T lymphocyte-associated protein 4 (*CTLA4*), tumor necrosis factor-α (*TNFA*), Fc receptor-like protein 3 (*FCRL3*), and cationic trypsinogen (*PRSS1*) [4–7]. More comprehensive analyses including genome-wide association studies are required in order to obtain a better understanding of the genetic risks of this condition. Whether the associated HLA types identified in Asian patients are also associated with AIP type 1 in Caucasians is presently unknown.

### Autoimmune Nature

Clinical findings showing that antinuclear antibodies are present in ~40% of patients with type 1 AIP suggest the involvement of autoimmunity in disease initiation or progression [8,9]. Patients also frequently have autoantibodies against carbonic anhydrase II (CA-II), lactoferrin, pancreatic secretory trypsin inhibitor, and/or trypsinogens [8,10]. Although the presence of these autoantibodies may explain predominantly lobular injury and other organ involvement (some of these enzymes are also expressed in other organs) in type 1 AIP, some may simply be secondary to extensive acinar destruction. None of the autoantibodies identified in patients with type 1 AIP have been proven to be of the IgG4 subtype.

In a recent study, circulating IgG1 and IgG4 isolated from patients with type 1 AIP were subcutaneously injected into neonatal mice in order to elucidate the tissue reactivity of patient-derived immunoglobulins [11]. IgG1 and IgG4 both caused pancreatic injury, as evidenced by stromal edema, acinar necrosis, hemorrhage, and the infiltration of polymorphonuclear leukocytes, and histologic changes were more extensive with IgG1. Interestingly, tissue destruction induced by IgG1 was suppressed by the simultaneous injection of patient IgG4, suggesting that IgG1 is the primary autoantibody against the pancreas, while patient IgG4 may exert inhibitory effects on pancreatic injury [11]. The similar anti-inflammatory induction of IgG4 was

previously reported in allergic individuals treated with desensitization therapy [12]. The underlying antigen of AIP type 1 remains currently unknown.

## T Cells, Cytokines, Chemokines

Among the T-cell subsets, Th2 cells and regulatory T cells (Tregs) are activated in this condition, with the Th1/Th2 balance shifting in favor of Th2 [13,14]. However, the Th1 reaction is not fully suppressed [15]. The expression of IFN-γ in the tissues of type 1 AIP is similar to that in those of primary sclerosing cholangitis and primary biliary cholangitis, while the expression of Th2 cytokines (e.g., IL-4, IL-5, IL-13, and IL-21) is markedly stronger in type 1 AIP, with a large number of IL-4+ lymphocytes infiltrating the pancreas (Fig. 64.1) [13]. The proportions of Tregs are also increased in both tissue-infiltrating lymphocytes and peripheral blood mononuclear cells [13,16].

Th2 cytokines such as IL-4, IL-5, and IL-13 supposedly contribute to tissue or serum eosinophilia and elevated serum IgE levels, which are sometimes observed in patients with type 1 AIP [17,18]. IL-10, a cytokine produced by Tregs, is also strongly expressed in type 1 AIP (Fig. 64.1) [13,14]. The combination of IL-4 and IL-10 may be relevant to the production of IgG4 because IL-4 induces the production of IgE and IgG4 from B cells and plasma cells, while IL-10 in addition to IL-4 suppresses the production of IgE, but selectively enhances that of IgG4 [19]. TGF-β, another regulatory cytokine, may play a central role in the fibrosing aspect of type 1 AIP.

The CCL1–CCR8 interaction appears to be crucial for the recruitment of Th2 cells and Tregs because 50% of Th2 lymphocytes and 60% of FOXP3+ Tregs express CCR8 [20]. CCL1 is expressed in the duct epithelium and endothelial cells, including those involved in obliterative phlebitis, in type 1 AIP [21]. CCL1+ sites are infiltrated by CCR8+ lymphocytes (Fig. 64.2). The CCL1–CCR8

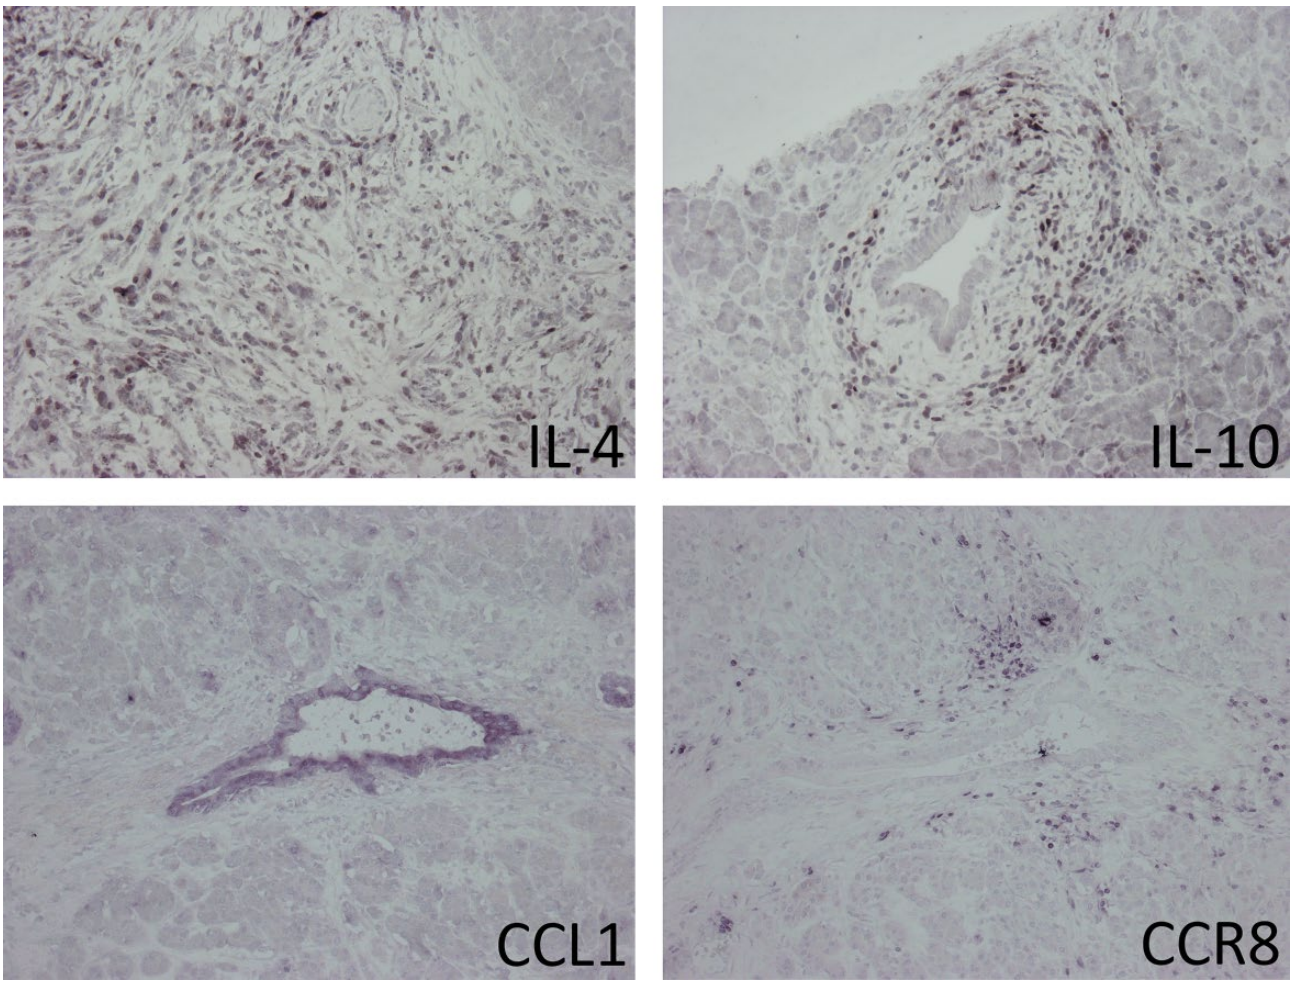

**Figure 64.1** Immunologic factors expressed in type 1 AIP (*in situ* hybridization). Lymphocytes expressing IL-4 or IL-10 are observed. The pancreatic duct positive for CCL1 is surrounded by CCR8+ lymphocytes. Sources: (Upper panels) Zen et al. 2007 [13]. Reproduced with permission of John Wiley & Sons. interaction may create a microenvironment in which Th2 cells and Tregs are abundant, leading to the IgG4 class switch through IL-4 and IL-10. This immunologic reaction is also probably responsible for the characteristic histologic changes observed in type 1 AIP such as periductal inflammation and obliterative phlebitis.

## Expansion of B Cells and Plasmablasts

B-cell depletion therapy with anti-CD20 antibodies is effective for type 1 AIP, which highlights the crucial involvement of B cells in its pathogenesis [22]. The proportion of circulating plasmablasts increases in type 1 AIP, and decreases rapidly upon treatment. Expanded plasmablasts are mainly of the IgG4 type and oligoclonal in nature, with dominant clones varying among patients [23]. Similarly, tissue-resident and circulating IgG4-switched B cells in type 1 AIP are oligoclonal [24]. The oligoclonality of IgG4-switched B cells/plasmablasts and the diverse dominant clones across patients support the hypothesis that IgG4 is less likely to be a pathognomonic autoantibody in this condition.

## Roles of Plasma Cells

IgG4 is generally regarded as a noninflammatory antibody because of its relative inability to fix complement and its poor capacity to bind to Fc receptors [25]. This minor IgG subclass also has the unique ability to exchange a pair of heavy and light chains (the "Fab-arm exchange") [26]. This immunologic process causes IgG4 molecules to lose their antigen cross-linking ability, behave as monovalent antibodies, and become incapable of forming large immune complexes. Based on these anti-inflammatory aspects, IgG4 induction in type 1 AIP may be secondary in order to suppress inflammatory reactions, as suggested

in the study described earlier, in which patient IgG1 and IgG4 were injected into mice [11].

In a recent global proteomic study, a robust proteomic approach with phosphopeptide enrichment methods identified 4,870 proteins including 1,121 phosphoproteins in frozen bile duct tissue involved in type 1 AIP [27]. In the pathway analysis based on strongly expressed or highly phosphorylated proteins, the immunologic pathway activated most significantly in type 1 AIP than in primary sclerosing cholangitis was Fc-γ receptor-mediated phagocytosis [27]. This signal cascade occurring inside macrophages is initiated by the interaction between IgG molecules and Fc-γ receptors on the cell membrane. Since the capacity of IgG4 to bind to Fc receptors is poor [25], this signal pathway may be activated by IgG subclasses other than IgG4.

A similar discussion will also be applied to hypocomplementemia, which is observed in ~40% of patients, particularly those with renal involvement [28]. Among the three complement activation systems, the classical pathway is predominantly activated in type 1 AIP. Since IgG4 cannot efficiently activate the classical pathway, complement fixation may be activated by other IgG subclasses, particularly IgG1, which fix complements more efficiently.

To summarize, the activation and expansion of particular subsets of lymphocytes have been identified in type 1 AIP, with the T-cell–B-cell interaction also being relevant to its pathogenesis (Fig. 64.2). The roles of IgG4 molecules in this condition have not yet been elucidated in detail. Other IgG subclasses, particularly IgG1, supposedly drive the disease, while IgG4 may be secondarily induced in order to suppress extensive immune responses in this markedly inflamed condition.

## Type 2 Autoimmune Pancreatitis

The rarity of this condition as well as the lack of serologic and immunologic biomarkers has restricted our investigations on the pathogenesis of type 2 AIP. A single potential clue is that one third of patients have inflammatory bowel disease, particularly ulcerative colitis [29]. In our recent study, the immunopathologic features of type 2 AIP were compared with those of type 1 AIP and ulcerative colitis [30].

Quantitative PCR using mRNA extracted from pancreatic tissues revealed the markedly higher expression of IL-8 in type 2 AIP than in type 1 AIP. The expression of other cytokines (e.g., IFN-γ, IL-4, IL-10, and TNF-α) was similar in types 1 and 2 AIP or weaker in type 2 AIP. Immunostaining revealed that IL-8 was mainly expressed in the damaged duct epithelium, infiltrating neutrophils, and lymphocytes, with its expression being particularly strong around injured ducts (Fig. 64.3). This expression pattern of IL-8 was not observed in other forms of pancreatitis. Since IL-8 is a chemotactic factor for neutrophils, its aberrant expression in pancreatic ducts may underlie pathognomonic duct-centered, neutrophil-rich inflammation, known as granulocytic epithelial lesions (GELs), in type 2 AIP [31,32].

A similar expression pattern of IL-8 was also observed in colonic biopsies of active ulcerative colitis. IL-8 appeared to be aberrantly expressed in the crypt epithelium, particularly at sites of cryptitis and crypt abscesses [30]. The colonic epithelium was largely negative for this immunologic marker in infectious colitis, another form of neutrophil-rich enteritis. These findings indicate that IL-8 is one of the key molecules involved in the pathogenesis of type 2 AIP, and also suggest a pathogenetic link between type 2 AIP and ulcerative colitis.

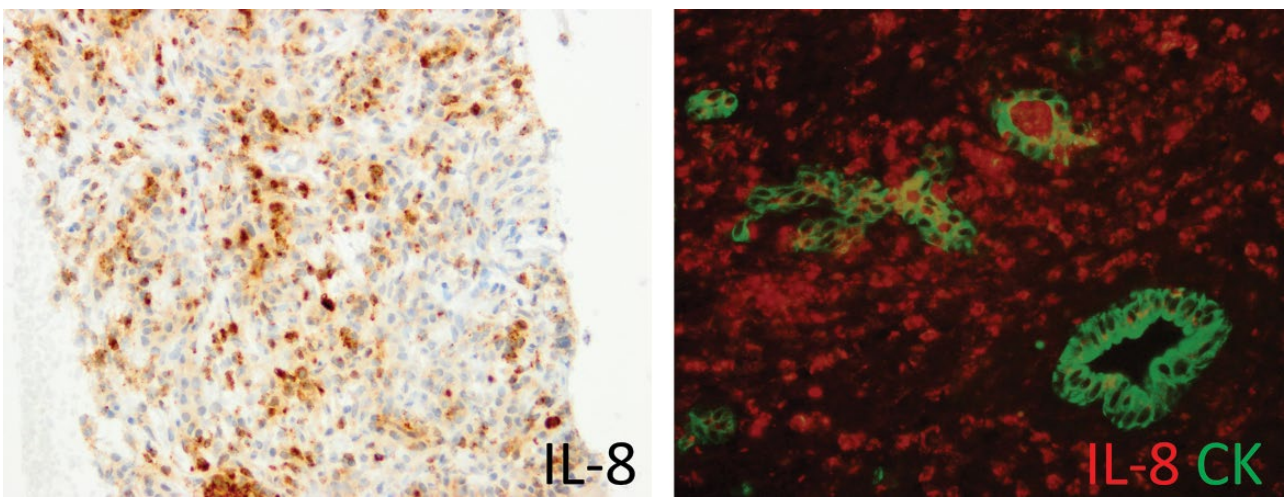

**Figure 64.3** IL-8 expression in type 2 AIP. Single immunostaining shows the extensive expression of IL-8 in pancreatic tissue. On double immunostaining, IL-8 (red) appears to be expressed in infiltrating inflammatory cells and pancreatic ducts that are also positive for cytokeratin (CK, green).

## Introduction

Autoimmune pancreatitis (AIP) is a distinct form of chronic pancreatitis, often presenting as a pancreatic mass, and characterized by a set of unique histopathologic features, frequent elevation of immunoglobulin IgG4 in serum and tissue and swift response to steroids. Although no specific antibody has been identified, the autoimmune nature of this disease is strongly supported by the finding of clonally expanded B- and T cells [1,2]. Currently there are two histologically distinct variants of AIP recognized: type 1 AIP and type 2 AIP. Type 1 AIP is the pancreatic manifestation of IgG4-related disease. In contrast, type 2 AIP bears no histologic resemblance to IgG4-related disease [3–5].

## Type 1 Autoimmune Pancreatitis

Type 1 AIP (alternate names: lymphoplasmacytic sclerosing pancreatitis; IgG4-associated pancreatitis; AIP-lobulocentric) generally presents as an isolated tumefactive pancreatic lesion, and less commonly, as a synchronous or metachronous mass-forming lesion at other sites such as lymphadenopathy, sclerosing cholangitis, and pulmonary lesions. Grossly, the resected pancreas does not show a discrete mass, and is instead characterized by diffuse gland enlargement, invariably accompanied by fibrosis, creating a rock-hard pancreas. The pancreatic duct is narrow and multiple strictures may be seen; a dilated main pancreatic duct is distinctly unusual.

Type 1 AIP is characterized by the presence of three histologic features: (i) dense lymphoplasmacytic infiltrate, (ii) storiform fibrosis (Fig. 65.1), and (iii) obliterative phlebitis (Fig. 65.2). Notably, these histologic features are also characteristic of IgG4-related disease [6,7]. While all three features are readily observed on a pancreatectomy specimen, obliterative phlebitis is seldom seen on a needle biopsy. Storiform fibrosis, a hallmark of type 1 AIP, is characterized by a swirling pattern of fibrosis consisting of short fascicles of spindle cells (which are either fibroblasts or myofibroblasts) and interspersed collagen, intimately intermixed with the dense inflammatory infiltrate composed of lymphocytes and plasma cells. These spindle cells are usually positive for smooth muscle actin and negative for desmin. This fibroinflammatory infiltrate is most prominent in the interlobular septa of the pancreas, but could also involve the pancreatic lobules and extrapancreatic adipose tissue. These characteristic histologic features may not be seen in patients with long-standing disease, instead pancreatic calculi may be observed in the late phase of the disease.

Although the inflammatory infiltrate may surround pancreatic ducts, histologic evidence of ductal injury is seldom observed. This is in contradistinction to type 2 AIP where ductal infiltration with neutrophils and/or intraductal aggregates of neutrophils, the so-called granulocytic epithelial lesions (GEL), is a prominent and defining feature of this disease. Other histologic features that may be observed include nonobliterative phlebitis, obliterative arteritis, markedly increased number of eosinophils in the pancreatic stroma and prominent lymphoid follicles with or without germinal centers.

Immunostaining for IgG4 usually reveals abundant IgG4+ plasma cells (>10 cells/HPF in core biopsies or 50 cells/HPF in resection specimens) in most cases of type 1 AIP [8,9]. A diffuse infiltrate of IgG4+ plasma cells is the norm; in contrast, focal pockets of IgG4+ cells are

identified in other inflammatory and nonneoplastic diseases of the pancreas. It is important to emphasize that the histologic features are paramount, and neither tissue nor serum IgG4 are entirely specific for IgG4-related disease; this immunoglobulin subclass is also identified in a wide range of inflammatory and neoplastic entities including pancreatic adenocarcinoma [10]. In addition, rare examples of type 1 AIP negative for tissue and/or serum IgG4 have been reported [11,12]. An elevated IgG4 to IgG ratio of greater than 40% represents a more specific marker of type 1 AIP [8,13].

The overwhelming majority of lymphocytes are CD4+ T cells [9]. Aggregates composed of B lymphocytes are invariably identified. Macrophages are only obvious on special stains such as CD68 and CD163. The B- and T lymphocytes as well as plasma cell populations are polyclonal. It should be noted that plasma cells bearing other immunoglobulins—IgE, IgG1, IgG2, and IgG3—are also found within the inflammatory infiltrate, although IgG4-bearing plasma cells tend to dominate.

### Differential Diagnosis

The histologic features on a resected pancreas are highly characteristic and unlikely to be mistaken for other inflammatory and neoplastic diseases of the pancreas. However, the diagnosis on a core biopsy is far more challenging [14]. The closest histologic mimic is well-differentiated pancreatic adenocarcinoma, a disease that may be associated with elevated serum and/or tissue IgG4. However, careful attention to the clinical, imaging, and histologic features should assist in excluding malignancy. Nevertheless, a needle biopsy may not capture the diagnostic areas, and such nondiagnostic biopsies are not uncommon. The primary role of a fine needle aspiration biopsy is to rule out malignancy; however, in some cases the fibro-inflammatory nature of the process may also be discerned [15]. Other forms of chronic pancreatitis such as groove pancreatitis and type 2 AIP may also mimic type 1 AIP, although these diseases show few, if any, IgG4+ plasma cells [16].

One recently described variant of chronic pancreatitis, follicular pancreatitis, also deserves mention [17,18]. Although both AIP and follicular pancreatitis cases show dense lymphoplasmacytic inflammation, the latter is characterized by the presence of large and prominent lymphoid aggregates with germinal centers, typically located in the periductal region and may surround the main pancreatic duct. Notably, the main pancreatic duct is often dilated, a feature not seen in AIP. Follicular pancreatitis does not appear to represent an IgG4-related disease, and tissue IgG4+ cells are either absent or fewer than typically seen in type 1 AIP. Anecdotal evidence suggests that like type 1 AIP, follicular pancreatitis may respond to immunosuppressive therapy.

## Pancreatic Cancer and Autoimmune Pancreatitis

In recent years, a number of cases of pancreatic ductal adenocarcinoma (PDAC) arising in patients with AIP have been reported [19–24]. One study has also looked at the association between pancreatic intraepithelial lesions (PanIN) and AIP and found that the number of PanIN lesions are increased in AIP, with fewer such preneoplastic lesions in chronic pancreatitis [25]. Whether there is an increased risk of PDAC in patients with AIP remains an open question.

## Type 2 Autoimmune Pancreatitis

On macroscopic examination, type 2 AIP (alternative names: idiopathic duct-centric pancreatitis; AIP with GELs; AIP-ductal) is similar to type 1 AIP, although a discrete mass may be appreciable. Although the disease is localized to the pancreas, there appears to be a strong association between type 2 AIP and inflammatory bowel disease.

Type 2 AIP is a pancreas-centric disease characterized histologically by: (i) dense periductal lymphoplasmacytic inflammation, and (ii) periductal and/or intraluminal infiltration of small and medium-sized interlobular ducts by neutrophils resulting in variable degree of duct destruction (Fig. 65.3) [4,7,26]. Neutrophils within acini are a frequent feature, and may represent the only diagnostic clue on a biopsy. Notably absent in type 2 AIP are storiform fibrosis, obliterative phlebitis, and diffuse infiltrates of IgG4+ plasma cells, although occasional clusters of IgG4+ cells may be seen. Other notable but inconstant features include: nonobliterative phlebitis, tissue eosinophilia, lymphoid aggregates, and periductal granulomas.

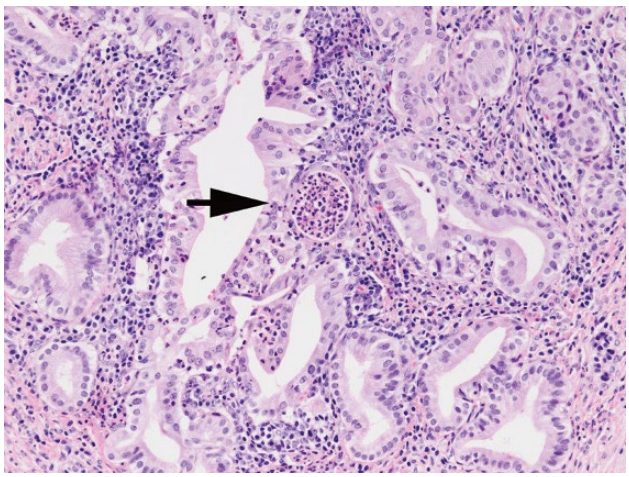

**Figure 65.3** Autoimmune pancreatitis type 2. The image shows a pancreatic duct surrounded by a lymphoplasmacytic inflammatory infiltrate. Intraductal neutrophils are identified (arrow), granulocytic epithelial lesions.

### Differential Diagnosis

Histologically, alcohol-related chronic pancreatitis may mimic type 2 AIP; however, both the presence as well as the severity of periductal inflammation and GELs is lower in alcohol-related pancreatitis. Additionally, alcohol-related pancreatitis shows characteristic histologic features, including dilated ducts containing inspissated proteinaceous material and calculi, features seldom seen in early-stage AIP. The differential diagnosis also includes groove pancreatitis, although GELs are uncommon in this disease.

## Unclassified Autoimmune Pancreatitis

In spite of general agreement regarding criteria pertaining to the histopathologic diagnosis of type 1 and type 2 AIP, a few cases such as examples of type 1 AIP with GELs defy classification, and these biopsies are best regarded as "unclassified AIP."

## Conclusions

The two forms of AIP are clinically, histologically, and immunologically distinctive (Table 65.1). The histologic diagnosis of AIP on a core biopsy relies on the coexistence of supportive clinical, laboratory, radiologic findings. In the absence of characteristic histologic features, the presence of elevated numbers of IgG4+ plasma cells is a relatively nonspecific feature and may be seen adjacent to a PDAC.

**Table 65.1** Histopathologic differences between type 1 and type 2 autoimmune pancreatitis

| Features | Type 1 AIP | Type 2 AIP |
|---|---|---|
| Storiform fibrosis in interlobular stroma | present | absent |
| Periductal lymphoplasmacytic infiltrate | usually mild | usually moderate to marked |
| Overt duct injury associated with infiltration by neutrophils (GEL) | usually absent | present |
| Lobular infiltration by neutrophils | usually absent | frequently present |
| Eosinophils in the stroma | common | rare |
| Lymphoid follicles in the stroma | can be present | rare |
| Phlebitis | present, usually obliterative in nature | uncommon; if present, nonobliterative in nature |
| Tissue IgG4 count | elevated, biopsy >10 per HPF, resection >50 per HPF | generally not elevated |
| IgG4/IgG ratio | >40% | <40% |

## Type 1 and Type 2 Autoimmune Pancreatitis

Professor Henri Sarles of Marseilles was first to point out that in some cases, autoimmunity may be involved in the pathogenesis of chronic pancreatitis [1]. In 1961, he investigated the pathology of 10 cases of noncalcifying chronic pancreatitis with poor prognosis showing unique clinical features such as fever, jaundice, abdominal pain, and emaciation. Pathologic findings, including the predominant appearance of inflammatory cells and severe fibrosis in the pancreas, the elevation of serum gammaglobulin, and the ineffectiveness of antibiotics, suggested the possible involvement of "self-immunization" in the pathogenesis.

The disease concept of autoimmune pancreatitis (AIP) was established in a case report by Yoshida et al. in 1995 [2]. The case was a 68-year-old female who presented with painless jaundice. After examining the patient in detail and comparing their findings with similar cases in the literature, Yoshida et al. proposed a new disease concept, which they coined AIP, characterized by the following: unique clinical finding of frequent onset of painless jaundice, the morphologic finding of diffuse enlargement of the pancreas with pancreatic duct narrowing, the serologic findings of elevated serum gamma-globulin levels and the appearance of autoantibodies, the histologic findings of abundant lymphocytes and severe fibrosis, the presence of other complicating diseases, such as other autoimmune diseases, and the therapeutic effectiveness of steroids. These clinical features coincide with those of the subsequently classified type 1 AIP. In 1991, Kawaguchi et al. had already reported a unique type of pancreatitis with a peculiar histology called "lymphoplasmacytic sclerosing pancreatitis (LPSP)," which is characterized by massive infiltration of lymphocytes with fibrosis and plasma cells centered around the pancreatic ducts, together with obliterative phlebitis [3]. LPSP is considered to be the current histopathologic definition of type 1 AIP. In 2001, Hamano et al. first reported the specific elevation of serum IgG4, the serologic feature of AIP [4], and subsequently confirmed the prominent infiltration of IgG4+ plasma cells in the affected tissues and organs [5]. These findings supported the view that most clinical features of AIP reported from Japan since the proposal of the disease concept by Yoshida et al. correspond to those of the later defined type 1 AIP [6].

Conversely, based on a pathologic re-evaluation of pancreatic tissues resected for suspected pancreatic cancer in Western countries, another type of pancreatitis involving immunologic mechanisms was proposed. In 2003, Notohara et al. reported the presence of inflammatory changes characterized by an infiltration of numerous granulocytes, chiefly around the inter- and intralobular ducts, with occasional destruction of duct epithelium and accumulation of granulocytes in the duct lumen in these pancreatic specimens. This finding subsequently became known as "idiopathic duct-centric pancreatitis (IDCP)" [7]. IDCP is considered to be a pathologic counterpart of "nonalcoholic duct-destructive chronic pancreatitis (NADCP)" previously reported by Ectors et al. [8]. Zamboni et al. also noticed an infiltration of granulocytes around ducts with occasional disruption of duct epithelium in a histologic examination of tumor-forming chronic pancreatitis, and pathologically defined this as "granulocytic epithelial lesions (GEL)" [9]. The pancreatitis characterized by GEL is understood to be a kind of AIP due to its histologic features involving the massive infiltration of inflammatory cells and fibrosis around

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

ducts, as well as the occasional association with inflammatory bowel disease (IBD). However, this tends to develop in younger patients with acute episodes of pancreatitis, regardless of sex, and with no specific serum markers [9].

As described earlier, while the AIP proposed in Japan shows various clinical features and has a histologic definition of "LPSP," AIP proposed in Western countries is pathologically defined as "IDCP/GEL" and shows clearly different clinical features [10]. The Mayo Clinic assigned the nomenclature of "type 1 AIP" to the former and "type 2" to the latter [11]. The classification of AIP was discussed as a topic at a satellite symposium of the Japan Pancreas Society and the American Pancreatic Association Joint Meeting held in Honolulu in 2009, and an international consensus referred to as the "Honolulu Consensus" was reached. The "Honolulu Consensus" approved the classification of AIP into two subtypes, type 1 and type 2, pathologically defined as LPSP and IDCP/GEL, respectively, and proposed additional investigation into the clinical and pathologic features of these subtypes in order to further clarify their identities [12].

## International Consensus Diagnostic Criteria (ICDC) for Autoimmune Pancreatitis

With regard to the diagnosis of AIP, various criteria have been proposed from many countries, with the Japanese criteria in 2002 being the first [13]. These include the following: Japanese clinical diagnostic criteria (2002 [13], 2006 [14]); Korean diagnostic criteria (2006 [15], 2007 [16]); the HISORt criteria of the Mayo Clinic (2006 [17], 2009 [18]); Asian criteria (2008 [19]); Italian criteria (2006 [10], 2009 [20]); and Spanish criteria (2005 [21]). Since all of these had been devised before the Honolulu Consensus, different types of AIP were mixed in the cases diagnosed using these criteria.

The international consensus diagnostic criteria of AIP (ICDC) proposed in 2011 are at present the sole criteria for classifying AIP into type 1 and type 2 [12] and can diagnose both types separately [22]. The ICDC are common global criteria that were compiled by world experts after discussion at a consensus symposium during the 14th meeting of the International Association of Pancreatology (IAP) held in Fukuoka, Japan in 2010.

Using the ICDC, AIP can be diagnosed by a combination of the following five cardinal features: (i) parenchymal imaging (P); (ii) ductal imaging (D); (iii) serology (S); (iv) other organ involvement (OOI); and (v) histology of the pancreas (H), with response to steroids (Rt) as an optional criterion. In order to provide a degree of flexibility in the diagnostic process, respective features are categorized as level 1 and 2 findings depending on their diagnostic reliability (Table 66.1) [22]. In addition, by employing a combination-based framework, the ICDC enable the diagnosis of AIP in any situation and in any country, even if the practice patterns and priority of diagnostic modalities are different.

The strategy of the ICDC is to reduce the number of other cardinal features necessary for the diagnosis of typical cases showing diffuse enlargement of the pancreas, whereas for cases with focal enlargement or atypical appearance, a stricter approach using a combination of more specific findings is employed for differentiation from pancreatic cancer. In addition to pancreatic imaging, the following are used to diagnose type 1 AIP: (i) elevation of serum IgG4 for serology; (ii) histologic findings of extrapancreatic organs, imaging of bile duct, retroperitoneal fibrosis (RF), physical evidence of sialadenitis, and radiologic finding of renal involvement for other organ involvement; and (iii) LPSP for histology of the pancreas. To diagnose type 2 AIP, IBD was adopted for other organ involvement and IDCP/GEL for histology of the pancreas (Table 66.2). A definitive or probable diagnosis is given for both types of AIP depending on the number of findings and their reliability. The diagnosis of not otherwise specified (NOS) is made for cases that satisfy the imaging findings but lack other cardinal features and show response to steroids (Table 66.3). Although the ICDC seem somewhat complicated, they were reported to show superior sensitivity, specificity, and accuracy compared with any other diagnostic criteria for AIP proposed in the past [23].

## Clinical Features of Type 1 Autoimmune Pancreatitis

To strictly separate type 1 AIP cases and clarify their specific clinical features, the selection of cases with histologically confirmed LPSP or cases diagnosed with type 1 by the ICDC [22] or the ICDC-based criteria [24] is required. Here we summarize the clinical features of type 1 AIP that satisfy the above conditions from eight recent studies which had a relatively large number of patients (Table 66.4) [25–32].

### Patient Profiles and Symptoms

Type 1 AIP shows a tendency to develop in elderly men with painless jaundice [25–32]. The average age range at onset was 60.5–66.3 years, which is clearly higher than that of type 2 AIP (34–52.5 years). Roughly more than 70% (66.7–91.9%) of the type 1 AIP cases were male, which

**Table 66.1** Level 1 and level 2 criteria for type 1 AIP.

| | Criterion | Level 1 | Level 2 |
|---|---|---|---|
| P | Parenchymal imaging | Typical: Diffuse enlargement with delayed enhancement (sometimes associated with rim-like enhancement) | Indeterminate (including atypical[†]): Segmental/focal enlargement with delayed enhancement |
| D | Ductal imaging (ERP) | Long (>1/3 length of the main pancreatic duct) or multiple strictures without marked upstream dilatation | Segmental/focal narrowing without marked upstream dilatation (duct size, <5 mm) |
| S | Serology | IgG4, >2 × upper limit of normal value | IgG4, 1–2 × upper limit of normal value |
| OOI | Other organ involvement | a or b<br>a) Histology of extrapancreatic organs (any 3 of the following)<br>1) Marked lymphoplasmacytic infiltration with fibrosis and without granulocytic infiltration<br>2) Storiform fibrosis<br>3) Obliterative phlebitis<br>4) Abundant (>10 cells/HPF) IgG4+ cells<br>b) Typical radiologic evidence (at least 1 of the following)<br>1) Segmental/multiple proximal (hilar/intrahepatic) or proximal and distal bile duct stricture<br>2) Retroperitoneal fibrosis | a or b<br>a) Histology of extrapancreatic organs including endoscopic biopsies of bile duct[‡] (Both of the following)<br>1) Marked lymphoplasmacytic infiltration with fibrosis and without granulocytic infiltration<br>2) Abundant (>10 cells / HPF) IgG4-positive cells<br>b) Physical or radiologic evidence (at least 1 of the following)<br>1) Symmetrically enlarged salivary/lachrymal glands<br>2) Radiologic evidence of renal involvement described in association with AIP |
| H | Histology of the pancreas | LPSP (core biopsy/resection)<br>At least 3 of the following:<br>1) Periductal lymphoplasmacytic infiltrate without granulocytic infiltration<br>2) Obliterative phlebitis<br>3) Storiform fibrosis<br>4) Abundant (>10 cells/HPF) IgG4+ cells | LPSP (core biopsy)<br>Any 2 of the following:<br>1) Periductal lymphoplasmacytic infiltrate without granulocytic infiltration<br>2) Obliterative phlebitis<br>3) Storiform fibrosis<br>4) Abundant (>10 cells/HPF) IgG4+ cells |
| Response to steroid (Rt)* | Diagnostic steroid trial<br>Rapid (≦2 wk) radiologically demonstrable resolution or marked improvement in pancreatic/extrapancreatic manifestations | | |

* Diagnostic steroid trial should be conducted carefully by pancreatologists with caveats only after negative workup for cancer including endoscopic ultrasound-guided fine needle aspiration.
† Atypical: Some AIP cases may show low-density mass, pancreatic ductal dilatation, or distal atrophy. Such atypical imaging findings in patients with obstructive jaundice and/or pancreatic mass are highly suggestive of pancreatic cancer. Such patients should be managed as pancreatic cancer unless there is strong collateral evidence for AIP, and a thorough workup for cancer is negative.
‡ Endoscopic biopsy of duodenal papilla is a useful adjunctive method because ampulla often is involved pathologically in AIP.
*Source:* Shimosegawa et al. 2011 [22]. Reproduced with permission.

appeared slightly higher than the ratio for type 2 (54.9–73.7%); however, this difference was not significant.

The most frequent initial symptom of type 1 AIP was painless jaundice, which occurred more frequently in type 1 (60–90%) than in type 2 (13–68.4%) AIP patients [25–32]. Meanwhile, abdominal pain showed a tendency to occur more frequently in type 2 (31.6–76.7%) than in type 1 AIP patients (10–58.3%). Acute pancreatitis (AP) was a rare initial symptom in type 1 AIP patients, whereas about 34–40% of type 2 AIP patients presented with AP. Diabetes mellitus (DM), mostly type 2 DM, was a complication in more than half (59.5–68%) of the type 1 AIP patients, which was considerably higher compared with the type 2 patients (14–26.7%) [28–31]. Among the patients with DM, 34.3% had DM before the onset of AIP, 56.9% developed DM concurrently, and only 8.8% developed DM after steroid treatment [33]. Mild to moderate exocrine dysfunction was frequently observed [34,35], and therefore caution should be exercised because 12–50% of type 1 AIP patients may experience weight loss [27,28,31].

## Imaging Findings

Characteristic imaging findings of AIP are diffuse or localized enlargement of the pancreas and narrowing of the main pancreatic duct (MPD). It is impossible to

* Diagnostic steroid trial should be conducted carefully by pancreatologists with caveats only after negative workup for cancer including endoscopic ultrasound-guided fine needle aspiration.
† Atypical: Some AIP cases may show low-density mass, pancreatic ductal dilatation, or distal atrophy. Such atypical imaging findings in patients with obstructive jaundice and/or pancreatic mass are highly suggestive of pancreatic cancer. Such patients should be managed as pancreatic cancer unless there is strong collateral evidence for AIP, and a thorough workup for cancer is negative.

differentiate type 1 from type 2 AIP solely by imaging findings [25–32]. Typical cases with a diffuse type show a prominently swollen hypoechoic pancreas referred to as a "sausage-like appearance" on ultrasound [36,37] (Fig. 66.1a). Delayed enhancement of the pancreas is a finding characteristic of AIP on dynamic computed tomography (CT) (Fig. 66.1b,c) and magnetic resonance imaging. In addition, some patients show a low-density rim-like structure referred to as a "capsule-like rim" that may reflect fibroinflammatory changes extending outside the pancreas [38] (Fig. 66.1d,e). The prevalence of a "capsule-like rim" is reportedly from 25–48.6% [27,28]. Since this finding is very specific to AIP, it is useful to differentiate AIP from pancreatic cancer [39]. A Korean report suggested a significantly higher rate of "capsule-like rim" in type 1 AIP compared with type 2 [28], whereas no difference was found in a report from North America [27].

MPD narrowing is another important finding of AIP, and the assessment should be done using endoscopic retrograde cholangiopancreatography imaging (ERCP) [36]

**Table 66.4** Comparison of clinical features of Type 1 and Type 2 AIP in eight recent reports.

| Diagnosis | | Type 1 AIP (LPSP) | Type 2 AIP (IDCP/GEL) |
|---|---|---|---|
| Mean age (y) | | 60.5–66.3 | 34–52.5 |
| Male ratio (%) | | 66.7–91.9 | 54.9–73.3 |
| Initial symptom | Jaundice (%) | 60–90 | 13–68.4 |
| | Abdominal pain (%) | 10–58.3 | 31.6–76.7 |
| | Acute pancreatitis (%) | 2.7–5 | 34–40 |
| Imaging | Diffuse swelling (%) | 15–75 | 16–73.3 |
| | Focal swelling (%) | 17.7–70 | 26.7–85 |
| Serology | Elevation of serumlgG4 (%) | 63–86.4 | 0–23 |
| | Elevation of serumlgG (%) | 54.1–56.4 | 0 |
| | ANA (%) | 18.2–33.5 | 0 |
| | RA (%) | 17.2–35 | 0 |
| Other organ involvement | Sclerosing cholangitis (%) | 10.3–42.9 | 0–23 |
| | Sialadenitis (%) | 8.1–22.2 | 0 |
| | Retroperitoneal fibrosis (%) | 1.6–11 | 0 |
| | Renal involvement (%) | 3.2–13.5 | 0–3 |
| | Lung involvement (%) | 1.6–4.1 | 0 |
| | Lymphadenopathy (%) | 8–26 | 0 |
| | Ulcerative colitis (%) | 1–3.2 | 15.7–33.3 |
| | Crohn's disease (%) | 0.2–1.6 | 2–3.9 |
| Steroid treatment | Response rate (%) | 92–100 | 100 |
| | Relapse rate (%) | 22.2–41.2 | 0–5 |

The data are the lowest and highest values shown in the 8 studies [Refs. 24–31].

(Fig. 66.2a). MPD narrowing with an irregular duct wall is characteristic of AIP, and branch ducts are often visible, even at the narrowed MPD [39]. Mild to moderate dilatation of ducts upstream of the narrowing is an important finding for differentiation from pancreatic cancer, because pancreatic cancer usually shows marked dilatation in the upstream section of the duct [39] (Fig. 66.2b,c). Magnetic resonance cholangiopancreatography (MRCP) is considered inadequate for the precise evaluation of narrowed ducts in AIP because of the insufficient resolution [40]. [$^{18}$F]fluoro-2-deoxy-D-glucose positron emission tomography (FDG-PET) is useful for judging the response to steroids. FDG accumulates densely in the affected pancreatic and extrapancreatic lesions in AIP, but promptly improves in response to steroids [41] (Fig. 66.2d,e).

Enlargement of the pancreas and narrowing of MPD are findings seen in almost all cases of AIP, and they often provide a clue for suspected AIP. Although no specific tendencies have been observed in the proportion of diffuse and localized types between type 1 and 2 AIP (Table 66.4), special care should be taken regarding the differentiation of focal type AIP from pancreatic cancer. According to a report from Japan [32], enlarged pancreas can be observed in 92.9% of AIP cases, and the proportion of diffuse (more than two-thirds), segmental (one third to two-thirds), and focal (less than one third) involvement was 52.6%, 27.6%, and 17.7%, respectively, whereas atypical imaging such as a tumor-like appearance was only seen in 0.5%. Similarly, MPD narrowing was observed in 89.6% of AIP patients, and the proportion of diffuse narrowing (more than two-thirds the entire length of the MPD), segmental narrowing (one third to two-thirds), and focal narrowing (less than one third) was 44.5%, 31.4%, and 17.3%, respectively, with multiple narrowing seen in 3.7%.

## Blood Tests

Serum IgG4 is a biomarker with high specificity to type 1 AIP and is elevated in 63–86.4% of all type 1 AIP patients [25–32]. It is far superior to IgG and gamma-globulin in terms of sensitivity and specificity, and therefore, the ICDC adopted IgG4 as the lone serum marker of type 1

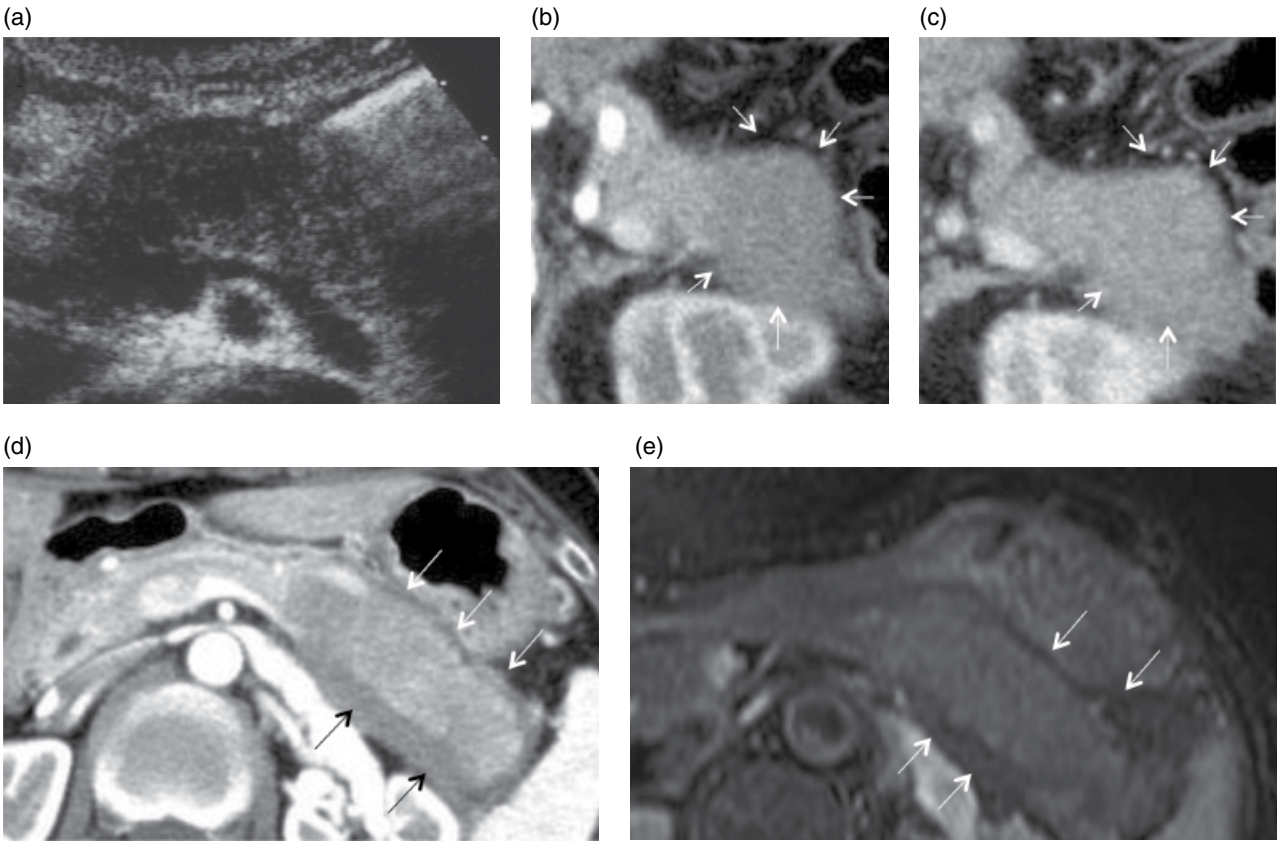

**Figure 66.1** Characteristic parenchymal imaging of type 1 AIP. (a) Diffuse enlargement of the pancreas called "sausage-like appearance" on US. (b,c) Delayed enhancement of the pancreatic lesion on the dynamic CT (arrows). The low-density area in the pancreatic tail (b) is enhanced in the late phase (c). (d) "Capsule-like rim" is shown in the body-tail region of the swollen pancreas (arrows) on the contrast-enhanced CT. (e) MRI T2WI imaging shows the "capsule-like rim" (arrows).

AIP [22]. Its elevation in blood is caused by an overproduction of polyclonal IgG4, and 135 mg/dL is usually employed as the cut-off value. However, since it is reported that up to 10% of pancreatic cancer patients may also show a value higher than the normal upper limit [42], the level 1 finding for serology in the ICDC set the cut-off at more than double the normal upper limit. The serum IgG4 level is considered to reflect disease activity, but the average value differs. For example, average IgG4 levels of 533 mg/dL and 241 mg/dL were reported in Japan [32] and Korea [28], respectively. The serum IgG level increases in 54.1–56.4% of type 1 AIP patients [25–32], and the prevalence of antinuclear antibody and rheumatoid factor are 18.2–33.5% and 17.2–35%, respectively [25–32]. In addition, there are some reports involving cases with excessive eosinophilia [43] and low serum complement levels with formation of IgG1 immune complex [44].

Other autoantibodies that may appear in AIP patients include anticarbonic anhydrase II antibody [45], antilactoferrin antibody [45], antipancreatic secretory trypsin inhibitor antibody [46], antiamylase α-2A antibody [47], and autoantibodies suspected of cross-activity with plasminogen-binding protein of *H. pylori* and ubiquitin-protein ligase E3 component n-recognin 2 [48], although their practical significance, usefulness, and specificity to AIP subtypes have not yet been clarified.

## Pathologic Findings of the Pancreas

LPSP is the histopathologic definition of type 1 AIP [11,12]. It consists of the following four items: (i) prominent infiltration of lymphocytes and plasma cells without granulocytes in the parenchyma and around ducts; (ii) storiform, that is, whirl-like fibrosis; (iii) obliterative phlebitis; and (iv) appearance of more than 10 IgG4+ plasma cells per a high-power field [22]) (Fig. 66.3a–d). In contrast to IDCP/GEL, which is characterized by a disruption of duct epithelium (Fig. 66.3e,f), the preservation of ductal lining is a distinct histologic feature of LPSP. The histologic diagnosis of type 1 AIP in the ICDC is categorized as level 1 when three or more of the four features are found, and categorized as level 2 when only two of four items are observed. Some rare cases

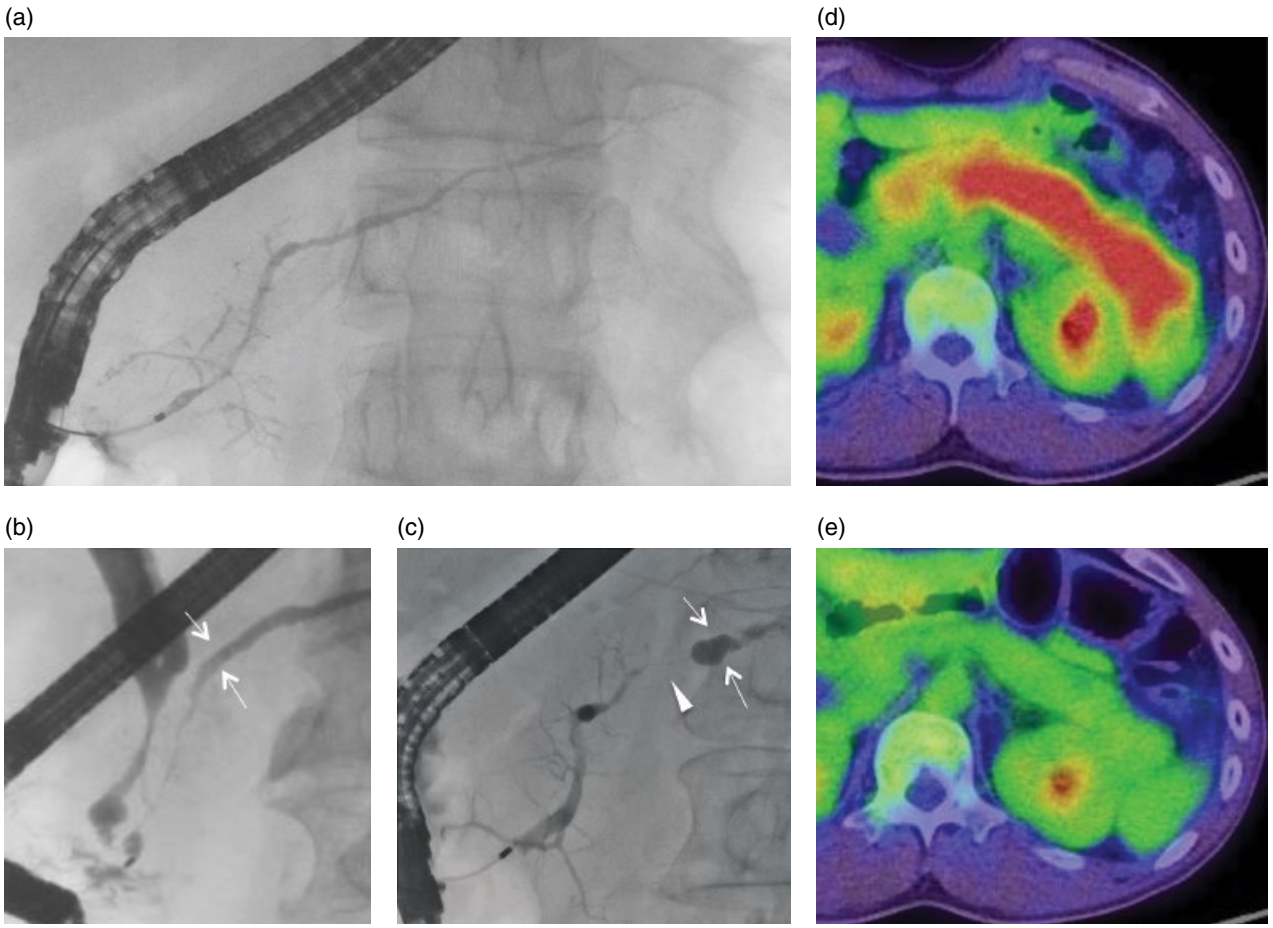

**Figure 66.2** (a) Characteristic ductal imaging of type 1 AIP on the ERCP. The main pancreatic duct (MPD) shows diffuse narrowing with irregular duct walls and visible branch ducts. (b) Focal narrowing of the MPD in the pancreatic head without association of remarkable upstream dilatation (arrows) in type 1 AIP. Intrapancreatic bile duct also shows severe narrowing. (c) Marked MPD dilatation (arrows) upstream of severe stenosis (arrowhead) by pancreatic cancer. (d,e) [$^{18}$F] fluoro-2-deoxy-D-glucose positron emission tomography (FDG-PET) imaging of the pancreas in a type 1 AIP patient. The pancreas showed diffuse and strong accumulation of FDG in the body and tail regions (d), which disappeared in response to steroid treatment (e).

showing LPSP with abundant eosinophils have been reported [49]. The use of resected or core biopsy specimens of the pancreas is the principle approach for pathologic diagnosis, because an adequate amount of pancreatic tissue is necessary for the correct diagnosis of type 1 and type 2 AIP [22].

## Extrapancreatic Lesions

Various extrapancreatic lesions appear synchronously and metachronously in about 45–80% of type 1 AIP patients [25–32]. Other than bile duct stenosis, these lesions are specific to type 1 AIP and are rarely seen in type 2. On the other hand, IBD such as ulcerative colitis and Crohn's disease are frequent complications, occurring at a rate of 15.7–33.3% in type 2 AIP, but at an extremely low rate in type 1 AIP (Table 66.4) [25–32].

The pathologic findings of extrapancreatic lesions are remarkably similar to those of the pancreas, which is the reason why type 1 AIP is regarded as the pancreatic manifestation of systemic IgG4-related disease [50]. Sclerosing cholangitis is the extrapancreatic lesion most frequently seen in type 1 AIP patients (10.3–42.9%) [25–32]. It appears as bile duct narrowing at the hepatic hilum and/or narrowing of the intrahepatic or intrapancreatic bile duct (Fig. 66.4a,b); however, proximal bile duct involvement is regarded as a more specific finding for sclerosing cholangitis in type 1 AIP [22,51–53]. Due to its prompt response to steroids and differences in imaging findings, sclerosing cholangitis occurring in type 1 AIP is a different pathologic condition from primary sclerosing cholangitis [51–53]. The second most frequent extrapancreatic lesion is sialadenitis, which appears in 8.1–22.2% of patients [25–32]. In typical cases, the bilateral lachrymal glands of the upper eyelids

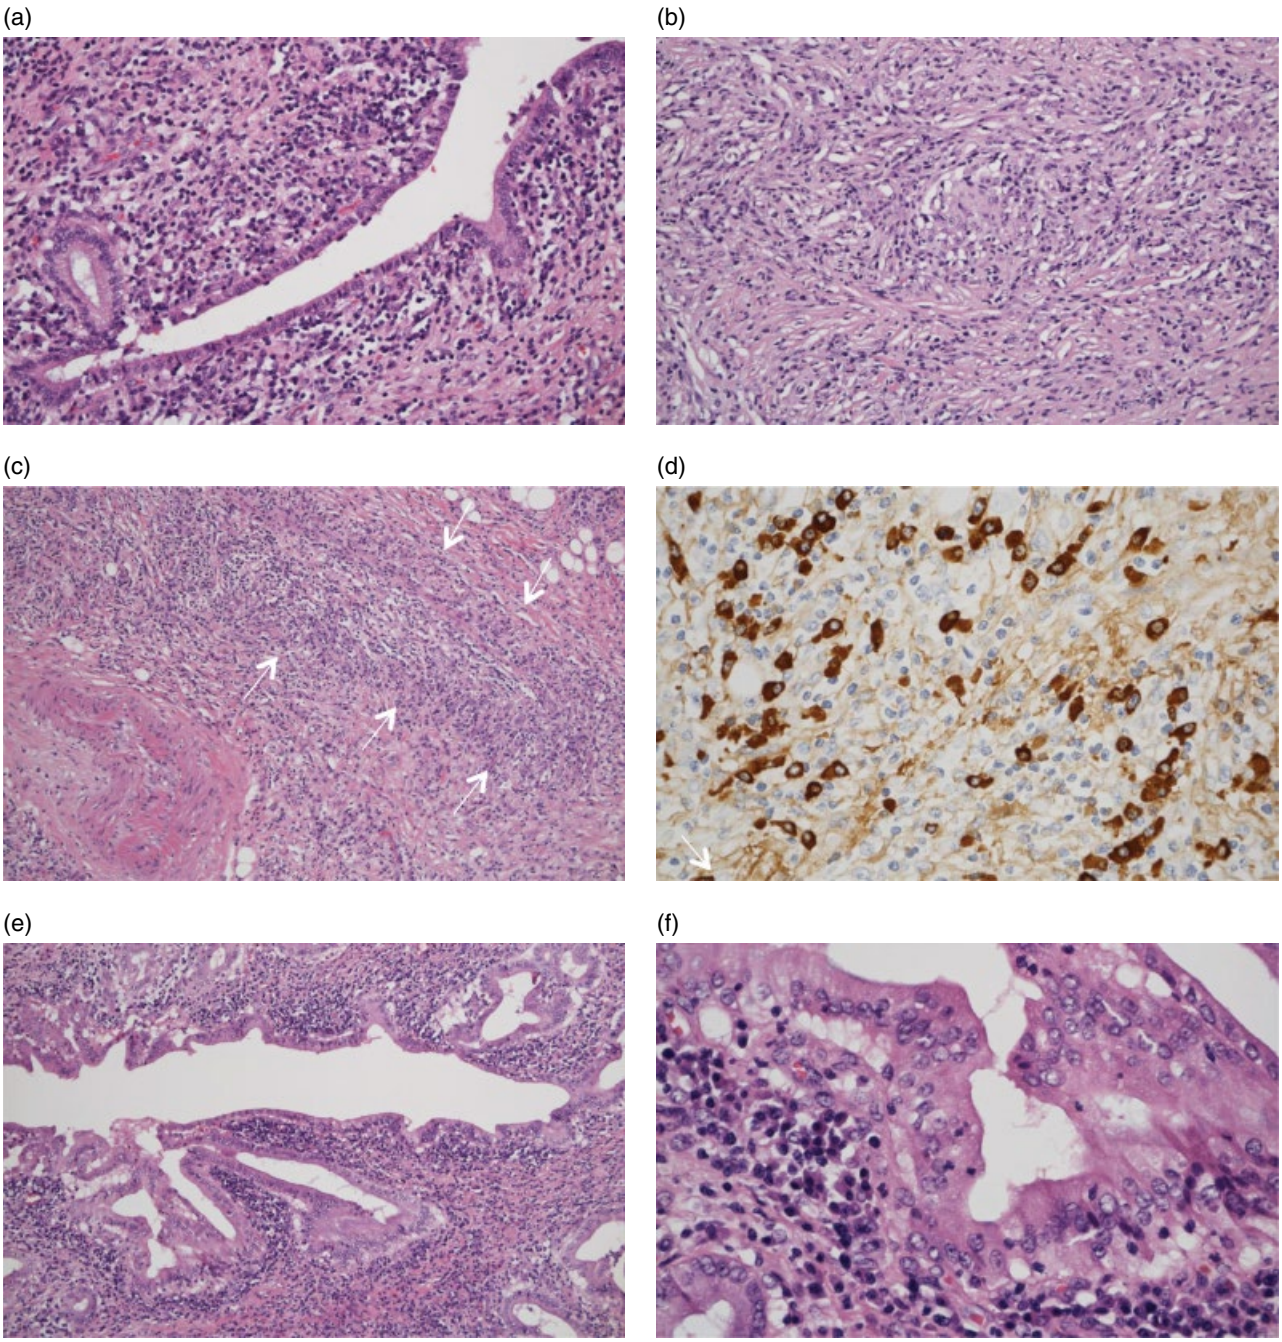

**Figure 66.3** LPSP (a–d) and IDCP/GEL (e,f). These images were kindly provided by Kenji Notohara (Department of Pathology, Kurashiki Central Hospital). (a) Numerous lymphocytes and plasma cells are seen around a duct with association of thick fibrosis. The ductal epithelium is preserved nearly intact. (b) Storiform fibrosis. (c) Obliterative phlebitis (arrows). (d) Immunostaining for IgG4 shows abundant IgG4+ plasma cells in the pancreas of type 1 AIP. (e) Massive infiltration of inflammatory cells with granulocytes around pancreatic ducts in the pancreas of type 2 AIP. (f) Granulocytes infiltrate into the duct epithelium and destroy the epithelial structure.

(Fig. 66.5a,b) and/or bilateral submandibular glands (Fig. 66.5c,d) swell symmetrically, becoming palpable, elastic hard, smooth surface nodules or tumors without tenderness that may correspond to Mikulicz disease [54] or Küttner tumor [55], and are considered to be clinical and pathologic entities distinct from Sjögren syndrome because the former involves predominantly submandibular glands, presents with milder dry mouth symptoms, shows negative SS-A/SS-B antibodies and infiltration of numerous IgG4-positive plasma cells, and shows good response to steroids. Retroperitoneal fibrosis (RF) occurs in about 10% (1.6–11%) of type 1 AIP patients and is

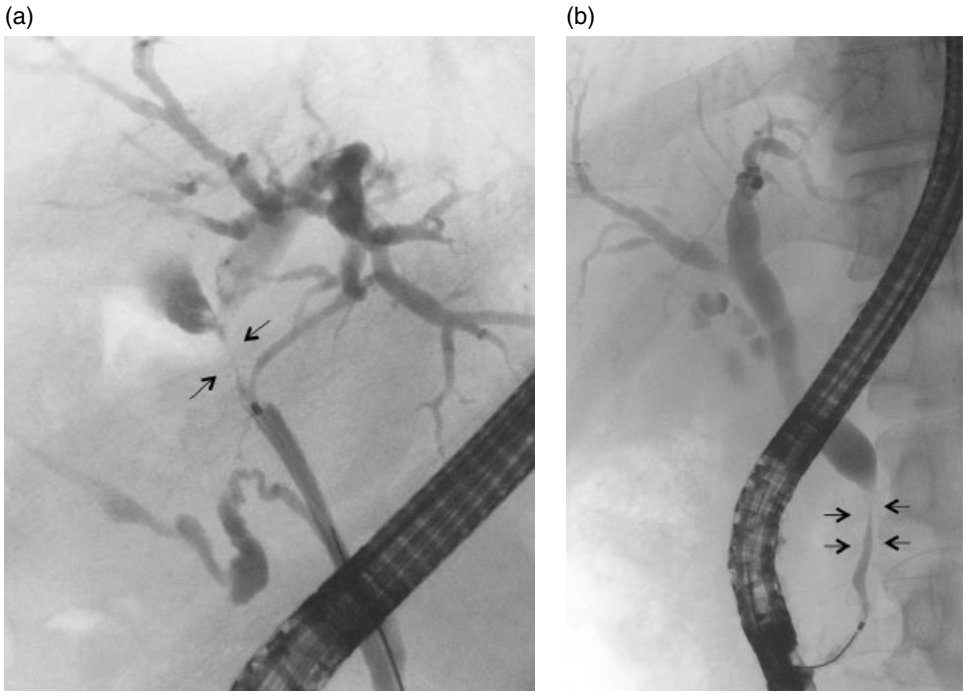

**Figure 66.4** Sclerosing cholangitis in type 1 AIP. (a) Severe stenosis (arrows) of the bile duct at the hepatic hilum. (b) Stricture of the intrapancreatic bile duct (arrows).

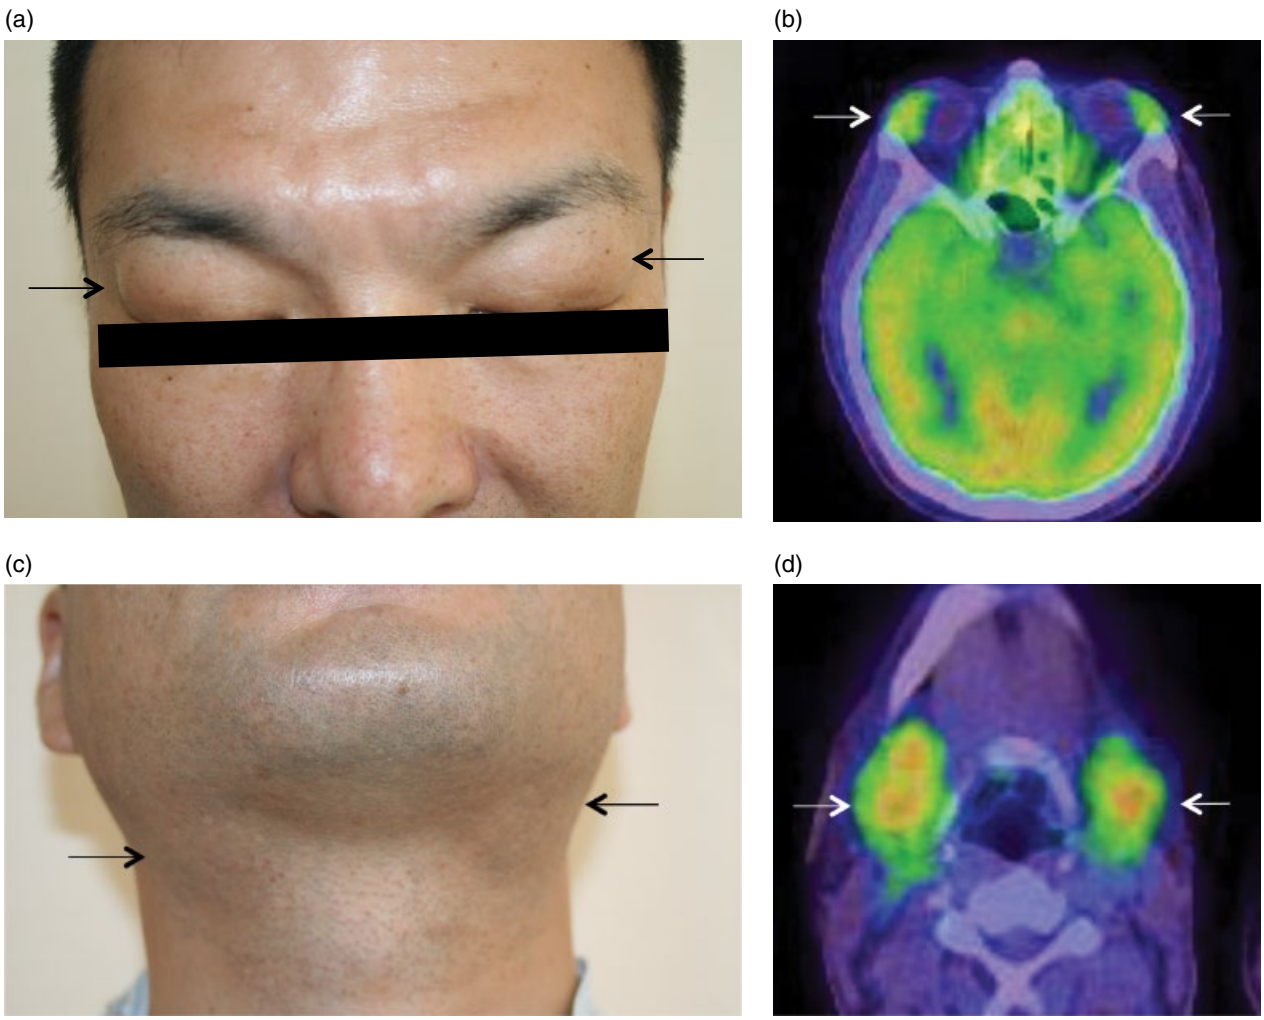

**Figure 66.5** Lachrymo-sialadenitis in type 1 AIP. (a) Bilateral lachrymal glands swell symmetrically (arrows). (b) FDG accumulation in the swollen lachrymal glands (arrows). (c) Bilateral submandibular glands swell symmetrically (arrows). (d) FDG accumulation in the swollen submandibular glands (arrows).

observed as a soft tissue band or mass in front of or around the abdominal aorta [5] (Fig. 66.6a). Renal involvement is seen as various imaging findings on contrast-enhanced CT such as tumor/nodule-like appearances and multiple perfusion defects in the renal cortex [56,57] (Fig. 66.6b,c). These findings are observed reportedly in 3.2–13.5% of AIP patients [25–32].

Other pathologic conditions suspected as extrapancreatic lesions of type 1 AIP include the following: inflammatory aortic aneurysm [58]; tubulointerstitial nephritis [59–61], swelling of the papilla of Vater [62–66] (Fig. 66.6d), hilar lymphadenopathy [67], chronic thyroiditis [68], inflammatory pseudotumors [69,70], prostatitis [71,72], interstitial lung disease [73] (Fig. 66.6e), hypophysitis [70] (Fig. 66.6f,g), autoimmune thrombocytopenia [74], hepatopathy [75], autoimmune neurosensory hearing loss [76], uveitis [77], and Schönlein-Henoch purpura [76].

## Response to Steroids and Relapse

The standard therapy for type 1 AIP is oral administration of prednisolone, which is effective in more than 92% of patients and shows nearly a 100% response rate [25–32] (Table 66.4). Response can be seen usually within 2 weeks after the initiation of steroid treatment, and improvements in swollen pancreas and extrapancreatic lesions are sometimes accompanied by a decrease in serum IgG and IgG4. Another important clinical feature of type 1 AIP is the high rate of relapse, which occurs in 22–41.2% of patients [25–32] (Table 66.4). It is reported that relapse occurs in the pancreas in 55.4% of type 1 AIP patients, in the bile duct in 28%, in the lachrymal and salivary glands in 8.3%, and as RF in 5.7% [32]. Type 2 AIP shows a significantly lower relapse rate (0–9%) than type 1 AIP [25–32].

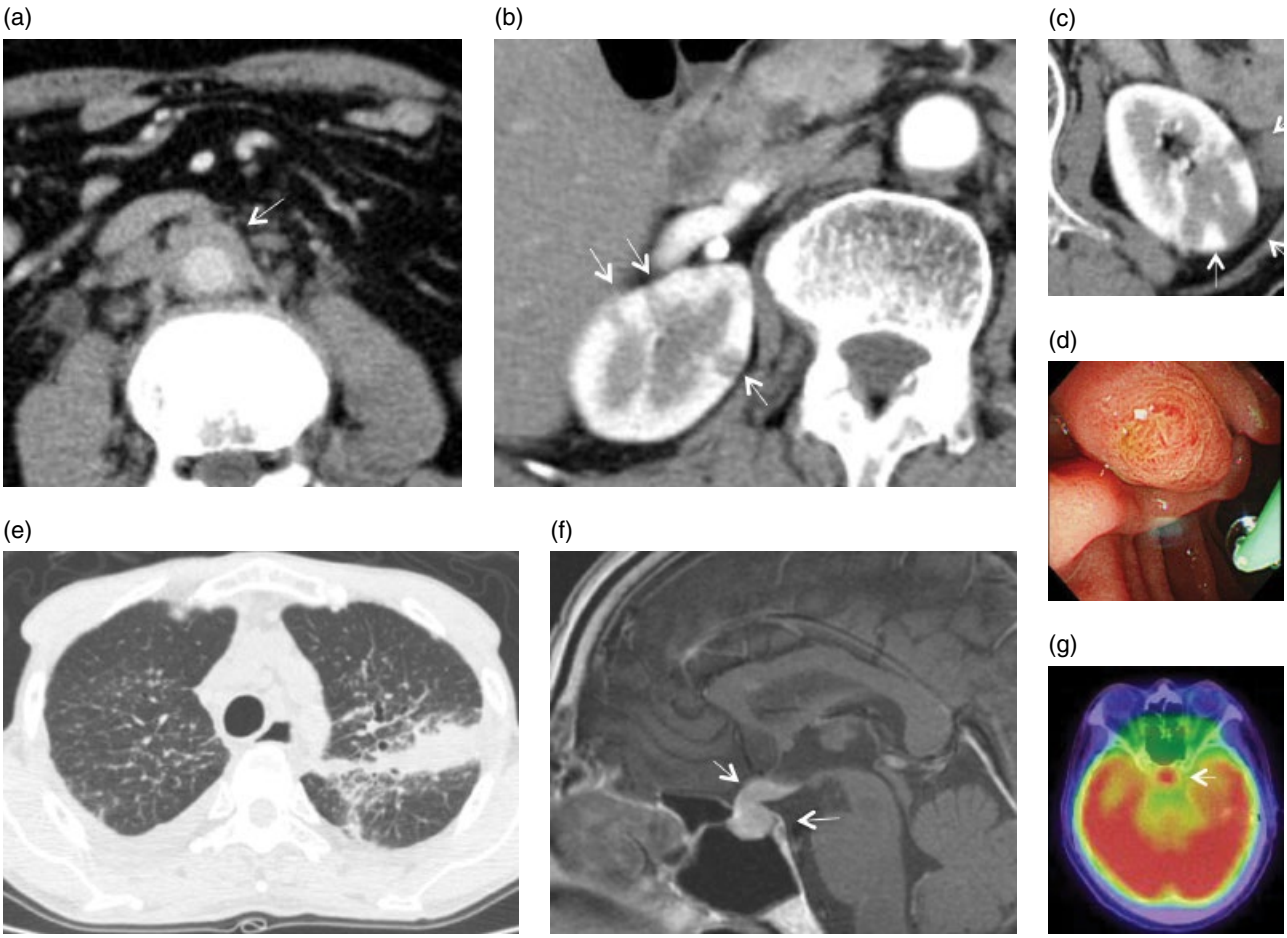

**Figure 66.6** Extrapancreatic lesions of type 1 AIP. (a) Retroperitoneal fibrosis can be seen as a soft tissue surrounding the abdominal aorta (arrow). (b,c) Low-density perfusion defects of the renal cortex on dynamic CT (arrows). (d) Swollen duodenal papilla Vater. (e) CT findings of the interstitial pneumonitis in type 1 AIP. (f,g) Hypophysitis associated with type 1 AIP. MRI imaging shows a remarkably swollen stalk and body of the pituitary gland (f, arrows). FDG-PET imaging shows an intense accumulation of FDG in the pituitary gland (g, arrow).

## IgG4-Related Disease (IgG4-RD)

Because type 1 AIP is considered to be a systemic fibrous disease characterized by an increased number of IgG4+ plasma cells with overproduction of IgG4 [50], in 2003, Kamisawa et al. proposed the new concept of "IgG4-related sclerosing disease" [78–80]. Various other names were proposed, including SHIPS (systemic IgG4-related plasmacytic syndrome) [81], with Mikulicz disease as one such representative, and IgG4-MOLPS (IgG4-related multiorgan lymphoproliferative syndrome) [82], from the viewpoint of IgG4+ plasma cell proliferative disease. The nomenclature was subsequently unified as IgG4-related disease (IgG4-RD) [83]. IgG4-RD includes sclerosing cholangitis (IgG4-SC), Mikulicz disease (IgG4-Mikulicz), tubulointerstitial nephritis (IgG4-nephropathy), RF, inflammatory pseudotumors, inflammatory aortic aneurysm, periaortitis, and periarteritis, among others [50,83].

Regarding the diagnosis of IgG4-RD, comprehensive diagnostic criteria for IgG4-RD were compiled in 2011 [84] and have been used for the screening of this disease. However, since the criteria are heavily based on histologic findings, other diagnostic criteria more specific to AIP [22], IgG4-SC [85], IgG4-Mikulicz [86], and IgG4-related kidney disease [87] should be applied to cases if tissue biopsy is difficult and/or confirmation of the respective diagnosis is necessary.

# Clinical Manifestations of Type 2 Autoimmune Pancreatitis

*Emma L. Culver*[1] *and George Webster*[2]

[1] *Translational Gastroenterology Unit, John Radcliffe Hospital, and Nuffield Department of Medicine, Oxford University, Oxford, UK*
[2] *Department of Hepatopancreatobiliary Medicine, University College Hospital, London, UK*

## Introduction

Over the last decade significant clinical and scientific attention has surrounded the concept and definition of autoimmune pancreatitis (AIP), a corticosteroid-responsive form of pancreatitis with two distinct histologic and clinical profiles. The focus of this chapter is the clinical manifestations of type 2 AIP, which incorporates idiopathic duct-centric pancreatitis (IDCP) and AIP with granulocytic epithelial lesions (GEL). The chapter includes a historical perspective on the discovery and terminology used to describe the condition, worldwide epidemiologic studies, demographics and clinical presentation, diagnosis, treatment, relapse, and clinical outcome.

## Search Criteria

We searched online literature databases including Pubmed, Medline, and EMBASE from January 1, 1961 until March 1, 2016. Search terms included "autoimmune pancreatitis type 2," "idiopathic duct-centric pancreatitis," "granulocytic epithelial lesions," and "duct-destructive pancreatitis." Publications were reviewed and high-quality original, review articles were included, predominantly from the last 10 years.

## Historical Perspective

A chronic inflammatory sclerosis of the pancreas was first described in 1961. Chronic pancreatitis with diffuse irregular narrowing of the entire pancreatic duct was later reported in 1992 [1], followed by the proposal of "autoimmune pancreatitis" (AIP) in 1995, to describe a corticosteroid-responsive disease associated with features of autoimmunity [2]. Nonalcoholic duct-destructive pancreatitis was later described in 1997 [3]. The clinical findings of elevated serum IgG4 levels and histologic evidence of abundant IgG4-bearing plasma cell infiltration in the pancreas were reported by Hamano et al. [4,5], and became important serologic and pathologic hallmarks for the diagnosis of AIP, now known as type 1 AIP or the pancreatic manifestation of IgG4-related disease. American and European pathologists highlighted two separate histopathology patterns in the pancreas in 2003, based on retrospective histologic assessments of resected specimens from patients who had mass-forming chronic pancreatitis [6], which were referred to as lymphoplasmacytic sclerosing pancreatitis (LPSP) and idiopathic duct-centric chronic pancreatitis (IDCP). The IDCP variant resembled duct-destructive pancreatitis, with neutrophil infiltration in the pancreatic duct epithelium [7], and was also termed AIP with granulocyte epithelial lesions [8]. These variants were shown to have distinct clinical profiles, and therefore two subtypes of AIP, called type 1 (LPSP) and type 2 (IDCP) AIP, were formally recognized [8,9]. This was later reinforced in the International Consensus Diagnostic Criteria (ICDC) for AIP in 2011 [10].

## Terminology

Several descriptive terms for type 2 AIP are used throughout the literature, and are listed in Table 67.1. The entity had been called "nonalcoholic duct destructive pancreatitis,"

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

**Table 67.1** Terminology used to describe type 2 AIP

| Nomenclature | Reference |
|---|---|
| Type 2 autoimmune pancreatitis | 32 |
| Nonalcoholic duct-destructive pancreatitis | 3 |
| Idiopathic duct-centric chronic pancreatitis (IDCP) | 6 |
| Idiopathic duct-centric pancreatitis (IDCP) | 33 |
| AIP with granulocytic epithelial lesions (GEL) | 8 |
| GEL-positive pancreatitis | 7 |

"GEL-positive pancreatitis," and "IDCP" [3,9,11]. All three terms highlight the duct-centric nature of the disease. For the purpose of this chapter, type 2 AIP is used.

## Epidemiology

The epidemiology of type 2 AIP is incompletely defined. In particular, the necessity for histologic assessment has rendered diagnosis difficult, almost certainly leading to underrecognition of the disease. A nationwide population survey of all AIP patients in Japan in 2011 estimated the annual incidence as 1.4 per 100,000 and prevalence as 4.6 per 100,000 of the population [12]. In an international multicenter survey of 1,064 patients with AIP across 10 countries, only 8% were defined as type 2 AIP [13]. The proportion of type 2 AIP patients was lower in Asia (3.7%) than in both Europe (12.9%, $P < 0.0001$) and North America (13.7%, $P < 0.001$) [13]. This was supported by retrospective review of 26 original articles involving 706 AIP patients in China, suggesting the estimated proportion of type 2 AIP was 4.7% [14]. However, when assessing all histologically confirmed AIP patients in Korea, the proportion of type 2 AIP was 28.8 % (15/52), suggesting that this entity may not be as rare as originally thought [15].

## Demographics

Type 2 AIP has a young to middle-age disease onset (30–40 years) with no gender bias, in contrast to type 1 AIP which carries an elderly male predominance [16].

## Disease Associations

A coexistent history of other autoimmune diseases has been reported in up to 20% of patients with AIP [17]. Type 2 AIP is most often associated with inflammatory bowel disease (IBD), studies suggesting a frequency of 25–44% of cases (compared to 3% to 5% in type 1 AIP) [18–20]. In one study from the Mayo group, the diagnosis of IBD was most often made preceding or simultaneous to AIP [20]. Ulcerative colitis (UC) was more frequent than either Crohn's colitis or IBD-colitis type unclassified, and was pancolonic in distribution and clinically mild in severity [20]. There were no differences in clinical profiles between type 2 AIP patients with and without IBD.

Conversely, the overall prevalence of AIP in patients with IBD is low. A Korean study of 1,106 UC patients estimated the crude prevalence of AIP (any subtype) as 0.54% [19]. Furthermore, a Japanese study reported that type 2 AIP was found in 5 (0.5 %) of 961 patients with UC and 2 (0.3 %) of 790 patients with Crohn's disease [21]. However, in a study of 138 cases of pancreatitis with complicating IBD from Japan, 10.8% (15/138 patients) had histologic evidence of type 2 AIP [16]. This high rate is likely due to the recruitment of patients from centers specializing in AIP. In general, pancreatic diseases that complicate IBD consist mainly of acute pancreatitis due to gallstones, alcohol consumption, medications such as mesalazine and azathioprine, and duodenal lesions from Crohn's disease [22]. Furthermore, in patients consecutively evaluated for acute pancreatitis, irrespective of the presence of IBD, AIP (any subtype) explained less than 5% of cases [23].

## Clinical Symptoms and Signs

The clinical characteristics of type 2 AIP have been reported to be different from those of type 1 AIP [13,15,24]. Patients often present with abdominal pain, consistent with acute pancreatitis [16]. In one study, almost half of type 2 AIP patients ($n = 25$) had more than one episode of acute pancreatitis prior to a diagnosis of AIP, and after diagnosis episodes were less frequent and clinically mild [20]. Obstructive jaundice occurs less often than in type 1 AIP, likely due to a lower prevalence of pancreatic head swelling and lower bile duct stenosis [16]. In accordance with these observations, serum amylase concentrations are higher, but serum total bilirubin, biliary enzymes, and transaminases are lower when compared with type 1 AIP. Patients can experience diarrhea, particularly in those with complicating IBD and also due to exocrine pancreatic insufficiency [25].

No specific symptoms allow reliable differentiation of AIP from other causes of a pancreatic mass. The diagnosis may also be reached during the investigation of nonspecific abdominal symptoms in the setting of elevated amylase. Disease may be asymptomatic and can be found incidentally on cross-sectional imaging performed for another reason. Other cases are identified in a patient presenting with symptoms related to IBD.

## Diagnosis

Two of the greatest challenges to accurately diagnosing type 2 AIP are its misclassification and the need for histology (core tissue biopsy or resected specimen) to make a definitive diagnosis. The goal of defining diagnostic criteria in AIP focused initially on type 1 AIP (LPCP variant), and type 2 AIP received limited attention [23,26]. Recently, development of the International Consensus Diagnostic Criteria (ICDC) for AIP sought to provide alternative means for diagnosing type 2 AIP when definitive histologic features are not present, that is, small sample size, sampling error, or when tissue is unavailable [10]. The ICDC incorporate five cardinal features: imaging characteristics of the pancreatic parenchyma and pancreatic duct, serology, organ involvement, pancreatic histology, and the optional criterion of response to steroid therapy. Depending on diagnostic reliability, the evidence for each feature is characterized by category (level 1 or 2). The diagnosis of type 2 AIP can be definitive or probable, depending on the strength of supportive evidence, although occasionally the two types can be indistinguishable (AIP-not otherwise specified) [10].

For a diagnosis of type 2 AIP, the presence of granulocytic infiltration and absent or scant IgG4+ cells on histology (definitive diagnosis), or the presence of concurrent clinical inflammatory bowel disease (IBD) with either supportive histology (definitive diagnosis) or a response to steroid therapy (probable diagnosis) are required [10]. Limited clinical experience suggests these diagnostic categories are appropriate. One study, which compared patient and disease-related characteristics of definitive and probable type 2 AIP patients, using IBD as a valid supportive criterion for probable disease, concluded that both groups were representative of the same disease entity [20]. Furthermore, a controlled study that compared the ICDC to four other criteria in the diagnosis of AIP in a Japanese cohort found the ICDC to be the most sensitive (ICDC 91%; Korean 90.2%; Japanese 86.9%; Asian 83.6%, HISORt 83.6%) [27].

## Differential Diagnosis

Type 2 AIP should be differentiated from other benign and malignant conditions. In particular, other causes of acute pancreatitis, chronic pancreatitis, and pancreatic neoplasms [28]. One Korean study advocated a 2-week steroid trial after negative investigation for malignancy, in those with a high suspicion of AIP but not fulfilling diagnostic criteria, to differentiate this from pancreatic cancer [29]. However, this study included predominantly type 1 AIP patients and experience suggests that inflammatory changes surrounding malignant neoplasms can resolve with high-dose corticosteroids and mimic the resolution of AIP. This approach should only be adopted under close observation in centers with experience in managing the disease.

## Treatment

The aims of treatment in AIP are to alleviate symptoms, and prevent disease-related complications and irreversible fibrosis. Significant spontaneous improvement of type 2 AIP can occur, but further episodes of acute pancreatitis are seen [20,24]. Type 2 AIP is a corticosteroid-responsive disorder, and the symptoms and inflammatory changes respond rapidly to therapy [13]. Steroid use induces remission quicker, more consistently, and with a reduced relapse rate than a conservative approach [30]. Over three-quarters of type 2 AIP patients with jaundice require biliary stent placement [13].

There is an absence of randomized placebo controlled trials in the treatment of AIP. International consensus regarding initiation therapy with oral steroids has been reached [31], and a starting dose of prednisolone 30–40 mg daily for 4 weeks, before reducing by 5 mg every 2 weeks, depending on response, is recommended. During treatment, patients are reviewed regularly for evidence of steroid-induced side effects, biliary obstruction, and cholangitis/sepsis. Clinical, biochemical, and radiologic improvement should be seen within 4–6 weeks of starting treatment, and should be confirmed by repeat imaging. Remission, defined as complete resolution of pancreatic mass and/or normalization of biochemical tests, was reported in 92% of type 2 AIP patients in response to steroid therapy in one multicenter study [13]. Nonresponse may be representative of a less inflammatory burnt-out disease, a more fibrotic phenotype, or importantly an alternative diagnosis.

## Disease Relapse

Disease relapses in type 2 AIP are uncommon (<10%) [13,24], and appear to be much lower than in type 1 AIP. The cumulative relapse rate has been reported in one study as 7.9% at 6 months, 10,6% at one year, and 10.6% at 3 years (median follow-up 2.9 years) [20]. When relapses occur, they remain isolated to the pancreas and respond to corticosteroid retreatment. Hence, the benefit of steroid therapy to prevent future episodes of recurrent acute pancreatitis remains uncertain. Steroid

treatment can be reserved for those with imaging evidence of persistent inflammation of the pancreatic parenchyma following resolution of acute abdominal pain. The use of immunosuppressive maintenance therapy for type 2 AIP is usually unnecessary; however, may be used in the context of IBD [25]. Relapse-free survival was decreased in those initially presenting with acute pancreatitis or treated with steroids (compared with surgery) [20].

## Clinical Course and Outcome

Long-term outcome data in type 2 AIP is lacking. If diagnosed and treated early, steroid-responsive type 2 AIP appears to have a favorable prognosis [13,20,24]. Side effects and intolerance of corticosteroid therapy are the most troublesome. Long-term complications, including pancreatic insufficiency, pancreatic duct stones, and malignancy, seem to be uncommon in type 2 AIP. In the international multicenter study of 1,064 AIP patients meeting ICDC criteria, including 86 type 2 AIP patients, there were no pancreatic duct stones or pancreatic cancers in the type 2 AIP group [13].

## Summary

Type 2 AIP is a pancreas-specific disorder that is rare and challenging to diagnose. There are a variety of different clinical presentations including abdominal pain consistent with acute pancreatitis, diarrhea consistent with IBD, and/or exocrine insufficiency, and less frequently obstructive jaundice or an incidental pancreatic mass. Diagnosis is based upon the ICDC for AIP incorporating pancreatic imaging, histologic findings, presence of IBD, and response to steroid therapy. Although acute pancreatitis is a common presentation in those diagnosed with type 2 AIP, AIP itself remains a rare etiology of acute pancreatitis. The presence of IBD, especially in young patients, may be a clue in this context. Histologic sampling is often insufficient and leads to complexity in securing a solid diagnosis. Current therapy with corticosteroids follows expert consensus, but there is a lack of randomized controlled trials, which will require international collaboration. Disease relapse and complications are seemingly infrequent. Greater awareness of type 2 AIP and identification of more accurate noninvasive biomarkers will further refine our approach to diagnosis and management of this disease.

# Laboratory Diagnosis of Autoimmune Pancreatitis

*J.-Matthias Löhr[1], Pia Maier[2], and Stephan L. Haas[2]*

[1] *Department of Gastroenterology & Hepatology, Karolinska Institutet, Stockholm, Sweden*
[2] *Gastrocentrum, Karolinska University Hospital, Stockholm, Sweden*

## Introduction

Autoimmune pancreatitis (AIP) is an enigmatic disease, which has stirred up the fields of pancreatology and gastroenterology. After the rediscovery of an autoimmune form of pancreatitis in the 1990s, a pivotal paper described the presence of elevated IgG and IgG4 in this form of pancreatitis (then called "sclerosing" pancreatitis). From histology (see Chapter 65) it became clear that there are two forms of AIP and only the type 1 AIP was associated with IgG4, both in serum and tissue. It became further apparent that type 1 AIP is part of a larger syndrome that is now known as IgG-related diseases (IgG-RD). With two types of AIP that may look similar upon imaging (see Chapter 70), but differ in their response to treatment and complications, the need for further blood-based markers became obvious.

## Serum Markers

### Generic Markers

The conventional markers of inflammation, that is, erythrocyte sedimentation rate (ESR) and leucocytes (WBC), are of no use in establishing the diagnosis of AIP. Depending on the character of the respective disease form, stage, and time point, these may or may not be elevated.

### Pancreatic Enzymes

In 1929, it was stated that "elevated amylase has become a cornerstone in the diagnosis of pancreatitis" [1]. Although the specificity of both serum amylase and lipase for chronic pancreatitis is acceptable (in the range of 90 to 95%), their sensitivity is extremely low, oscillating at around 10%. As a consequence, serum markers cannot be used either for establishing the diagnosis of chronic pancreatitis or for the diagnosis of AIP. There are many possible reasons for elevated serum amylase and lipase levels and thus, elevated levels in patients with abdominal pain have a low specificity for chronic pancreatitis [2]. Serum elastase-1 is useful as a marker for acute pancreatitis [3] but has no better performance in diagnosing chronic pancreatitis or AIP than amylase and lipase [4].

Plasma trypsin-like activity has been claimed to be a sensitive and specific marker for early (mild) chronic pancreatitis; however, the only study in this patient population comprised 16 patients and had some methodological ambiguities [5]. Trypsinogen concentrations have also been suggested to be a good indicator for chronic pancreatitis [6].

While plasma trypsin-like activity and trypsinogen concentrations are elevated in a quarter of patients with established chronic pancreatitis, they seem to remain normal in early chronic pancreatitis. While we could not demonstrate significant differences for absolute values of cationic (PRSS1) and anionic trypsinogen (PRSS2) [7] in AIP, CP, and healthy controls, we found a change in the PRSS1–PRSS2 ratio: in healthy individuals (ratio 1:3) and in AIP (ratio 1:2) PRSS2 dominates [7]. In non-AIP CP [6] the ratio is shifted towards PRSS1 (ratio 2:1).

If one reflects on how amylase, like any other enzyme, reaches the circulation (serum) [8], its low specificity and sensitivity are not surprising. After massive damage of exocrine pancreatic tissue, that is, leakage through dead cells, serum levels rise significantly; however, this condition is not chronic (autoimmune)

pancreatitis, but acute pancreatitis. Other promising markers such as pancreatic stone protein [9] and procarboxypeptidase B [10] have also not fulfilled their promise as sensitive markers for chronic pancreatitis and are of no use in diagnosing AIP.

Taken together, neither a generic marker nor serum levels of pancreatic enzymes can be used to establish the diagnosis of AIP.

## Markers of Autoimmunity

Generic markers of autoimmune disease are certain immune globulin classes, and some other markers. Elevated IgG, and especially IgG4, has been the first marker for AIP [11], later found to be elevated in the type 1 (lymphoplasmacytic sclerosing pancreatitis, LPSP) that was determined to be part of the IgG4 syndrome, IgG4-RD [12]. As a result of many studies in AIP, increased levels of both IgG and/or IgG4 have been determined to be defining for AIP type 1 in the International Consensus Diagnostic Criteria (ICDC) for AIP [13].

Approximately two-thirds of patients with AIP have elevated serum IgG4 levels [14]. However, mild elevations of serum IgG4 levels (1–2 times the upper limit of normal) have also been observed in 10–15% of patients with pancreatic cancer, cholangiocarcinoma, and primary sclerosing cholangitis (PSC) [15]. Even though higher elevations may improve specificity, the extremely low disease prevalence results in a low positive predictive value (10–15%) of elevated serum IgG4 levels for the diagnosis of AIP/IgG4-RD when the pretest probability of disease is low [15]. Thus, although elevated serum IgG4 levels are one characteristic of AIP type 1, they are helpful only for establishing a diagnosis of AIP in conjunction with other diagnostic findings [16].

Other measures of autoimmunity (i.e., nonspecific markers) that can be found are ANA (54–69%), RF (23–33%), and ASMA (15%) [16,17]. Measures such as ICA (3.8%), anti-DS (4.5%), and AMA (0–2%) are rarely found [16,17]. In an attempt to define a serum marker profile, we could not identify a specific set for AIP [18], even if this was successful for pancreatic cancer [19]. Taken together, autoimmune markers cannot establish the diagnosis of AIP.

Autoantibodies against specific target tissue-related antigens are the hallmark of any autoimmune disease. Autoantibodies can be divided into two categories: non-organ and organ-specific autoantibodies. Shortly after the initial description of IgG4, the first autoantibodies against pancreatic antigens were reported in AIP: against lactoferrin and carbonic anhydrase type II, the lead enzyme of the pancreatic duct epithelial lining producing bicarbonate [20]. However, only a small subset of patients seem to be positive [21] (Table 68.1). The third autoantibody described was directed against SPINK1 [17], a protein known to be disease-facilitating once mutated in some genetically determined forms of hereditary pancreatitis [22]. These autoantibodies against SPINK1 were confirmed in an independent patient group by other investigators [7].

Another autoantibody merits a mention because it could suggest a link to the possible etiology or causing agent/precipitating event: the ubiquitin protein ligase E3 component n-recognin 2 (UBR2), an enzyme highly expressed in acinar cells of the pancreas [23]. There is a certain degree of homology to the plasminogen-binding protein (PBP) of *Helicobacter pylori*—an agent that has been suggested to be linked to AIP for another homology between *Helicobacter pylori cag-A* and human carbonic anhydrase type II in a molecular mimicry fashion [24–26]. However, no confirmatory studies have been performed with URB2. We were also unable to detect *H. pylori* DNA in pancreatic tissue samples from AIP [27].

**Table 68.1** Disease-specific autoantibodies and immunoglobulins in autoimmune pancreatitis

| Antigen | % pos all AIP | AIP 1 | AIP 2 | Sensitivity | Specificity | % pos in PDAC | References |
|---|---|---|---|---|---|---|---|
| CA II | 53.8 | | | | | n.d. | 17, 20 |
| Lactoferrin | 73 | | | 73 | | 0 | 17, 20 |
| SPINK1 | 42 | | | 79* | | n.d. | 17, 7 |
| Trypsinogens | 79 | | | | | 0 | 7 |
| UBR2 | 95 | | | | | 10 | 23 |
| Amylase α2A | 79 | 67 | 75 | | | 0 | 28 |
| IgG, IgG4 | 40 | 80 | <5 | 41 | 99 | 10 | 11 |

CA-II, carbonic anhydrase II; *, SPINK1 and ALF together; n.d., not determined; PDAC, pancreatic ductal adenocarcinoma.

Recently, another antibody against the acinar compartment, amylase α2A, was described with good sensitivity and reasonable specificity [28] (Table 68.1).

None of the autoantibodies could be correlated with the expression levels of IgG or IgG4, and when investigated, the autoantibodies were not of the IgG4 class [16]. None of these antibodies were sufficiently disease-specific, and this is one of the distinct features of AIP compared to other GI and liver autoimmune disease, which are characterized by disease-specific autoantibodies such as AMA in PBC and anti-LKM1 in AIH [16].

Taken together, autoantibodies have been found against ductal (carbonic anhydrase type II) but mostly acinar (SPINK1, lactoferrin, trypsinogen, amylase α2A) antigens. There are no data indicating a correlation to subtypes of AIP. It is also of note that only the autoantibodies against SPINK1 together with carbonic anhydrase and lactoferrin could be confirmed by independent studies.

We propose a possible pathomechanism, based on the RNA expression profiling and proteomics data in conjunction with blood findings that explain the occurrence of these antibodies, at least against the acinar antigens (Fig. 68.1). This is based on the fine description of IgG-RD elsewhere [12].

## Other Markers

For the diagnosis of (chronic) pancreatitis, especially AIP, some other body fluids could be used. One option is pancreatic juice collected during ERCP or in the duodenum stimulated after secretin injection. In an attempt to describe markers from pancreatic juice samples, we could not detect any with high-resolution 2D-PAGE [29]. The cytologic analysis did not reveal anything diagnostically relevant for establishing the diagnosis of AIP.

Fecal elastase-1 (FE-1), a marker of pancreatic exocrine insufficiency (PEI), can also be measured. It is a rather crude marker, which if positive (below 200 μg/g) enables the diagnosis of PEI, and in so doing would confirm the diagnosis of any sort of chronic pancreatitis. In itself, however, FE-1 is not specific, either for chronic or autoimmune pancreatitis.

## Conclusion

The only clinical relevant possibilities for diagnosing AIP with blood-based assays are serum IgG and IgG4 when considered together with clinical findings. The only commercially available autoantibody assays exist for

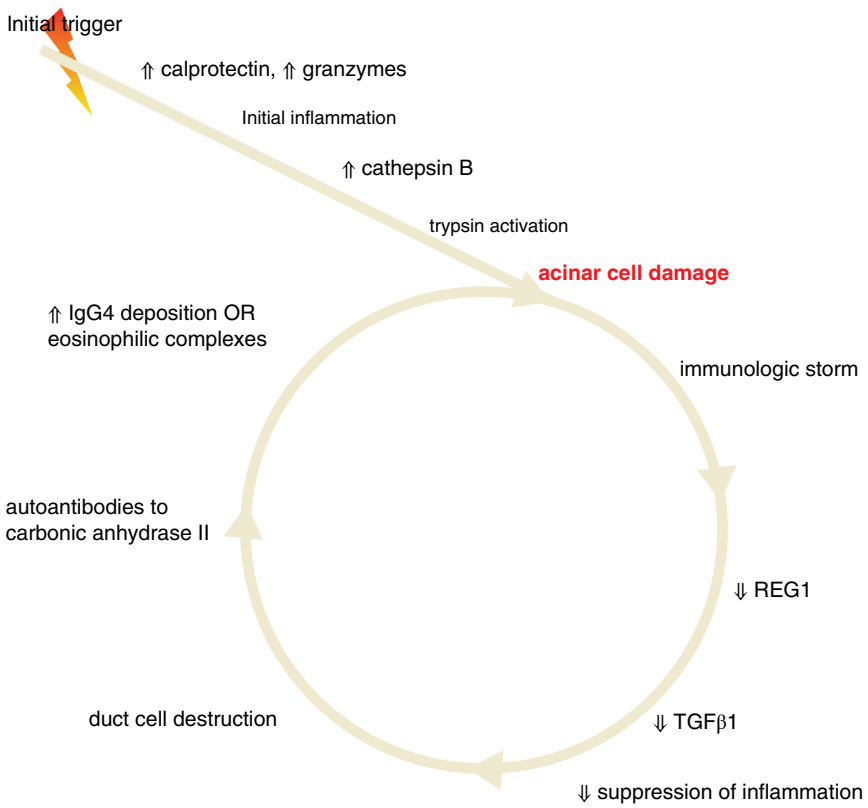

**Figure 68.1** Pathomechanism explaining the occurrence of autoantibodies in AIP. Expression profiling data from Löhr et al. 2010 [7].

autoantibodies against lactoferrin, carbonic anhydrase type II, and SPINK1, the latter only in Japan and not in Europe. These three autoantibodies have been shown to be of relevance in more than one study. Especially the newer autoantibodies against URB2 and trypsinogens require confirmation and the availability of commercial ELISA tests. So far, attempts to find novel markers have been unsuccessful.

# What is the Evidence Measuring Immune Markers

*Shigeyuki Kawa*

*Department of Internal Medicine, Matsumoto Dental University, Shiojiri, Japan*

## Introduction

Autoimmune pancreatitis (AIP) is a distinct type of chronic pancreatitis that is presumed to be caused by autoimmune mechanisms. Although several immune markers have been identified for the purpose of AIP diagnosis, its differentiation from such mimicking conditions as pancreatic cancer, and the prediction of relapse during follow-up [1], immunoglobulin (Ig) G4 has been established as the most reliable [2]. This chapter will discuss the evidence measuring immune markers in AIP, with special reference to their usefulness in diagnosis, differentiation, and prediction of relapse. AIP has been restricted to type 1 in this chapter as the detailed clinical features of type 2 AIP remain unclear.

## Evidence of the Utility of Markers in Autoimmune Pancreatitis Diagnosis

In earlier paper electrophoresis assays, most patients with AIP were observed to display a polyclonal band in the rapidly migrating fraction representative of the now characteristic phenomenon of β-γ globulin bridging (Fig. 69.1). Immunoprecipitation trials revealed that this finding was due to high serum concentrations of IgG4 [2]. Comprising only 4–7% of total IgG, IgG4 represents a minor component of the four IgG subclasses whose serum elevation is observed only in specific disorders, such as various forms of atopy, parasitic infestations, and pemphigus. However, it has also been confirmed that serum IgG4 concentrations in patients with AIP were over 10-fold higher than those in healthy subjects. Moreover, approximately 90% of AIP patients exhibited increased serum IgG4 values, whereas few patients with other diseases, including pancreatic cancer, chronic pancreatitis, primary biliary cholangitis (PBC), primary sclerosing cholangitis, and Sjögren syndrome, showed such elevations (Fig. 69.2) [2]. In contrast, elevated total IgG and IgE were detected in 70% and 33% of AIP patients, respectively, both of which were also positive in a variety of other conditions, and the immune markers of antinuclear antibody and rheumatoid factor showed respectively low sensitivities of 40% and 30%. Disease-specific autoantibodies, such as anti-Sjögren syndrome A (SSA)/Ro, anti-Sjögren syndrome B (SSB)/La, and anti-mitochondrial antibodies, which have been useful in the diagnosis of Sjögren syndrome and PBC, were rarely also observed for AIP [1,3]. The aforementioned results strongly indicated that IgG4 was a particularly sensitive and specific biomarker for AIP diagnosis. The efficacy of IgG4 in the diagnosis of AIP has since become well recognized worldwide, showing an overall sensitivity, specificity, and diagnostic odds ratio (DOR) from seven representative studies [2,4–9] of 82%, 95%, and 63.9, respectively, and a favorable area under the receiver operating characteristic curve (AUROC) value of $0.920 \pm 0.073$ [10]. Another recent systemic review of 15 studies [2,7–9,11–19] demonstrated similar overall IgG4 results for sensitivity (74%), specificity (94%), DOR (62.91), and AUROC (0.953) [20]. Consequently, serum IgG4 measurement has been adopted as a key item in numerous diagnostic criteria systems for AIP [21–24], while the infiltration of IgG4-bearing plasma cells in affected pancreatic tissue has been established as a histologic hallmark of AIP for its pathologic diagnosis [25]. Most recently, the discovery of extrapancreatic involvement with IgG4-bearing plasma cell infiltration in various tissues has helped establish the new disease concept of IgG4-related disease. AIP has now been recognized as a pancreatic manifestation of this systemic disease, for which IgG4 seems to exert a major role in pathogenesis [3].

Apart from IgG4, the serum values of several other immunoglobulins represent novel diagnostic markers of AIP. Taguchi et al. measured the serum levels of IgG, IgA, IgM, and IgG4 in individuals with AIP and other hepatopancreatic diseases and witnessed that IgM and IgA were markedly decreased in patients with untreated AIP, indicating a reciprocal correlation between IgM or IgA and IgG. Thereafter, the ratios of IgG to IgM and IgG to IgA in AIP were determined to be significantly higher than in other diseases, providing a diagnostic sensitivity and specificity for the differentiation of AIP from other hepatopancreatic conditions almost equivalent to those of IgG4 [26]. These ratios show promise as useful, low-cost markers that require only simple calculations based on routine immunoglobulin examinations.

## Evidence of the Utility of Markers in Differentiating Autoimmune Pancreatitis from Mimicking Conditions

AIP is characterized by the reported clinical features of elderly male preponderance, onset with obstructive jaundice, apparent pancreatic swelling in various imaging tests,

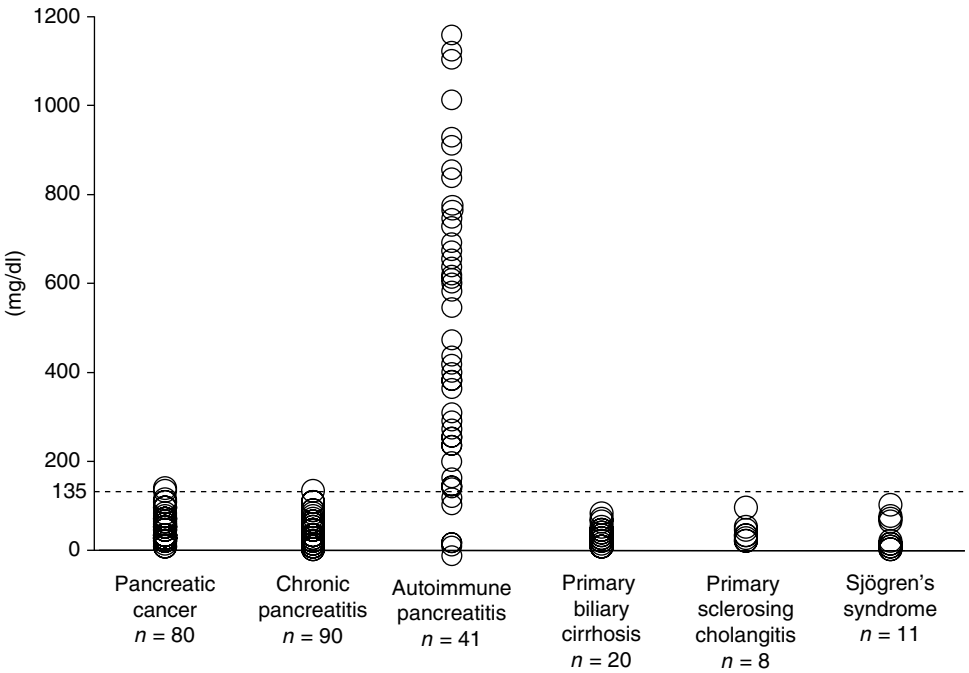

**Figure 69.2** Scattergram of serum IgG4 values in AIP and various other conditions. *Source:* Hamano et al. 2001 [2]. Copyright © 2001 Massachusetts Medical Society. Reprinted with permission.

irregular narrowing of the main pancreatic duct, and stenosis of the lower bile duct [1,3]. As these features mimic those of pancreatic cancer, extensive examination is needed for their proper differentiation; in fact, 2–3% of individuals who had undergone surgery based on a diagnosis of pancreatic cancer were later revealed to have AIP [27,28]. At a cut-off value of 135 mg/dL, IgG4 as a biomarker displayed a sensitivity of 90%, specificity of 98%, and accuracy of 95% in distinguishing between AIP and pancreatic cancer [2]. The efficacy of IgG4 in the differentiation of AIP and pancreatic cancer has since been supported worldwide, with an overall sensitivity, specificity, and DOR from four representative studies [2,7–9] of 82%, 95%, and 144.6, respectively, and a favorable AUROC value of 0.914 ± 0.191 [10]. A recent systemic review of 13 studies [2,7–9,11–13,15–17] showed comparable overall results of 73% sensitivity, 93% specificity, 60.61 DOR, and 0.926 AUC [20]. However, mild (<twofold cut-off value) elevations in serum IgG4 have also been seen in pancreatic cancer [8,19]. It must therefore be stressed that IgG4 elevation alone does not necessarily rule out the existence of malignancy since AIP complicated with pancreatic cancer has been reported as well [29,30].

AIP is histologically defined as lymphoplasamcytic sclerosing pancreatitis (LPSP) with abundant lymphoplasmacytic infiltration, storiform fibrosis, and obstructive phlebitis [31]. However, another type of AIP histologically identified as idiopathic duct-centric chronic pancreatitis (IDCP) [32] or AIP with granulocytic epithelial lesion (GEL) [33] that is characterized by granulocytic infiltration in the ductal epithelium has been reported mainly in Europe and America. Although both types of AIP share certain imaging finding similarities, IDCP/AIP with GEL has no correlation with IgG4 [32,34]. AIP is now classified as either type 1 or type 2 based on the pathologic subtypes of LPSP and IDCP/AIP with GEL, respectively [35]. In an international survey of AIP, type 2 AIP was observed in 8% of cases, with the proportion of this subtype being remarkably lower in Asian countries (3.7%) than in European (12.9%) and North American (13.7%) populations [36].

## Evidence of the Utility of Markers in Predicting Relapse

Although individuals with AIP usually respond well to corticosteroid treatment, relapse is a characteristic feature of AIP that occurs in an estimated 30–50% of patients based on several long-term follow-up studies [37–40]. Relapse may be a predisposition factor for pancreatic calcification, which in turn possibly triggers the transition to a chronic pancreatitis state with exocrine and endocrine dysfunction [41,42]. Accordingly, useful biomarkers that predict AIP relapse are needed for the establishment of effective prophylactic measures.

In a 3-year follow-up study, IgG4 seropositivity was found to be a significant independent factor of relapse prediction in AIP patients during maintenance corticosteroid treatment [43]. Other investigations have also reported significantly higher AIP relapse rates of approximately sixfold in AIP groups with elevated serum IgG4 levels than in those with normal IgG4 values [44,45].

In the clinical course of a 69-year-old woman with AIP who experienced two relapses, serum elevations of IgG4 and immune complex (IC) preceded the overt appearance of each clinical relapse by several months (Fig. 69.3)

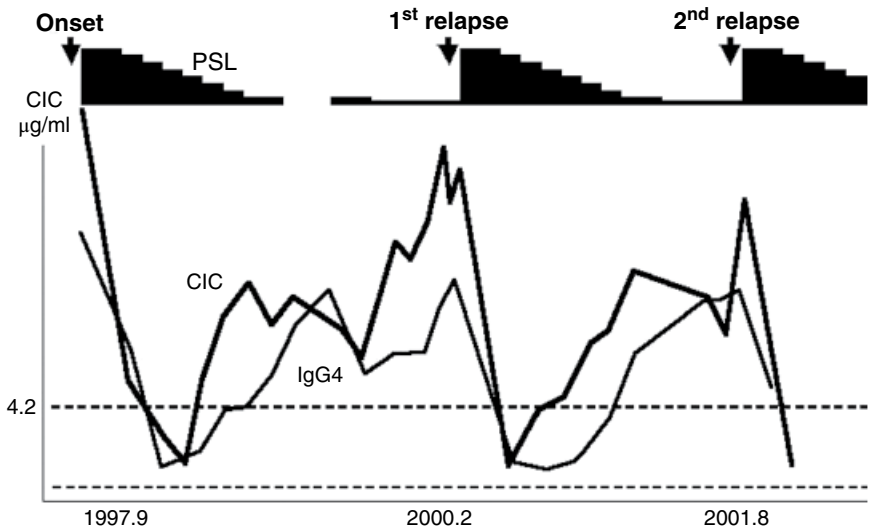

**Figure 69.3** Clinical course of a 69-year-old female patient with AIP demonstrating a correlation between two recurrences and preceding IgG4 and IC values. CIC, circulating immune complex; PSL, prednisolone. *Source:* Kawa and Hamano 2007 [46], Figs 4 and 5. Reproduced with permission of Springer.

[46], indicating that IgG4 and IC could sensitively predict relapse and represent disease activity. Elsewhere, persistently elevated serum IgG4 values were associated with AIP relapse and failure of disease control by steroid therapy [47], and Matsubayashi et al. reported that high serum IgG4 levels were related to severe clinical profiles that included jaundice, large pancreatic lesions, a high frequency of extrapancreatic lesions, and relapse [48].

While steroid therapy is generally effective for AIP, the incidence of relapse within 3 years after the start of treatment is relatively high [49]. Thus, it will be crucial to identify good predictors of relapse related to the eventual tapering or discontinuation of steroids. Shimizu et al. found that the rate of serum IgG4 decrease after the start of treatment was significantly higher in a non-relapse group than in a relapse one, suggesting that AIP patients responding to initial steroid therapy with a rapid drop in serum IgG4 are less likely to experience a relapse and thereby implicating the rate of IgG4 decrease as a predictor AIP recurrence [50].

Regarding other immune markers, IC value at treatment onset was significantly higher in a relapse group compared to a non-relapse group and displayed a good sensitivity (62%), specificity (70%), and accuracy (67%) at a cut-off value of 10 mg/dL. The probability of relapse was 60% at IC 10 mg/dL and 30% at IC 10 mg/dL [51]. Yet other activity immune markers of AIP are total IgG, complement C3 and C4, soluble interleukin-2 receptor, and β2-microglobulin, all of which may have use in the prediction of AIP relapse [1,3]. Especially since IgG and complement C3 and C4 are low cost and routinely measured, these parameters represent readily available means of predicting relapse in regular clinical practice and require further study.

## Introduction

The disease concept of autoimmune pancreatitis (AIP) was proposed in 1995 by Yoshida et al. [1], and subsequently this condition has been recognized as the pancreatic manifestation of IgG4-related disease (IgG4-RD) [2]. After several revisions of the concept, AIP is currently recognized as being classified into two distinct types [3,4]. AIP is subclassified according to the International consensus of diagnostic criteria (ICDC) for autoimmune pancreatitis as either type 1 (IgG4-related) or type 2 (GEL). Both types of AIP present with pancreatic swelling or mass formation often leading to obstructive jaundice. These features are similar to pancreatic cancer on the basis of the clinical and radiologic findings alone.

Histopathologic features of type 1 (IgG4-related) AIP, termed lymphoplasmacytic sclerosing pancreatitis, are characterized by abundant infiltration of lymphocytic and IgG4+ plasma cells, obliterative phlebitis, and fibrosis [3,5,6]. Type 2 AIP is characterized by granulocytic epithelial lesions (GEL) [5,7], histopathologically termed as idiopathic duct-centric chronic pancreatitis (IDCP) [8], and appears to be more common in Western countries than in Asian countries, whereas type 1 AIP accounts for the majority of cases in the world [9,10,11].

This chapter outlines pancreatic imaging based on current diagnostic criteria because of the particularly important role of these techniques in the diagnosis of AIP. Abdominal US, CT, and MR imaging are useful in the morphologic diagnosis of the pancreatic parenchyma. Magnetic resonance cholangiopancreatography (MRCP) and endoscopic retrograde pancreatography (ERP) are useful in the morphologic diagnosis of the pancreatic duct. In addition, positron emission tomography (PET) may be useful in evaluating the response to steroid therapy and also extrapancreatic involvements. ERP has long been considered essential in Japan for potential AIP cases marked by localized pancreatic swelling [1]. However, in the ICDC and Japanese diagnostic criteria of 2011 it is stated that a possible diagnosis of AIP can be made without ERP if a fine needle aspiration under endoscopic ultrasonography excludes malignancy, and the patient responds to steroid treatment.

## Pancreatic Parenchyma Imaging

Diffuse swelling of the pancreas corresponding to a sausage-like appearance is highly characteristic for AIP. This feature can be demonstrated by US, CT, or MRI. However, localized (segmental or focal) swelling in AIP requires differentiation from pancreatic cancer. Concerning the definition of pancreatic swelling many investigators use the Haaga criteria (pancreatic head: ≥1 vertebral body, pancreatic body and tail ≥2/3 of a vertebral body define a pancreatic swelling and correspond to roughly a head of ≥3 cm and a body and tail of ≥2 cm) [12]. As the pancreas may be atrophic in the elderly a strict definition is difficult to achieve, but these criteria make it possible to recognize pancreatic swelling also in cases with shrinkage of the pancreas due to steroid treatment. Although "diffuse" and "localized" are not strictly defined, the ERP findings in the majority of cases with chronic pancreatitis are consistent with the Cambridge classification (2/3 diffuse, 1/3 segmental 2/3, focal 1/3) [13].

### Abdominal Ultrasonography (US) [5,11]

The typical US appearance of the pancreas in AIP shows a diffusely swollen organ that resembles a sausage. The swollen portion is hypoechoic with scattered hyperechoic spots. In cases with localized swelling, the differential

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

diagnosis between pancreatic cancer and mass-forming pancreatitis is problematic. Dilatation of the main pancreatic duct is frequently not detected by US, but delineation of the main pancreatic duct within the mass—known as the "duct penetration sign"—is helpful in differentiating AIP from pancreatic cancer [14]. However, the findings of only mild ductal dilatation or multiple hypoechoic masses within the pancreatic parenchyma make a differentiation between AIP and metastatic pancreatic tumors or lymphoma difficult.

## Abdominal CT Imaging [5,11]

The CT features are pancreatic swelling, a pattern of delayed contrast enhancement on dynamic CT, and a capsule-like rim surrounding the pancreas (Fig. 70.1) [15,16]. Most AIP patients are elderly and therefore tend to have some atrophy of the pancreas before the onset of AIP. This can obscure the presence of pancreatic swelling in the early stages of the disease. On the other hand, there are also cases in which pancreatic swelling can be judged to have been present at onset based on a decrease in the size of the pancreas following steroid therapy. Other cases are characterized by atypical findings of mild diffuse swelling alone of the pancreas, and/or partial dilatation of the MPD, cystic lesions, or, in rare cases, calcification of the pancreatic parenchyma.

### Pancreatic Swelling and Delayed Enhancement

Delayed enhancement is characteristic on the portal phase of dynamic CT, but the specific findings vary according to disease stage and activity. The enhancement effect can be altered by the degree of fibrosis. If the extent of fibrosis is only mild, the amount of enhancement may be difficult to distinguish from normal pancreas. Thus, the absence of delayed enhancement does not exclude AIP in the early stages of the condition, when extensive fibrosis is unlikely.

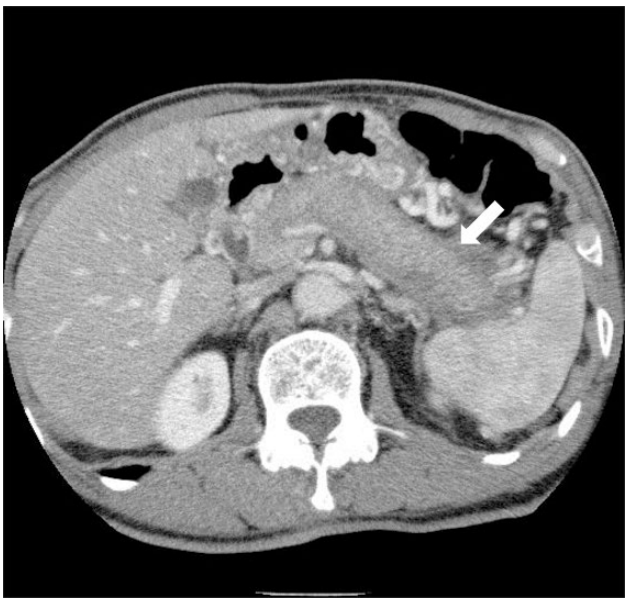

**Figure 70.1** Abdominal CT image of autoimmune pancreatitis (diffuse swelling) showing pancreatic swelling with delayed enhancement (sausage-like) and capsule-like low-density rim (arrow).

### Capsule-Like Low-Density Rim

The finding of a low-density, capsule-like rim around the pancreas is less common than delayed enhancement, but such a finding has a high specificity for AIP [15]. The capsule-like rim is thought to reflect fibrosis at the edge of the lesion, corresponding to the delayed pattern of enhancement observed on dynamic CT. A capsule-like rim is extremely helpful in differentiating AIP from pancreatic cancer. The absence of such a rim, however, by no means excludes AIP. Pancreas imaging alone cannot distinguish type 1 from type 2 AIP due to the similarity of their morphologic appearance.

## Abdominal MR Imaging [5,11]

### Pancreatic Swelling and T1/T2-Weighted Pancreatic Parenchyma Findings

Hypointensity on T1-weighted MR images and delayed enhancement on the portal phase of dynamic MRI are characteristic of AIP in addition to diffuse swelling. Because the normal pancreas is hyperintense relative to the liver on T1-weighted images, any relative hypointensity detected must be considered abnormal. However, hypointensity on MR is also found in both pancreatic cancer and chronic pancreatitis from other causes, and therefore does not distinguish AIP among these entities. Similar to CT, differentiation of the normal pancreas from cases of only mildly fibrotic AIP is challenging. Conversely, severe fibrosis can be associated with only slight hypointensity on T2-weighted images, because of the limited inflammation present at that point.

### Capsule-Like Rim

Both a capsule-like rim and a delayed enhancement pattern can be detected by MRI. Both of these findings reflect fibrosis and are highly characteristic for AIP. The capsule-like rim is visualized as a hypointense region on T2-weighted images. Dynamic MRI is the most effective means of demonstrating delayed enhancement.

## Nuclear Medicine Examinations

Gallium citrate (Ga-67) scintigraphy and fluorine-18 fluoro-deoxyglucose positron emission tomography (FDG-PET) [5,11].

Ga-67 and FDG accumulate in pancreatic lesions, making the differentiation from lymphoma difficult. Ga-67 and FDG accumulation is not limited to pancreatic lesions alone, but is also found at sites of extrapancreatic involvement, notably in the hilar lymph nodes of the

chest, the lacrimal glands, and the salivary glands. Such lesions frequently disappear rapidly after glucocorticoid administration [16–18]. However, the expense of these examinations further limits their clinical utility and has so far prevented them from entering routine practice.

## Pancreatic Duct Imaging

### ERCP Findings [5,11]

A characteristic irregular narrowing of the MPD constitutes strong evidence in favor of the diagnosis of AIP (Fig. 70.2a) [19]. Irregular narrowing of MPD refers to a situation in which the pancreatic duct diameter is thinner than usual and irregular. These lesions tend to affect greater lengths of the duct than do occlusive or stenotic lesions. In typical cases, irregular narrowing accounts for more than one third of the entire pancreatic duct length (~5 cm). Even in localized lesions marked dilatation of the main pancreatic duct upstream to the stenotic portion is frequently not observed. In cases with a short irregular narrowing pancreatic duct (roughly <3 cm), the differentiation from pancreatic cancer is difficult. Side branches arising from the narrow area of the MPD and skip lesions are useful signs in the differentiation from pancreatic cancer [20]. In the earlier diagnostic criteria

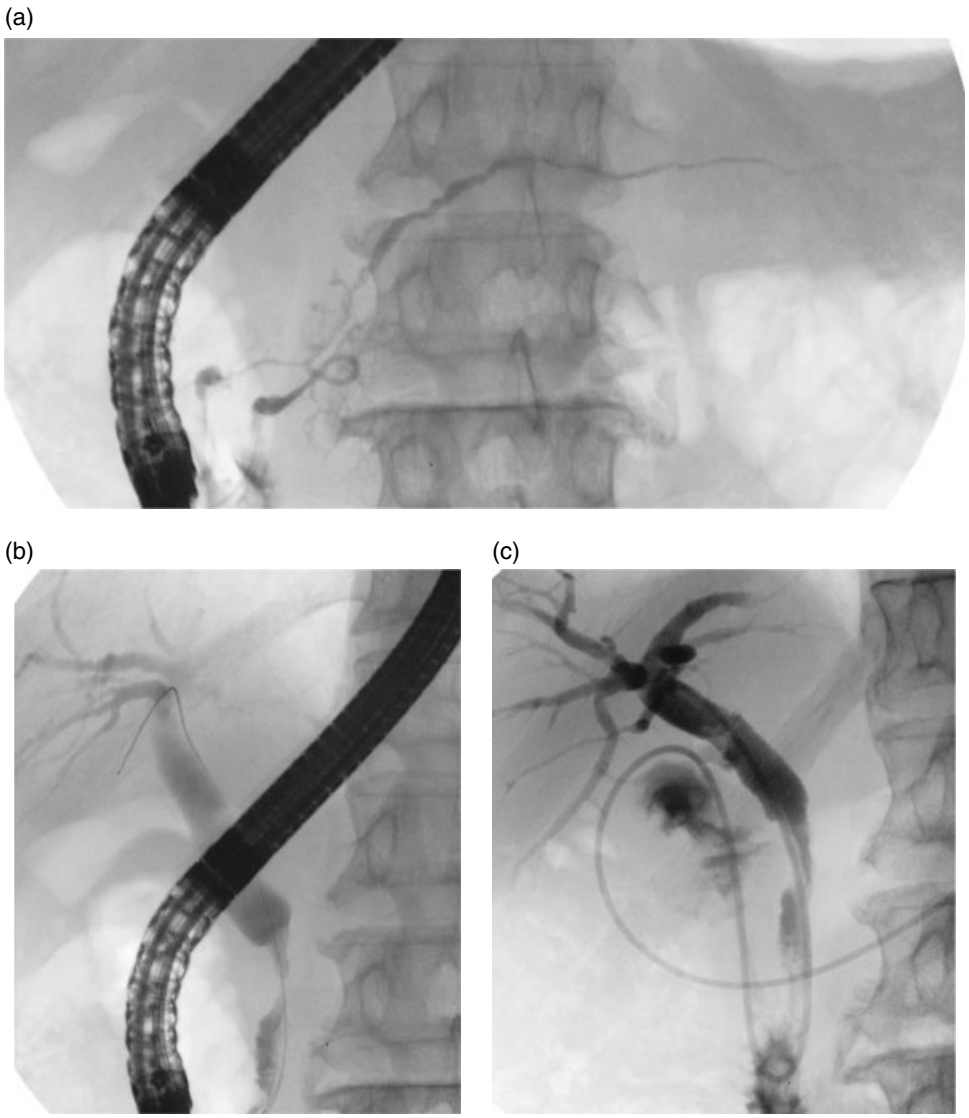

**Figure 70.2** ERCP images of autoimmune pancreatitis. ERP (a) shows irregular narrowing in the pancreatic head and tail. Side branches arising from the stenotic portion of the main pancreatic duct (MPD) in the pancreas head can be observed. Before steroid treatment, ERC (b) shows stenosis of the terminal common bile duct and improvement of stenotic change after steroids (c).

for AIP put forth in Japan, the finding of characteristic irregular narrowing within the MPD was considered to be an essential piece of diagnostic evidence [5,11]. In cases with focal irregular narrowing, the need to differentiate AIP from pancreatic cancer must be kept in mind. In AIP, bile duct stenosis is found in about 80% of cases. Bile duct stenosis is most common in the inferior bile duct (Fig. 70.2b,c), but may also develop in the extrahepatic and intrahepatic bile ducts.

### MRCP Findings [5,11]

When evaluating patients with possible AIP and other disorders that mimic it, delineation of the morphologic features of the MPD by ERP or another direct visualization method is essential. At present, MRCP does not delineate the pancreatic duct with sufficient accuracy for reliable diagnosis of AIP or the precise evaluation of irregular narrowing in the MPD. Its ability to demonstrate noncontinuity of the duct is helpful in making the diagnosis of AIP (Fig. 70.3), although the specificity of this finding is, in itself, imperfect. However, three-dimensional MRCP can now detail the main pancreatic duct within a normal pancreas and failure to identify the main duct suggests the presence of irregular narrowing. With the recently introduced 3.0 Tesla MR imagers, further enhancement of the image quality of MRCP is anticipated and MRCP may have a greater role to play in the assessment of the response of AIP to therapy and in follow-up observations.

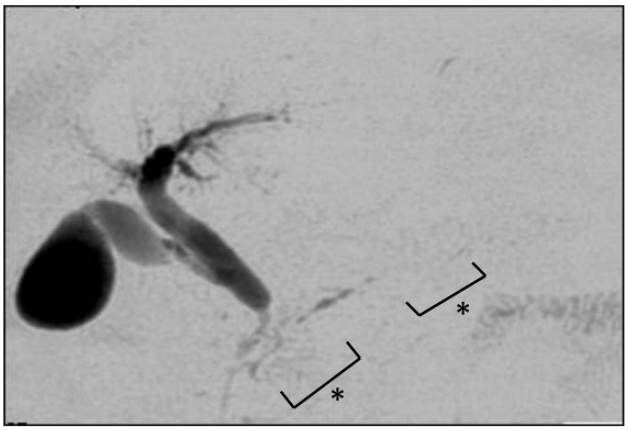

**Figure 70.3** MRCP findings of autoimmune pancreatitis. MRCP usually fails to identify the correct presence of irregular narrowing of the MPD. In this case, MRCP shows the segmented MPD (skip lesions), suggesting the possibility of autoimmune pancreatitis (*).

# Medical Management of Autoimmune Pancreatitis

*Shounak Majumder and Suresh T. Chari*

*Division of Gastroenterology and Hepatology, Mayo Clinic College of Medicine, Rochester, MN, USA*

## Introduction

In 1995, Yoshida et al. coined the term autoimmune pancreatitis (AIP) to describe a condition reminiscent of autoimmune hepatitis because it was corticosteroid-responsive and associated with elevated levels of autoantibodies and gamma globulins [1]. Earlier, Kawaguchi had described its histopathologic features and called it lymphoplasmacytic sclerosing pancreatitis (LPSP) [2]. Subsequently, this entity was shown to be part of a multiorgan disorder called IgG4-related disease (IgG4-RD).

A different disease entity was seen to share histopathologic and clinical features with LPSP and its histopathologic pattern was termed idiopathic duct-centric chronic pancreatitis (IDCP) [3]. The term AIP came to be used for both diseases with LPSP called type 1 AIP and IDCP as type 2 AIP. Here we will use the terms AIP and IDCP, respectively to describe the two entities.

## Management of Autoimmune Pancreatitis: An Overview

AIP is to be managed medically; surgical intervention, usually pancreatic resection or biliary bypass for "unresectable" disease, occurs when the condition is mistaken for pancreatic cancer. Like other autoimmune disorders, treatment of AIP includes induction of remission, treatment of relapse, and maintenance of remission. The cornerstone of medical management of AIP is the use of corticosteroids to target the inflammatory response in the affected organ. This provides symptom relief, often dramatic, which in some instances can be helpful for confirming the diagnosis. Although the early use of corticosteroids may delay progression to fibrosis, pancreatic parenchymal fibroatrophic changes that accompany the initial presentation of the disease are usually permanent. Steroid-sparing agents are mostly used for long-term maintenance of remission or in steroid-intolerant patients.

## Definitions

The consistent use of well-defined terms to describe treatment goals is an important component of the treatment algorithm of AIP. AIP is a fibroinflammatory disease and treatment targets the inflammatory component; the accompanying fibrosis may permanently alter organ structure and function. Currently, there are no therapies that specifically prevent or halt fibrosis.

"Remission" indicates the complete resolution of the inflammatory component of the disease with or without restitution of normal structure and function. The rapid and complete resolution of symptoms such as jaundice or abdominal pain after initiation of corticosteroids has diagnostic utility; persistent symptoms on high-dose steroids indicate an alternate diagnosis. Even with remission organs affected may never return to normal morphology and function due to fibrosis-related damage. Biochemical abnormalities in liver tests and pancreatic enzymes often resolve completely with disease remission. Confirmation of histologic remission after treatment, although ideal, is not feasible and is almost never needed in clinical practice. Normalization of serum IgG4 levels is not a reliable treatment target and does not correlate with disease remission.

"Recrudescence" is the worsening of disease or "flare" during treatment when the disease is still not in remission.

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

This may happen in the setting of corticosteroid dose reduction or premature withdrawal.

"Relapse" refers to disease recurrence after complete remission has been achieved. This could be in the form of recurrent clinical, radiologic, or biochemical features of disease that often mimic the initial presentation. AIP being part of a multiorgan disease (IgG4-RD), relapse may occur in the organ being treated or in another, previously unaffected, organ. Abdominal pain as a standalone symptom is rarely a manifestation of relapse. Similarly, isolated "serologic relapse," that is, elevation of IgG4 without biochemical or radiologic change, is not indicative of disease relapse and should not be treated.

## Management of Initial Presentation

### Induction of Remission

Corticosteroids are the mainstay of initial treatment. High-dose induction therapy with 30–40 mg/day of prednisone or equivalent-dose corticosteroid is typically administered for 4 weeks. Clinical and radiologic response is assessed at the end of 4 weeks of high-dose therapy and in patients demonstrating remission or significant interval improvement in target organ inflammation, this is followed by a gradual corticosteroid taper using a decremental dose of 5 mg per week. Subsequent need for therapy is determined by treatment response. For patients with no previous history of AIP who have limited disease burden that rapidly resolves, steroid therapy is typically tapered to discontinuation at this stage.

While steroid-resistance is rare, therapeutic options are fairly limited in patients who are unable to be weaned off high-dose corticosteroids following induction therapy. Rituximab (RTX), a chimeric monoclonal antibody against CD20 antigen on B cells is the only currently known agent other than corticosteroids that has the ability to induce remission. Generally reserved for treatment of relapsing disease, it can be used as a first-line agent in select clinical scenarios where patients need high-dose steroids to maintain remission, or when steroids are contraindicated or poorly tolerated. The most commonly used induction regimen for RTX is 2 doses (1 gm each) 2 weeks apart. There is limited data and no consensus on the use of RTX as first-line treatment for AIP. In a Mayo Clinic series, complete remission was achieved in three out of three patients who were corticosteroid-naïve and were treated with RTX as the first-line agent [4]. However, experience from treatment of other manifestations of IgG4-RD and additional unpublished experience from our center suggests that RTX can be used as first-line and sole agent for induction and maintenance of remission, if necessary [5].

### Maintenance of Remission

In patients who achieve complete remission with induction therapy, there is considerable debate regarding the continued use of low-dose corticosteroid treatment for maintenance of remission. Several Asian centers favor the long-term continuation of low-dose corticosteroid therapy for several years and even indefinitely, whereas most centers in Europe and North America recommend weaning to discontinuation over 8–10 weeks after the initial 4 weeks of high-dose treatment. However, in a large study of 459 subjects with AIP from Japan who received maintenance corticosteroid treatment nearly one fourth relapsed (23%, 63/273). Though this was lower compared to patients in whom corticosteroids were discontinued after achieving remission (34%, 35/104; $P = 0.048$), the authors do not provide treatment alternatives for those who did relapse on steroids [6].

An alternative approach to steroid maintenance therapy is the use of immunomodulators as a steroid-sparing agent. The choice of immunomodulator does not impact treatment outcomes with 6-mercaptopurine, mycophenolate mofetil, and azathioprine all having similar efficacy. Intolerance to one agent can be managed by substituting one of the other agents. The optimal dose and duration of treatment is not well defined. However, for azathioprine, higher doses similar to those used in the management of inflammatory bowel disease (2.0–2.5 mg/kg), have a greater likelihood of preventing subsequent relapses compared to lower doses (1 mg/kg) [4].

Maintenance therapy is of greatest benefit to patients at the highest risk of relapse. This includes patients with proximal biliary tract disease, diffuse enlargement of the pancreas, elevated baseline IgG4, IgE, peripheral eosinophilia, and possibly those with persistent elevation of IgG4 at the end of induction therapy [7]. For patients who only have a partial response or in whom it is difficult to wean corticosteroids to a maintenance dose, early use of immunomodulators or RTX needs to be considered to avoid long-term high-dose corticosteroid use. However, immunomodulators do not induce remission; hence, if the disease is still active when steroids are withdrawn, there is a high likelihood of disease recrudescence, despite use of immunomodulators.

## Management of Relapse

Although the majority of patients with AIP have a dramatic response to corticosteroid treatment, relapse is common and up to 60% of patients experience a disease flare either during steroid taper or after discontinuation [6,8,9]. There are four treatment strategies that have

been variably implemented for the treatment of relapsing AIP. These include (i) high-dose corticosteroid for 4–6 weeks followed by gradual taper and either maintenance on low-dose steroids (2.5–10 mg daily) or discontinuation, (ii) high-dose corticosteroids for 4–6 weeks along with coadministration of immunomodulator followed by steroid taper and discontinuation, (iii) RTX induction therapy alone with either 4 weekly doses (375 mg/m2 BSA) or 2 doses (1000 mg each) administered 2 weeks apart, and (iv) RTX induction therapy followed by maintenance dose infusions (375 mg/m2 BSA) every 2–3 months for a 2-year period.

There is limited data comparing the relative efficacy of these different strategies. In our previously published experience of treating 51 patients for a first relapse, a subsequent relapse occurred in 9 out of 24 (38%) patients in the steroid monotherapy group and 8 out of 27 (30%) in the group treated with corticosteroids and an immunomodulator [4]. Relapse-free survival was not significantly different in the two groups.

In the same study, 12 patients who were resistant or intolerant to steroids and immunomodulators were treated with RTX induction and maintenance. Ten patients (83%) in this group achieved complete remission with no disease recurrence during a median follow-up of 10.6 months [4]. In a larger cohort of 60 patients with IgG4-RD (12 with pancreatic involvement) treated with RTX induction therapy alone (two infusions separated by 15 days), a clinical response was noted in 95% [7]. In this study, 21 patients (37%) experienced relapses following RTX treatment and the median time interval between RTX treatment and relapse was 244 days [7]. In our experience, relapses are distinctly uncommon in patients on RTX maintenance therapy. However, this needs to be confirmed in future studies comparing outcomes of RTX induction alone versus maintenance therapy.

## Follow-Up and Management of Disease-Related Sequelae

### Exocrine Insufficiency

Steatorrhea is uncommon in patients with AIP. A study using a diagnostic cut-off of FE-1 < 200 μgm/gm reported an abnormal test result in more than 80% of patients with AIP [10]. This is discordant with our clinical observations and it is unlikely that FE-1 values at that cut-off accurately reflect the true prevalence of exocrine pancreatic insufficiency in patients with AIP. Significant pancreatic parenchymal atrophy is seen in up to 25% patients after corticosteroid therapy and may contribute to the development of exocrine dysfunction over time [11]. The use of PERT should be limited to patients with clinical evidence of fat malabsorption.

### Endocrine Insufficiency

Risk factors for the development of new-onset diabetes in patients with AIP include extensive pancreatic parenchymal atrophy, long duration of disease, advanced age, smoking, and alcohol consumption. Periodic monitoring of glycemic status should be considered for early detection and timely intervention, especially in patients with the above-mentioned risk factors.

## Risk of Pancreatic Malignancy

There is conflicting evidence regarding the risk of pancreatic cancer in patients with AIP. Although some studies have shown increased risk, the vast majority have failed to establish an association. The risk of cancer appears to be highest in the first year after diagnosis of AIP [12]. In a recently published study of 107 AIP patients with a median follow-up of 74 months, none of the study subjects developed pancreatic cancer [13]. Interestingly, eight patients developed a non-pancreatic malignancy and the cancer risk in this study cohort was comparable to an age- and gender-matched reference population. The concomitant diagnosis of AIP and pancreatic cancer has also been reported [14]. Although this phenomenon is exceedingly rare, it highlights the importance of a detailed diagnostic work-up to exclude pancreaticobiliary malignancy before embarking on an AIP treatment protocol. Also, malignancy should be considered in the differential diagnosis of patients who do not respond to corticosteroid induction since primary nonresponse to steroid therapy is extremely unusual.

## Management of Medication Side-Effects

### Corticosteroids

Hyperglycemia and altered mood are the two most frequent and clinically relevant treatment-related complications linked to high-dose corticosteroid therapy. For those with a pre-existing mood disorder, careful assessment of mental health status, and if necessary medication dose adjustment should be considered prior to initiation of treatment. A baseline fasting plasma glucose should be obtained in all patients and those with a pre-existing diagnosis of diabetes mellitus closely monitored to modify steroid and insulin dosing. Less commonly encountered serious side-effects of high-dose

steroids include avascular necrosis, osteoporosis, hypertension, and worsening heart failure.

### Immunomodulators

Unfortunately, in most reported series up to a quarter of patients treated with immunomodulators have experienced treatment-limiting side effects [4]. The commonly encountered adverse effects that result in drug discontinuation include nausea, liver enzyme elevation, drug rash, myelosuppression, and bacteremia. A switch to a different immunomodulator is tolerated in about half of these patients.

### Rituximab

Rituximab treatment is fairly well tolerated. All patients should be screened for hepatitis B virus (HBV) prior to initiation of therapy since reactivation hepatitis B can potentially result in fulminant liver failure [15]. Common infusion-related adverse reactions include flu-like symptoms, pruritus, transient hypotension, and bronchospasm. Serious infusion reactions are rare, but near-fatal infusion reactions have been reported [16]. Other rare serious reactions that would necessitate discontinuation of therapy include toxic epidermal necrolysis and progressive multifocal leukoencephalopathy.

## Management of Idiopathic Duct-Centric Pancreatitis

IDCP is exquisitely steroid-responsive. The dose and duration of induction treatment with corticosteroids is similar to AIP. Clinical response is often dramatic and relapses are infrequent. A Mayo Clinic study of 31 subjects with a definitive diagnosis of IDCP reported a relapse rate of 10.6% at 12 months [17]. Initial presentation with acute pancreatitis predicted a lower relapse-free survival. Relapses almost always respond to retreatment with corticosteroids. In view of the relatively low relapse rate, maintenance therapy with steroids or immunomodulators is currently not recommended. Long-term disease related sequelae such as pancreatic duct stones, pancreatobiliary malignancy also appear to be less common compared to type 1 AIP.

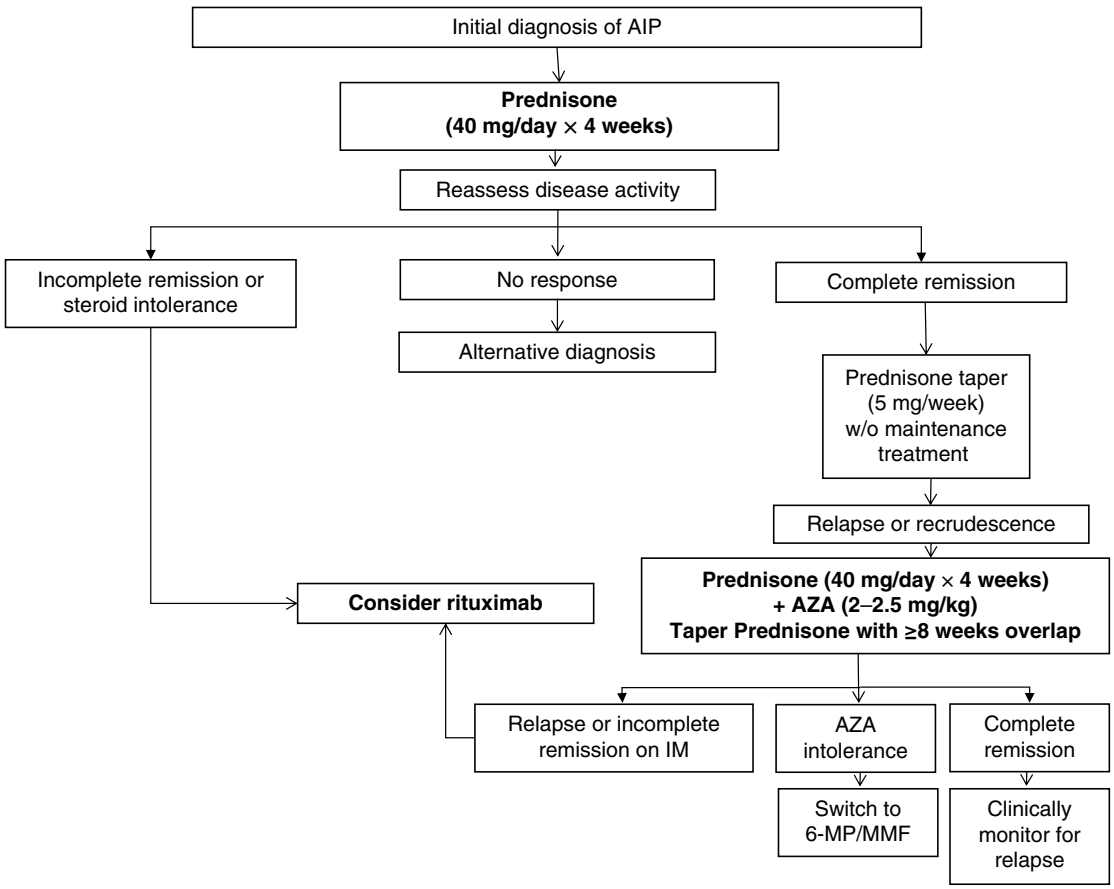

**Figure 71.1** Mayo Clinic treatment algorithm for management of initial presentation and subsequent disease relapses for patients with established autoimmune pancreatitis.*Source*: Adapted from Hart et al. 2013 [4]. Reproduced with permission of BMJ Publishing Group Ltd.

## Conclusion

In patients with a confirmed diagnosis of AIP the initial medical management is straightforward. Treatment of relapses and disease that does not respond or incompletely responds to high-dose corticosteroids requires a thoughtful approach with the judicious use of immunomodulators and B-cell depletion therapy (Fig. 71.1). Although, based on preliminary experience RTX appears to be the agent of choice for the treatment of patients with refractory disease, the optimum dosing regimen and duration of treatment continues to evolve and needs further study. Novel biomarkers that allow disease activity surveillance and predict relapse may facilitate more accurately tailored treatment regimens in the future.

# Long-Term Outcome of Management of Autoimmune Pancreatitis

## 72

## Long-Term Outcome After Treatment of Autoimmune Pancreatitis

*Luca Frulloni and Nicolò de Pretis*

*University of Verona, Verona, Italy*

### Introduction

Autoimmune pancreatitis (AIP) is a clinical entity that is well described in clinical and imaging findings at the onset of the disease [1]. The early phase is also known, in particular the outcome after steroid treatment, which represents a diagnostic criterion. However, the long-term outcome of patients suffering from AIP is still largely unknown. Many aspects are not yet fully clarified, particularly the need for and efficacy of treatment with nonsteroidal immunosuppressants (azathioprine) or biologics (rituximab (RTX)) in preventing disease relapse and progression toward chronic pancreatitis in terms of loss of pancreatic function (exocrine and endocrine insufficiency), onset of pancreatic calcifications, and the risk for pancreatic cancer. Since the term "autoimmune pancreatitis" was introduced in 1995 [2] and the disease was recognized as an entity, and thus early treatment has become the norm, the long-term clinical outcome of the disease has been modified by the use of steroids, nonsteroidal immunosuppressant drugs, and/or biologics (RTX). Therefore, while the natural history of the disease remains obscure, what can be observed nowadays is the long-term outcome of AIP after therapy.

An unanswered question is the fate of patients suffering from AIP before 1995 and appropriate immune suppressive treatment. We know that some of them underwent surgery because of the suspicion of pancreatic cancer. To answer this question may well lead to a better understanding of the natural history of AIP.

### Disease Relapse after Steroids and Treatment

Relapse of AIP may be symptomatic, evident on imaging, serology, and/or histology [3]. However, an AIP relapse may be clinically asymptomatic and detectable only on imaging [4]. The site of the relapse is mainly in the pancreas, but may involve extrapancreatic organs (kidney, salivary glands, biliary tree, and retroperitoneum) [4–7]. Relapse rates reported in the literature include symptomatic and asymptomatic patients with both, pancreatic and extrapancreatic involvement without distinction.

After a first course of steroids, disease relapse has been reported in between 13% and 64% of cases (Table 72.1) [6,8–16]. Disease relapse does not differ between patients who underwent surgery compared to those treated conservatively (Table 72.2) [6,9–13,15,17]. Furthermore, relapse rates are significantly higher and more frequently observed in AIP type 1 compared to type 2 [6,18,19]. Ikeura et al. [18] reported a 20% relapse rate of AIP NOS (not otherwise specified), lower than in type 1 (34%) and higher than in type 2 AIP (6%). High levels of serum IgG4 [6,7,9,12,19–22], intrahepatic biliary involvement [6,20,23], and other organ involvement [7], have all been identified as risk factors for relapse. These factors were all strictly correlated with type 1 AIP, which may therefore be considered as a more aggressive disease.

The treatment of choice for disease relapse is a new course of steroids (prednisolone) to induce remission [25]. This therapeutic approach is widely accepted, even if it is based only on cohort studies. The dosage of prednisolone is the same as that proposed after the diagnosis

of AIP (prednisolone, 30–40 mg/day or a weight-adjusted dose range from 0.5 to 1 mg/kg of body weight per day), which can be varied according to disease activity. After the induction of remission in relapsing AIP a maintenance regimen has been suggested. Long-term maintenance therapy with low-dose steroids (prednisolone, 5–10 mg/day) is used in Asian countries, but is still debated elsewhere. Steroid-sparing agents, in particular azathioprine (2–2.5 mg/kg/day), have been proposed for long-term treatment of relapsing AIP [20], even in the absence of controlled trials, but again their use is still being debated. However, experts recommend an add-on therapy with steroid-sparing agents for IgG4-related disease [26], to which AIP type 1 belongs.

RTX, an anti-CD20 antibody inducing B-cell depletion, seems to be effective in inducing specific serum IgG4 reductions and for better disease control in IgG4-RD, even in steroid refractory cases [27]. RTX would probably interfere with the immunologic processes underlying IgG4-RD, but the exact mechanism is still unknown. Since AIP type 1 is considered a manifestation of IgG4-RD, the use of RTX has been suggested for this subtype of AIP [26,28]. Some preliminary cohort studies seem to confirm the efficacy of RTX in AIP type 1 [29]. There is still no consensus regarding the dosage and the RTX schedule. A rheumatologic (intravenous infusions at a dosage of 375 mg/m$^2$ body surface area at time points 0 and 15 days, repeated after 6 months) rather than a hematologic schedule (intravenous 375 mg/m$^2$ body surface area four times at weekly intervals, then repeated infusions every 2–3 months up to 24 months) can be suggested, but randomized trials are needed to better understand the most appropriate protocol for AIP patients.

## Loss of Pancreatic Function and Evolution Toward Chronic Pancreatitis

The long-term outcome of AIP patients is described in only few studies, and limited to the first 10 years after clinical onset. The key points about the natural history of AIP are the deterioration of exocrine and endocrine function, the onset of pancreatic calcifications, and, more generally, the evolution toward "ordinary" chronic pancreatitis.

Exocrine pancreatic function is already reduced at clinical onset of the disease (Table 72.3) [5,9,11,30–32] and its improvement has been observed in a significant proportion, but not all, patients after steroids [32,33]. The exocrine pancreatic function evaluated by secretin-cerulein test is reduced at clinical onset of the disease in nearly all AIP patients, involving particularly enzyme production more than bicarbonate secretion [34]. After steroids, studies have shown that exocrine pancreatic insufficiency evaluated by PABA test [32] or fecal elastase-1 [33] improved, but severe pancreatic insufficiency remained in 33–50% of cases. However, pancreatic exocrine insufficiency remains present in a large portion of AIP patients (80%) in the long-term follow-up after steroids [30]. Therefore, evaluation of pancreatic function in AIP is recommended to identify patients who may benefit from pancreatic enzyme replacement therapy.

Similar data have been published for endocrine pancreatic function (Table 72.3) [5,9,11,30–32], and diabetes is quite common in AIP. Steroid-induced diabetes is frequently observed at clinical onset of the disease, particularly in older patients [33,35].

The results of long-term follow-up suggest that some patients with AIP could develop pancreatic calcifications, generally after several disease relapses [21,22,36].

Loss of pancreatic exocrine and endocrine function, onset of calcifications, and atrophy of the pancreatic gland seem to suggest that AIP can transform into "*ordinary*" chronic pancreatitis. This hypothesis, even if not completely supported by clinical data and imaging findings, could explain why AIP was not identified in the past and may have been confused with chronic calcifying pancreatitis in its advanced stage.

This hypothesis also implies that imaging is only typical for AIP in the early phase of the disease and the diagnosis can be more easily achieved. In the more advanced stage, the radiologic features are less suggestive for AIP, and it is highly probable that the diagnosis of AIP will be missed.

Fig. 72.1 shows a diagram of the postulated natural history of AIP.

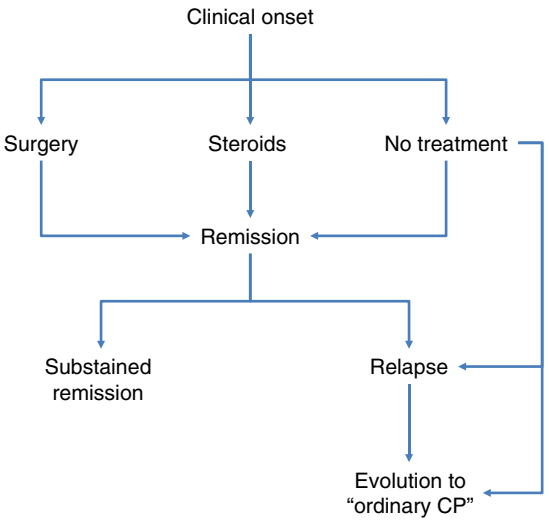

**Figure 72.1** Natural history of autoimmune pancreatitis hypothesized on the basis of evidence in the literature.

**Table 72.3** Frequency of pancreatic exocrine and endocrine insufficiency in patients suffering from AIP.

| Author | Year | Patients N. | Follow-up months | PEI | Diabetes |
|---|---|---|---|---|---|
| Kamisawa et al. [32] | 2003 | 12 | 41 | 67% | 83% |

| Lopez-Serrano et al. [5] | 2016 | 47 | 50 | 36% | 36% |

PEI, pancreatic exocrine insufficiency.

## Risk for Pancreatic and Extrapancreatic Cancer

A risk for pancreatic cancer in AIP has been reported [21,31,37–44], as for other chronic inflammatory gastrointestinal diseases, but studies are limited to case reports or small series. The risk for pancreatic adenocarcinoma is highest in the early phase of the disease, probably because the imaging features of AIP and pancreatic cancer can overlap, and lower in a more advanced phase. The clinical implication is therefore to exclude cancer at the clinical onset of the disease, and to monitor AIP patients by imaging techniques during follow-up, not only to diagnose the disease relapse, often asymptomatic, but also for an early diagnosis of cancer.

The incidence of extrapancreatic cancer within 5 years from diagnosis of AIP is high, ranging from 6.6% to 13.9% [6,45–47]. The increased risk for extrapancreatic malignancy has been reported for AIP type 1, but not for AIP type 2, which may be related to the patient's age more than the AIP subtype. It is still debated whether this incidence is increased compared to general population. In any case, physicians should be aware that 10% of patients could develop a cancer after diagnosis of AIP and, therefore, the use of immunosuppressant drugs and biologics should be carefully evaluated.

## Introduction

Pancreatic cystic lesions (PCL) can be histopathologically classified as nonneoplastic or neoplastic. Nonneoplastic cysts do not have any malignant potential and include pseudocyst, lymphoepithelial cyst, retention cyst, hydatid cyst, enteric duplication cyst, and mucinous nonneoplastic cyst. Neoplastic cysts, termed as pancreatic cystic neoplasms (PCN) have a potential to develop malignancy or are malignant at diagnosis. PCN are further classified as serous cystic neoplasm (SCN), mucinous cystic neoplasm (MCN), intraductal papillary mucinous neoplasm (IPMN) (including branch-duct and main-duct IPMN), solid-pseudopapillary neoplasm (SPN), and cystic change in an otherwise solid tumor (e.g., ductal adenocarcinoma or neuroendocrine tumor (CPNT)). The risk for developing malignancy in these cysts varies from <1% in SCN to >60% in main-duct IPMN [1–3].

PCL are being increasingly identified in asymptomatic patients on routine imaging studies [4]. While a neoplastic nature of PCL <5 mm in size is not always certain, the majority of larger, resected cysts are neoplastic [5]. However, the vast majority of PCL are not resected [6] and therefore, PCL >10 mm in size are presumed to be PCN and are managed accordingly. Studies based purely on imaging diagnosis of pancreatic cysts can provide information on incidence and prevalence of PCL in the general population [7,8]. However, these studies lack confirmatory histopathologic diagnosis. In contrast, surgical series cannot be used to determine the incidence and prevalence in the general population, but they provide information of the histopathologic spectrum of pancreatic cysts [5,6]. We use the term PCL in reference to data from imaging studies and PCN for data from surgical series. Although, some studies on PCL do make presumptive histopathologic diagnoses based on imaging and, when available, cyst fluid characteristics; however, preoperative diagnosis may be incorrect in nearly one third of PCL when correlated with surgical histopathology [9].

## Pancreatic Cyst Lesions

### Incidence

There is limited information on incidence of PCL in the general population. A study from Olmsted County, MN showed the prevalence of PCL suspected to be IPMN was 4.35 per 100,000 persons in 2005 [8] (Fig. 73.1). The age- and sex-adjusted incidence had risen 14-fold compared to 1985, when it was 0.31 per 100,000 (Fig. 73.1). This growing incidence was felt to be secondary to diagnostic scrutiny rather than a true increase in incidence over time. In this study, other non-IPMN pancreatic cysts such as SCN were excluded.

### Prevalence

In hospital-based studies, the prevalence of PCL has been reported to range between 0.2% and 41.6% [4,10–17]. Various risk factors affect the prevalence of PCL, including study-related factors and patient-related factors. Study-related factors include study design, imaging modality, and year of study. A recent study showed that incidental PCLs were documented in only 31% of radiology reports [11]. Thus, retrospective studies based on review of radiology reports rather than review of images underestimate the prevalence rates of PCL. Type of imaging modality also affects the prevalence rate, with increasing prevalence rates reported in studies using US,

CT, MRI, and EUS, respectively [17,18]. Older studies report lower prevalence rates compared to newer studies. For instance, PCL were identified in 1.4% of abdominal scans in a study from 1980 [19], compared to 9.3% in a recent study from 2015 [7]. Higher prevalence in the newer studies is likely to be due to better quality of cross-sectional imaging hardware and software. In an interesting study by Moris et al., newer versions of MRI hardware and software were independently associated with higher PCL detection rates [4].

## Risk Factors

### Age

Older age is a risk factor for PCL (Fig. 73.2). In general, when study populations consist of older individuals the reported prevalence is high. For example, an autopsy series reported PCL prevalence of 24.3% in a population with a mean age of 79.3 years [16]. A study based on MRIs in asymptomatic individuals with a mean age of 51.1 years, the prevalence was 2.4% [14]. PCL are infrequent under the age of 40 years; the prevalence in this age group varies from 0–1.2%, depending on the imaging modality used to identify PCL [12,13]. However, in one study using single-shot fast spin-echo MRI sequence, the overall prevalence of PCL was 9.1% in this age group [20]. The risk rises gradually over age 40 years. In a large study the odds of a PCL being present increased by 1.06 for each additional year after age 40 [12]. In individuals over 70 years, up to 40% patients appear to have a PCL [11]. In older patients, not only does PCL prevalence increase, but also the size and number of cysts increases [11,20]. In addition, compared to younger patients, older patients have a greater likelihood of finding malignant pathology and also a greater probability of undergoing pancreatic surgery for PCL [21].

### Gender

Although one study showed greater prevalence of PCL in women [22], the majority of studies have not shown any difference in prevalence of PCL between the two sexes [11,12,14,15]. Most studies have not shown a difference in size of PCL between men and women [11,14,21], except one study, which showed larger cyst size in men compared to women [12]. There is no difference between rates of malignancy and number of PCL between the sexes [11,21].

### Race and Geography

There are limited data on prevalence of PCL based on racial background. Only one study showed that the cysts are 3.5 times more prevalent in Asians compared to non-Asians after controlling for age as a risk factor [12]. Although the prevalence was higher in Asians, cyst size, location, or number was not different compared to non-Asians.

In an autopsy study from Japan the prevalence was 24.3% [16]. By contrast, in an ultrasound-based study from Japan the prevalence was 0.21%. In a study from the Netherlands, MRIs done in asymptomatic individuals showed a prevalence of 2.4% [14]. In a recent study based on CT scans from San Marino, prevalence in asymptomatic individuals was 5.4% [7]. The estimated standardized population prevalence for the state of San Marino was 2.2% [7]. An MRI study from Brazil reported a prevalence of 9.3% [13]. Studies from the United States have shown a prevalence rate of 1.2–19.6% [11,12,20]. It is

unclear if this difference in prevalence is due to geographical factors, since various other factors that could impact prevalence, such as age and modality of imaging, were not adjusted.

#### Family History of Pancreatic Cancer

Based on a case-control study, PCL were reported to be nearly three times more common in individuals with a first-degree relative who had pancreas cancer [15]. A multicenter US screening study in high-risk individuals for pancreatic cancer, such as individuals from familial pancreatic cancer families, hereditary pancreatitis, familial atypical multiple mole melanoma, familial breast-ovarian cancer with breast-related cancer mutation and hereditary nonpolyposis colorectal cancer, and Peutz–Jeghers syndrome have shown a prevalence of 42% with multiple modalities—CT, EUS, and MRI [18]. The prevalence increased with age, as nearly 65% high-risk individuals over 70 years of age were noted to have a PCL. Another similar study from Sweden, showed a prevalence of 40% in such high-risk individuals undergoing MRI screening for pancreatic cancer [23].

In the authors' experience, 5–10% of patients with PCL have a family history of pancreatic cancer in first-degree relatives. Whether risk for pancreatic cancer is higher in this subgroup is not known.

#### History of Pancreatitis

PCN such as IPMN can cause acute pancreatitis. IPMN have also been reported in patients with chronic calcifying pancreatitis [24]. On the other hand, individuals with a history of pancreatitis can develop pseudocysts, which are often indistinguishable from PCN [25–27]. Given such issues, studies on the prevalence of PCL have typically excluded patients with a history of pancreatitis. Studies including patients with a history of pancreatitis have reported a prevalence of 16.6–42% [20,21]. However, whether these cysts represented pseudocysts or PCN was not known.

#### Miscellaneous

Recent studies have shown diabetes mellitus and insulin use as independent risk factors for PCL [15]. Presence of extrapancreatic cysts has also been strongly associated with PCL [4,14,20]. In a study, 70% patients with PCL had an extrapancreatic cyst [4]. The most frequent organs involved were kidneys (50%) and liver (50%). The presence of liver cysts is independently associated with PCL [14]. PCLs are seen in 11% of solid organ transplant recipients [28]. Fortunately, pancreatic cancer is rarely seen in this group of patients. Lifestyle factors such as cigarette smoking and alcohol consumption are not associated with development of PCL [11–14,20,21].

PCL are seen in association with autosomal dominant polycystic kidney disease (ADPKD). About 5% to 10% of individuals with ADPKD have PCL, based on ultrasound [29]. However, ADPKD is rarely seen in patients with pancreatic cysts (~1%) [20]. In contrast, pancreas involvement is frequently seen in patients with von Hippel–Lindau disease (VHL). In a large French multicenter study, 77.2% of patients with VHL had pancreatic involvement, mostly PCLs [30]. In 7.6% of these patients, the pancreas was the only organ involved. In this series, VHL patients with PCL had fewer pheochromocytomas than those without.

#### Cyst Size and Morphology

The majority of incidentally identified PCL are subcentimeter in size, the average cyst size being 8–10 mm [11–14,20]. However, cyst size increases gradually with age. For instance, in a study by Lee et al., the median cyst size in patients >90 years was 14 mm compared to 3 mm for those <39 years [11]. Large cysts (>3 cm) are infrequent, seen in <5% cases.

Among patients with incidentally identified cysts, almost half have more than one cyst [13,20]. Multifocal (>5) cysts have been reported in 10% to 40% of cases [13,14,20]. Cyst distribution is generally equal throughout the gland, with half the cysts located in the proximal part of gland (head, neck, or uncinate) and the other half in the distal part of the gland (body or tail) [11,14].

Morphologically, the majority of PCL (80–90%) identified incidentally are simple in nature without any wall thickening, septations, or mural nodules [11,14]. Communication with the main pancreatic duct is seen in 8% to 35% of cases [11,20].

## Pancreatic Cystic Neoplasms

As discussed in the preceding section, PCL are commonly seen, especially in older patients. Most of these are suspected to be PCN. The majority of these patients do not undergo surgery and therefore, their pathologic diagnosis is never known. In the few patients who undergo surgery, the histopathologic characteristics can be used to classify PCN. In one of the largest surgical series of 851 patients at Massachusetts General Hospital undergoing surgery for PCL, IPMN were the most common PCN, seen in 38% of cases [5] (Fig. 73.3). MCN were the next most common (23%), followed by SCN (16%), CPNT (7%), and SPN (3%). There was a trend towards an increasing number of surgeries for PCN in the recent time period—376 between 2005 and 2011, compared to 67 between 1978 and 1989.

IPMN are mucinous neoplasms arising from the pancreatic ducts. When they arise from the side branches,

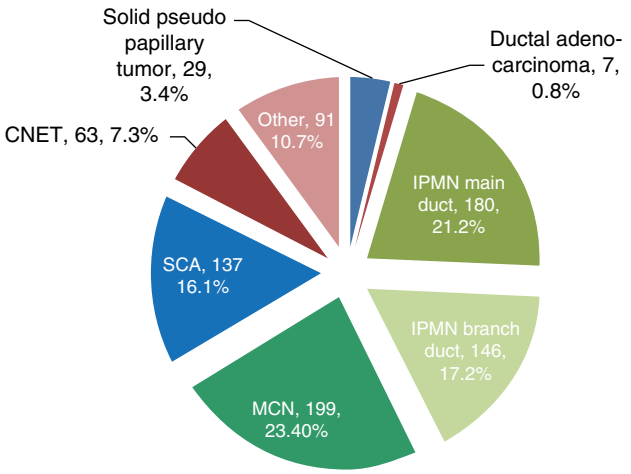

**Figure 73.3** Distribution of pathologic diagnoses in 851 resected cystic neoplasms of the pancreas. Lesions classified as "other" included pseudocysts, 25; benign epithelial cysts, 11; acinar cell cystadenomas and cystadenocarcinomas, 3; lymphoepithelial cysts, 5; choledochal cysts, 4; lymphangiomata, 4; hemangiomata, 2; and other unclassified epithelial cysts. *Source:* Valsangkar et al. 2012 [5], Fig. 1. Reproduced with permission of Elsevier.

they are referred to as branch-duct IPMN (BD-IPMN) and are called main-duct IPMN (MD-IPMN) if they involve the main pancreatic duct. Mixed-IPMN involve both branch and main ducts, but for practical purposes they are considered together with MD-IPMN.

The median age of surgery for BD-IPMN is about 65 years with an almost equal distribution between males and females [31]. However, studies from Asia have reported male sex predilection with a 3:1 ratio [32]. The median size of resected BD-IPMN varies between 2 to 3 cms [31,33]. BD-IPMN appear as a solitary cyst, multifocal cysts, or a cluster of cysts. They arise from the side branches of the pancreatic duct, although the communication with the main pancreatic duct may not always be visible. Almost 60% are located in the head of the pancreas and 40% in the body/tail region; 15–40% are multifocal [31,33]. Malignancy can be present in about 20% of cases [31,33]. About 12% have a history of pancreatitis and 35% have a history of smoking [31,33].

Similar to BD-IPMN, the median age for MD-IPMN is between 65 and 70 years [5]. They appear as dilation of the main pancreatic duct without any obstructing mass or stricture. The majority (64%) are in one location, most commonly in the head of the pancreas [3,5]. Among the 36% involving multiple locations, almost half have diffuse involvement of the entire pancreatic duct [3]. Malignancy can be seen in up to 60% of MD-IPMN, and is associated with older age, jaundice, and new-onset diabetes mellitus [3]. Mixed-IPMN have a similar risk for malignancy as MD-IPMN. One fourth of MD-IPMN have a history of pancreatitis. Most (50–60%) of MD-IPMN patients are smokers. Nearly 12% have a history of diabetes [3].

MCN are almost exclusively seen females (>95%) [34–37]. The median age is 40–50 years, and the majority of patients are <60 years [34–37]. The median size of MCN typically varies between 5 cms to 10 cms [34,37]. MCN with an associated invasive carcinoma are generally larger than benign MCN and an associated invasive carcinoma is rarely seen in those <4 cms [34,37]. They are solitary and often have septations and a thick wall. Wall calcification can be seen in about 25% of cases [35,36]. They are almost always (>90%) located in the body/tail region of the pancreas [34–37]. Less than 5% have communication with the main pancreatic duct [36]. An associated invasive carcinoma at the time of surgical resection is found in 10–20% [35–37]. Older age, larger cyst size, presence of mural nodules, and elevated CA-19-9 are associated with malignant transformation [34–37]. About 5–10% of patients with an MCN have a history of pancreatitis [35,36]. Nearly 30–40% are smokers [34,37] and 7% have a history of diabetes mellitus [34].

SCN are seen more commonly in females (75%) and the median age is 58 years [1]. Their median size is about 3 cms [38]. They are solitary, and generally appear as a cluster of multiple cysts separated by thin fibrous septae with a characteristic central scar seen in 30% of cases [39]. The pattern of cysts is microcystic in 45%, macrocystic in 32%, both microcystic and macrocystic in 18%, and solid in 5% of cases [1]. Cyst calcification is seen in about 15% of cases [1]. They are equally distributed in the pancreas with 40% in the head, 34% in the body, and 26% in the tail [1]. Malignancy is very rare (0.1%) [1]. They are seldom associated with pancreatitis and about 5% of cases have a history of diabetes [1].

SPN are mostly seen in females (>85%) [40,41] with a median age of 35 years [41]. They are generally very large at the time of diagnosis with an average size of 8.5 cms [40]. They are solitary, well encapsulated, round-oval, and have a variable amount of solid and cystic component, hemorrhage, and necrosis [41,42]. Cyst calcification can be seen in nearly half the cases [42]. They are equally distributed between the head, body, and tail of the pancreas [41]. Metastases can be seen in 15–20% of cases at surgery [41,42].

CPNT are seen at a median age of 55–60 years and are equally distributed between the sexes [43,44]. The mean size varies between 2 to 5 cms [43,44]. They are solitary cystic lesions with a varying degree of solid/cystic component. Most have arterial hyperenhancement of solid component, as is seen with other solid neuroendocrine tumors of the pancreas [43,44]. Nearly half of these have a characteristic hypervascular rim [43]. Calcification is rarely seen and 3% of cases have a history of pancreatitis [44]. They are associated with multiple endocrine neoplasia (MEN) syndrome in 6% of cases [43,44].

[2] *Department of Pathology, University of Verona, Ospedale S. Cuore-Don Calabria, Negrar, Verona, Italy*

## Introduction

With the increased use of cross-sectional imaging in the work-up of numerous abdominal complaints, cystic lesions of the pancreas have been increasingly identified. The prevalence of incidental pancreatic cystic lesions in the adult population is high, and ranges from 2.6% to 19.6% [1]. Autopsy series report an increase in pancreatic cystic neoplasms prevalence with age: 8% in patients <70 years of age, up to 35% >90 years of age [2]. In clinical practice, only 5–15% of pancreatic cysts have been reported as neoplastic (Table 74.1) [3]. Recently most of pancreatic cysts are considered to be small intraductal papillary mucinous neoplasms (IPMN) or retention cysts. Cystic neoplasms, including serous cystic neoplasms (SCN), mucinous cystic neoplasms (MCN), intraductal papillary mucinous neoplasms (IPMN), solid pseudopapillary neoplasms (SPN), and some types of acinar cell neoplasms can be classified according to their malignant potential into benign, premalignant, and malignant [4]. It is important to recognize pancreatic cystic neoplasms before an invasive carcinoma develops, especially in MCN and IPMN. MCN and IPMN show ductal differentiation of the neoplastic epithelium; however, the differentiation of epithelial cells in SCN and SPN has not been fully recognized. The histopathologic classification and staging of major cystic neoplasms are discussed in this section.

## Serous Cystic Neoplasms

Serous cystic neoplasms (SCN) are almost always benign, and are indolent pancreatic neoplasms composed of innumerable small cysts lined by epithelial cells showing a clear cytoplasm and round, uniform nuclei. Patients are usually women (female/male ratio: 7:3) with a mean age at diagnosis of 60 years [5–7]. Approximately 40% of SCN are incidentally detected by imaging studies at routine physical examinations or for other diseases. Other patients complain of symptoms related to local mass effects, such as abdominal pain, palpable mass, nausea, and vomiting. Patients with von Hippel–Lindau (VHL) syndrome are at an increased risk for development of serous cystic neoplasms. SCN are observed in 15% of patients with this syndrome [8]. Sporadic SCN have been found to feature somatic mutations in the *VHL* gene in 50% of cases [8].

Macroscopically, SCN are multilocular, large cystic neoplasms and their cut surface typically shows a well-circumscribed, sponge-like appearance (called "microcystic type") with a central scar (Fig. 74.1a). The size of the cysts is variable, and there are several variants described in the following text. The cysts contain serous watery fluid. They usually do not communicate with the pancreatic larger ductal system.

Histologically, the cysts are separated from one another by thin fibrous septa and the internal surface of the cysts is covered by a monolayer epithelium (Fig. 74.1b). The lining epithelial cells have a clear cytoplasm and round, uniform, centrally located nuclei. Although a moderate nuclear pleomorphism is not unusual, necrosis and mitoses are not identified.

Because the cells contain large amounts of glycogen, they stain strongly with the periodic acid–Schiff (PAS) reaction, but only without diastase digestion. Immunohistochemically, the epithelial cells lining the cysts express cytokeratins (CK), such as CK7 and CK19, and epithelial membrane antigen (EMA), MUC6, inhibin alpha, and GLUT-1, but not CEA, trypsin, or chromogranin A [3,4].

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

According to the current World Health Organization (WHO) classification, variants of serous neoplasms are classified into macrocystic serous adenomas, solid serous adenomas, VHL-related serous cystic neoplasms, and mixed serous neuroendocrine neoplasms [4]. The lining epithelium of these subtypes of SCN is the same as that of the common type (microcystic type) of SCN.

The most important differential diagnoses are with the two mucinous neoplasms, MCN and IPMN. Malignancy (serous cystadenocarcinoma) is defined by the presence of distant metastases because SCN with locally aggressive features, such as direct invasion into adjacent tissues, can rarely recur or even metastasize [5,6].

**Table 74.1** Classification of cystic lesions of the pancreas.

| |
|---|
| Cystic neoplasms – Epithelial |

| Endometrial cyst |

## Mucinous Cystic Neoplasm

Mucinous cystic neoplasm (MCN) occurs almost exclusively in women (male/female ratio: 1:10–20), arises in more than 90% of cases in the body-tail of the pancreas, and has no, or very infrequent, communication with the pancreatic ductal system [9,10]. The mean age at diagnosis is approximately 45 years. Like the other cystic neoplasms of the pancreas, growing numbers of MCN are being detected in asymptomatic patients through imaging studies.

Macroscopically, MCN present as a round mass with a smooth, intracystic surface and a fibrous pseudocapsule with variable thickness and frequent calcifications. The tumor size ranges from 2 cm to 35 cm at greatest dimension. The cut surface shows unilocular or multilocular tumor cysts (so-called "cyst-in-cyst appearance") that contain mucus, watery fluid, or hemorrhagic-necrotic material (Fig. 74.2a). The internal surface can be smooth or may present with papillary projections and/or solid nodules. The presence of larger dimension papillary projections and/or mural nodules correlates significantly with malignancy.

Histologically, MCN is composed of the following two distinct components: a mucinous epithelium and a densely cellular ovarian-type stroma (OS) that represents the entity-defining feature (Fig. 74.2b). The epithelium frequently displays areas with pseudopyloric, gastric foveolar, and small and colonic intestinal differentiation. According to the recent international consensus, on the basis of the highest degree of dysplasia, noninvasive MCN are subcategorized into low and high grades [11]. Low-grade MCN are characterized by a minimally

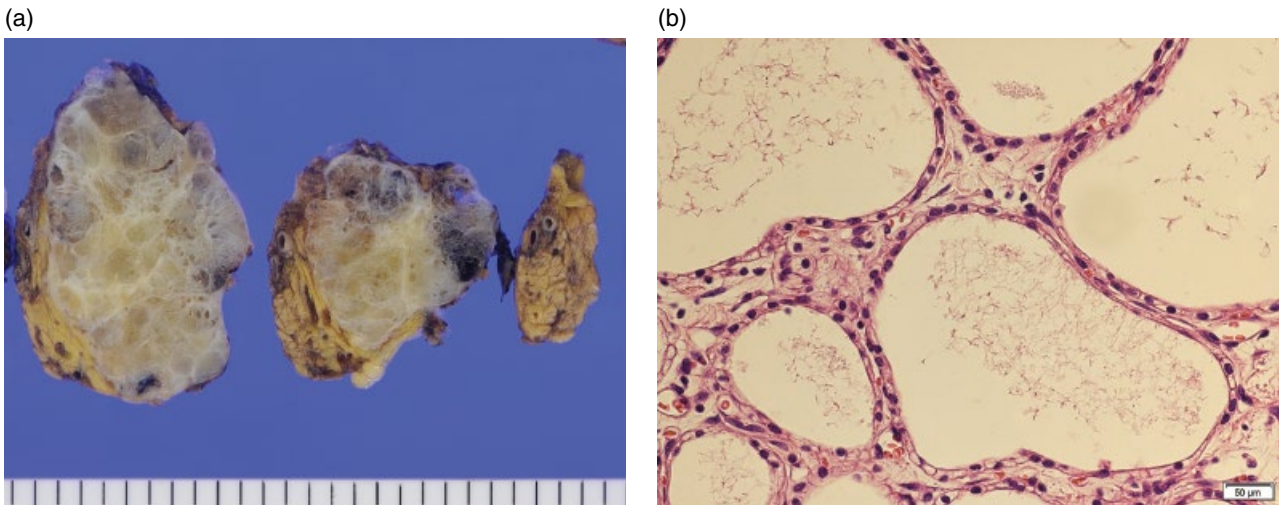

**Figure 74.1** (a) Macroscopic feature of serous cystadenoma (microcystic type). The cut surface shows the well-circumscribed sponge-like appearance with a central scar. (b) Histology of serous cystadenoma (microcystic type). The internal surface of the cyst is covered by a monolayer epithelium. The lining cells show clear cytoplasm and small, round nuclei.

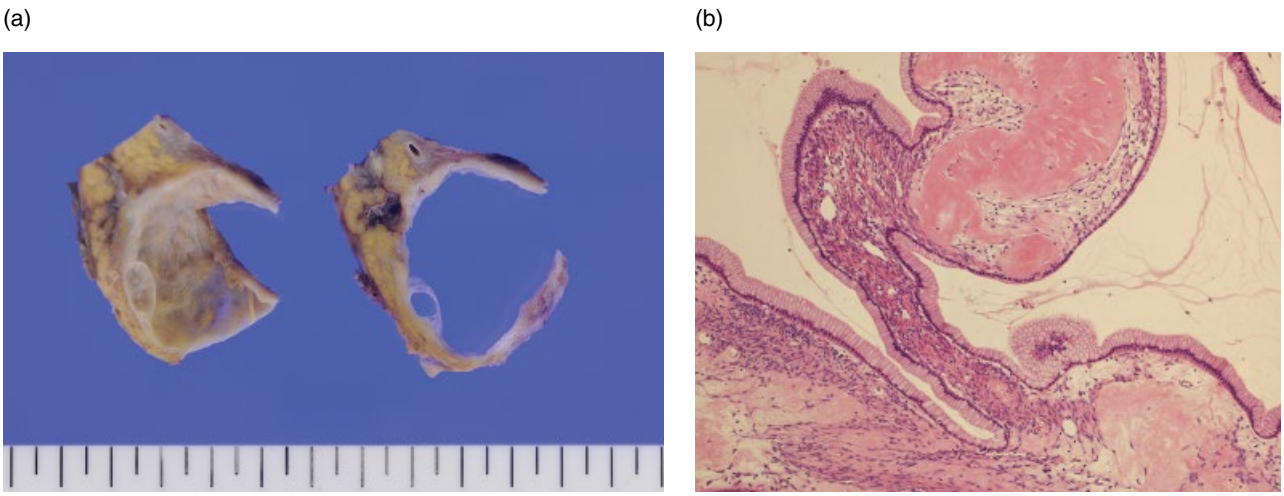

**Figure 74.2** (a) Macroscopic feature of mucinous cystic neoplasm. The cut surface shows a "cyst-in-cyst appearance." (b) Histology of mucinous cystic neoplasm. MCN is composed of a mucinous neoplastic epithelium and a subepithelial densely cellular ovarian-type stroma.

dysplastic epithelium, whereas the high-grade MCN (the equivalent of carcinoma *in situ*) show papillae with irregular branching, budding, severe nuclear atypia, and frequent mitosis. The epithelial cells frequently show immunoreactivity for gastric foveolar type mucin marker MUC5AC, whereas MUC2 is only present in the goblet cells and MUC1 is usually expressed in high-grade MCN and invasive carcinomas.

The OS is a compact layer of cellular stroma that underlines the mucinous epithelium. It is constituted by spindle cells that show immunoreactivity for vimentin, smooth-muscle actin, progesterone receptors (PR), and estrogen receptors (ER). Occasional plump, eosinophilic cells, resembling luteinized cells and expressing alpha-inhibin, may be present. The presence of OS, currently requested for the diagnosis of MCN, in some cases can be hard to identify, because the OS can be replaced by a hyalinized stroma, secondary to a long history and high pressure-related atrophy.

Up to one third of MCN are associated with an invasive carcinoma, which usually resembles the common ductal adenocarcinoma; colloid carcinomas are extremely rare [12].

The staging of the MCN with invasive carcinoma should be determined following the recent scheme proposed by Tanaka et al. [13]. The term "minimally invasive," that has been variably defined by different authors, should be avoided and replaced by the conventional staging protocols, including the AJCC/TNM. The overall size of the invasive carcinoma should be recorded and categorized as early (≤2 cm, pT1) and advanced (>2 cm, pT2, and beyond). pT1 tumors should be subcategorized into pT1a (<0.5 cm), pT1b (0.5–1 cm), and pT1c (>1 cm) [13].

The majority of MCN show an indolent clinical course. However, the survival of invasive MCN may vary from excellent [14] to 53% and 63% at 5 years [9,15]. Recently, Jang et al. [10], using the UJCC/TNM staging, reported an aggressive clinical course with 3- and 5-year survival rates of 44% and 26%, respectively, with a worse prognosis for pT2 than pTl invasive tumors. However, three of their pT1a patients died of the disease.

## Intraductal Papillary Mucinous Neoplasm

Intraductal neoplasms of the pancreas are a heterogeneous category of radiographically and grossly detectable lesions defined as cystic or mass-forming epithelial neoplasms with ductal differentiation that grow primarily within the ductal system, and that can progress to invasive carcinoma [4].

Recently, intraductal neoplasms were classified into IPMN and intraductal tubulopapillary neoplasms (ITPN) [4,16]. ITPN is an epithelial neoplasm proliferating within the pancreatic duct. The neoplastic epithelium shows nonmucinous and high-grade morphology. This neoplasm is an important entity in the differential diagnosis of IPMN; however, this is usually not recognized as a cystic lesion [16].

IPMN are more common in men than in women. The mean age is approximately 65 years. Most IPMN are solitary and located in the pancreatic head, although 20–40% are multifocal.

IPMN can be classified by several viewpoints, such as localizations (main duct or branch duct), histologic grading (low to high grade), histologic differentiation

(gastric, intestinal, oncocytic, or pancreatobiliary), and mucin hypersecreting or not.

Macroscopically, IPMN is an intraductal neoplasm usually showing flat to papillary epithelial proliferation within the dilated pancreatic ducts (>1 cm) by abundant mucus (Fig. 74.3a). IPMN can be classified into main-duct type IPMN (MD-IPMN), branch-duct IPMN (BD-IPMN), and combined-type IPMN according to the ductal portion of tumor involvement [4,13]. MD-IPMN typically show diffuse dilatation of the main pancreatic duct with abundant mucus and villous neoplastic components. BD-IPMN show multiple cystic dilatations of pancreatic ducts called "grape-like appearance." They arise more often in the head and neck and frequently involve the uncinate process.

Histologically, the direction of differentiation of the neoplastic epithelial cells varies among IPMN, including gastric, intestinal, oncocytic, and pancreatobiliary types of differentiation. IPMN have varying degrees of cytologic and architectural atypia, and noninvasive IPMN can be categorized into low- and high grades with the same grading system as MCN. These various differentiations and grades of neoplasm are frequently mixed up within one neoplasm. Many intestinal type IPMN arise in the larger pancreatic ducts, such as the main pancreatic duct (MD-IPMN), and usually show villous or high papillary projections of neoplastic epithelium with abundant extracellular mucus (Fig. 74.3b). If they invade outside the pancreatic duct, invasive components often form a colloid (mucinous) carcinoma. Intestinal-type IPMN show MUC2, MUC5AC, and CDX2 on immunohistochemistry. Gastric-type IPMN frequently occur in branch ducts (BD-IPMN). Their inner surface is covered by low papillary or flat neoplastic epithelium with low-grade dysplasia. Many of these gastric-type IPMN have an indolent course. Gastric-type IPMN are immunoreactive with MUC5AC and MUC6 in some cases. Pancreatobiliary and oncocytic-type IPMN characteristically grow with arborized pattern. Pancreatobiliary-type and oncocytic-type IPMN are immunoreactive with MUC1, MUC5AC, and MUC6 in some cases. These different phenotypes can be observed together, with the IPMN classified according to the predominant type.

The 5-year survival rate for patients with a surgically resected IPMN without invasion is 90–95%. There are significant differences in the prevalence of invasive cancer between the MD-IPMN and the BD-IPMN. Carcinomatous transformation is reported in 30–50% of MD-IPMN or mixed-IPMN, whereas the BD-IPMN have a lower risk of carcinomatous transformation, with 24% of surgically resected BD-IPMN found to have high-grade dysplasia or invasive adenocarcinoma [13]. Most of the invasive carcinomas that arise in MD-IPMN are colloid carcinomas, whereas tubular-type adenocarcinomas, characterized by the presence of malignant glands similar to conventional pancreatic ductal adenocarcinoma (PDAC), are associated with both pancreatobiliary-type IPMN and, in a small percentage, with gastric type BD-IPMN. The type of invasive carcinoma has major prognostic implication: colloid carcinoma has a better prognosis than tubular adenocarcinomas, with the latter behaving like a conventional PDAC.

In contrast, approximately 10% of IPMN are concomitant with the conventional PDAC (histologically

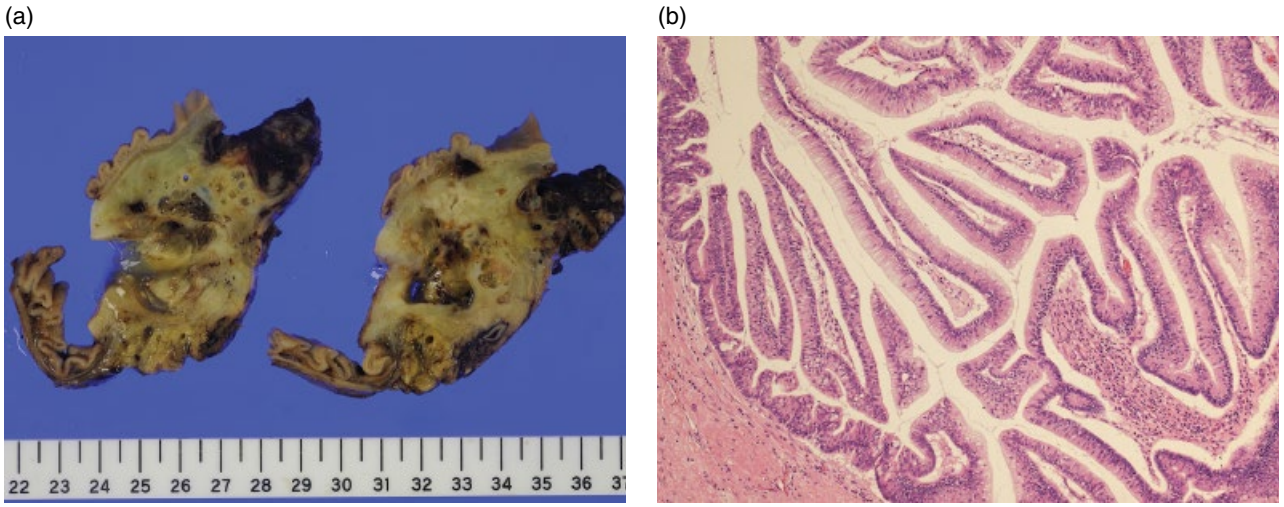

**Figure 74.3** (a) Macroscopic feature of intraductal papillary mucinous neoplasm (main-duct type). The cut surface shows intraductal papillary lesions within the dilated main pancreatic duct. (b) Histology of intraductal papillary mucinous neoplasm (intestinal type). Intestinal type IPMN shows villous projections of neoplastic epithelium.

separated from the IPMN) [17]. Although the identification of the concomitant carcinomas has biologic (GNAS mutations) and prognostic (worse prognosis) relevance, at times their correct identification can be hard to achieve. The most frequent molecular abnormalities of IPMN are either a *GNAS* or a *KRAS* mutation, and more than half IPMN have both mutations. The targeted genes found in PDAC, including *KRAS2*, *p16*/*CDKN2A*, *SMAD4*, and *TP53* genes, are found much less frequently [18,19].

The stage of the invasive carcinoma, similarly to invasive MCN, is one of the most important prognostic parameters, and should be determined following the criteria suggested by Tanaka et al. [13] and the recent recommendations of the Consensus at the Verona meeting on IPMN [20]. The UICC/AJCC staging protocol is suggested, with their subcategorization of pT1 into pT1a (<0.5 cm), pT1b (0.5–1 cm), and pT1c (>1 cm).

## Solid Pseudopapillary Neoplasm

Solid pseudopapillary neoplasm (SPN) of the pancreas is a low-grade epithelial neoplasm primarily occurring in girls and young women (20–40 years) and shows solid and cystic areas at macroscopy and pseudopapillary and poorly cohesive features at histology.

Macroscopically, SPN are frequently large, round, well-circumscribed masses and show variable proportions of solid and cystic areas filled with hemorrhagic fluid and necrotic debris (Fig. 74.4a). At the extreme ends of the spectrum of macroscopic appearances, some cases can be exclusively solid (usually the smaller lesions), whereas others (usually the larger tumors) may be entirely cystic.

Histologically, the tumors are composed of a mixture of solid and cystic areas, usually surrounded by a fibrous capsule. The tumor cells, collected in solid areas or lining pseudopapillae, are monomorphous with round to oval nuclei and eosinophilic, granular cytoplasms (Fig. 74.4b). PAS-positive globules, stromal myxoid degeneration, necrotic changes with foam cells, and hemorrhage are distinctive features of SPN. Mitotic figures are virtually absent.

The histogenesis of SPN remains unknown. The neoplastic cells show positivity for the endocrine markers CD56, NSE, and occasionally for synaptophysin, but the staining for chromogranin is always negative. Similarly, staining for acinar and ductal markers is consistently negative. Consistent positivity is present for vimentin, CD10, CD117, and progesterone receptors. Paranuclear dot-like immunostaining for CD99 is characteristic [21]. The most constant and diagnostically useful finding is the abnormal nuclear immunoexpression for β-catenin, which reflects the somatic point mutations in exon 3 of the β-catenin gene [22].

SPN are considered to be potentially malignant neoplasms, but most of the cases do not recur after complete resection of the tumor. Only 10–15% of cases progress aggressively, almost always involving the liver or the peritoneum. Even in such cases, the patients survive for many years. Only a few patients have died of a metastasizing tumor [23,24].

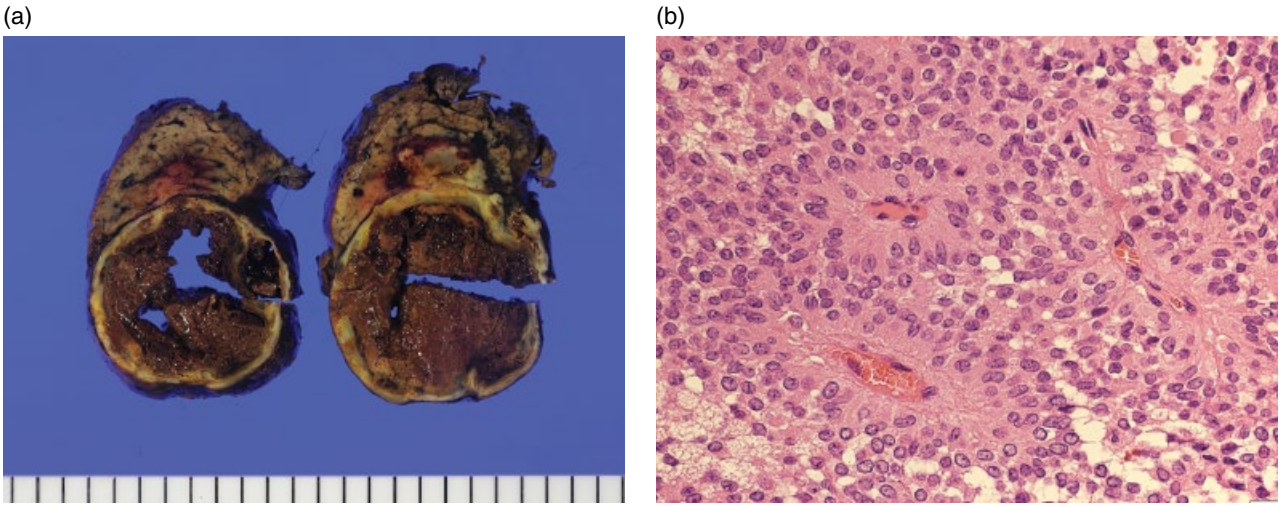

**Figure 74.4** (a) Macroscopic feature of solid pseudopapillary neoplasm. The cut surface shows round, well-circumscribed masses with hemorrhagic and degenerative material. (b) Histology of solid pseudopapillary neoplasm. Solid area of the tumor shows pseudopapillary structures composed of monomorphous cells with round to oval nuclei and eosinophilic, granular cytoplasm.

## Acinar Cell Cystadenoma

Acinar cell cystadenoma is a recently recognized cystic lesion lined by cells with acinar differentiation, and is believed to behave in a benign fashion. Many of these lesions, particularly those that diffusely involve the gland, are considered not neoplastic [25]. The lining cells of the cystic inner surface lack atypia, and transitions between the cysts and pre-existing acinar structures are often observed. Acinar cell carcinomas may rarely form intraductal papillary tumors.

## Mature Cystic Teratoma

Mature cystic teratomas, also known as dermoid cysts, are rare, benign cystic neoplasms commonly composed of multiple cell types derived from one or more of the three germ layers (ectoderm, mesoderm, and endoderm). These cystic neoplasms are filled with thick, yellow, sebaceous material. Histologically, the cysts are lined by a simple ciliated or stratified squamous epithelium and skin appendages and other tissues, such as cartilage, bone, and brain, can be seen

## Introduction

Cystic neoplasms of the pancreas can pose significant clinical challenges. Some cystic neoplasms are precursors to invasive pancreatic cancer and they therefore are concrete opportunities to save lives through early detection and early treatment [1]. Other cystic neoplasms are, however, entirely benign, and will never progress to invasive cancer. These harmless cystic neoplasms, because they can be hard to distinguish clinically from high-risk cystic lesions, present a real risk for over-treating patients [2–4].

While enhancements in imaging and years of experience have improved the pre-operative clinical classification of cystic neoplasms, currently available imaging technologies still have relatively poor sensitivity and specificity in diagnosing cyst type, and there is still enormous room for improvement [5,6]. Simply put, too many pancreatic cysts are clinically misclassified, and when they are, patients can be harmed [2,3]. Preoperative misclassification of pancreatic cysts is the result of lack of accurate classifiers compounded by the fact that sometimes a cyst of one type can radiographically mimic a different cyst type (Table 75.1). A common consequence of misclassification of a cyst is surgery. The surgical resection of a benign pancreatic cystic lesion for the reason that it clinically mimics a potentially malignant tumor is a significant clinical problem, because pancreas surgery, even at high-volume centers, is associated with significant morbidity and a 1–2% risk of operative mortality [2].

A great deal of effort has therefore gone into defining the molecular alterations underlying the development of the different pancreatic cyst types, with the hope that knowledge of these alterations may be translatable into clinical tests to determine cyst type and the need for surgery preoperatively.

All of the major cystic neoplasms of the pancreas have recently been well-characterized at the molecular level, providing insights into the fundamental processes driving these tumors, and providing tools that can be used to classify them better preoperatively (Table 75.2) [7–9]. Importantly, studies in which both the cyst fluid and tissue form the same neoplasm were available showed excellent concordance between the genetic changes present in the cyst fluid and in the tissue, suggesting that the cyst fluid can be used preoperatively to identify genetic changes present in the neoplastic cells lining cysts.

In this chapter we will review the molecular mechanisms driving each of the major types of cystic neoplasms of the pancreas, with emphasis placed on translating this new knowledge to patient care.

## Serous Cystic Neoplasm

Serous cystic neoplasms (SCNs) are cyst-forming neoplasms composed of uniform cuboidal neoplastic cells containing abundant glycogen[10]. Although SCNs are benign and most can simply be observed clinically, many SCNs are surgically resected because they cannot be distinguished clinically from potentially malignant cystic neoplasms. For example, the oligocystic variant of SCN forms large cysts, and these large cysts can clinically mimic other cystic neoplasms of the pancreas, particularly mucinous cystic neoplasms [2,10]. Similarly, the solid variants of SCN can mimic pancreatic neuroendocrine tumors.

The exomes of a series of well-characterized SCNs have been sequenced [7,11]. SCNs contain an average of 10 intragenic somatic mutations per tumor, and the *VHL* gene on chromosome 3p is mutated in ~50% of SCNs [7]. These mutations are typically inactivating mutations. In

**Table 75.1** Identification of cyst type can be problematic.

| Cyst type | Clinical characteristic | Clinical management goal | Reason for misclassification |
|---|---|---|---|
| SCN | Benign | Surveillance | Cystic SCNs mimic MCNs; solid SCNs mimic PanNETs |
| IPMN | A fraction progresses to malignancy | Surgery for high grade; surveillance for low grade | Difficult to identify the grade |
| MCN | A fraction progresses to malignancy | Surgery for malignant; surveillance for the rest | Sometimes radiographically mimic SCN; hard to decipher malignant from nonmalignant |
| SPN | Malignant | Curative surgery | Cysts associated with SPNs can radiographically mimic other types of pancreatic cystic |

IPMN, intraductal papillary mucinous neoplasm; MCN, mucinous cystic neoplasm; PanNET, pancreatic neuroendocrine tumor; SCN, serous cystic neoplasm; SPN, solid-pseudopapillary neoplasm.

addition, the neoplastic cells of SCNs also often have loss of heterozygosity (LOH) on chromosome 3p at the *VHL* locus, providing a "second hit" that inactivates gene function [7]. Germline mutations in the *VHL* gene can lead to the development of serous cystadenomas, as patients with the von Hippel Lindau syndrome often develop serous cystadenomas of the pancreas [12]. As will be discussed later in the section on clinical implications, both *VHL* gene mutations, and LOH on 3p are detectable in cyst fluid and cyst fluid analysis for these markers can therefore be used to characterize a cyst as an SCN [11].

The *VHL* gene codes for a protein, VHL, which functions in the hypoxia-induced factor (HIF) pathway [13]. The VHL protein forms a complex with other proteins, and this complex has E3 ubiquitin ligase activity, functioning in the ubiquitination and subsequent degradation of hypoxia-inducible factor alpha (HIFα) [13]. HIFα is a transcription factor that functions to control gene expression in response to cellular oxygen levels. HIFα stabilization created by the inactivating mutations in *VHL*, among other things, promotes the expression of a number of genes including vascular endothelial growth factor (VEGF) which in turn promotes angiogenesis and ultimately tumorigenesis [13].

The role of the VHL in the HIF1 pathway led Yip-Schneider and colleagues to hypothesize that vascular endothelial growth factor A (VEGF-A) levels may be elevated in SCNs [14]. They therefore determined VEGF-A levels in cyst fluid samples obtained from surgically resected pancreatic cysts [14]. VEGF levels were determined by a simple enzyme linked immunosorbent assay (ELISA) test. Although the number of cases they examined was relatively small, they found that VEGF-A levels are significantly increased in cyst fluid from SCNs compared with cyst fluid from all other types of pancreatic cysts ($P < 0.0001$). They reported that VEGF-A has 100% sensitivity and 97% specificity as a biomarker for SCN [14]. Yip-Schneider and colleagues also found that the presence of a *VHL* mutation in the neoplastic cells of an SCN correlated with elevated cyst fluid VEGF levels. These studies nicely illustrate that gene and protein markers can both be useful clinically, and how genetic changes can be used to inform protein expression studies.

MicroRNA expression has not been well-studied in SCN.

## Intraductal Papillary Mucinous Neoplasm

Intraductal papillary mucinous neoplasms (IPMNs) are distinct mucin-producing neoplasms that are usually papillary and which, by definition and name, involve the pancreatic duct system [10]. IPMNs are common in the general population, especially in the elderly [15,16]. Imaging studies suggest that ~3% of the population has an IPMN [15,16]. A small fraction of IPMNs progress to invasive carcinoma, and it can be difficult to determine clinically which IPMNs need to be resected and which can be safely followed.

Intragenic somatic mutations have been reported in a number of genes in IPMNs. These genes include *KRAS, GNAS RNF43, PIK3CA, p16/CDKN2A, SMAD4*, and *TP53* [7,9].

*KRAS* (v-Ki-ras2 Kirsten rat sarcoma viral oncogene homolog) gene mutations are present in ~80% of IPMNs [7,9]. These are almost always activating point mutations in codons 12, 13, or 61 of the *KRAS* gene. *KRAS* gene mutations activate a number of very complicated downstream pathways including the RAF (rapidly accelerated fibrosarcoma)/MAPK (mitogen activated protein kinase) and phosphoinositide 3′-kinase (PI3′K) pathways [17–19]. Activated KRAS also upregulates the GLUT-1 glucose transporter and alters the expression of enzymes involved in glucose utilization producing the so-called "Warburg effect" in the neoplastic cells [17–20]. In addition, activated KRAS signaling leads to constitutively high levels of autophagy [18]. All of these changes conspire to promote tumorigenesis.

**Table 75.2** Types of cysts with their major genetic alterations.

| | AVG # of intragenic mutations | *CTNNB1* | *GNAS* | *KRAS* | *PIK3CA* | *RNF43* | *SMAD4* | *TP53* | *VHL* |
|---|---|---|---|---|---|---|---|---|---|
| IPMN | 27 | | X | X | X | X | X (HGD) | X (HGD) | |
| MCN | 16 | | | X | X | X | X (HGD) | X (HGD) | |
| SCN | 10 | | | | | | | | X |
| SPN | 3 | X | | | | | | | |

HGD, high-grade dysplasia; IPMN, intraductal papillary mucinous neoplasm; MCN, mucinous cystic neoplasm; SCN, serous cystic neoplasm; SPN, solid-pseudopapillary neoplasm.

Activating point mutations in the *GNAS* (Guanine nucleotide binding protein (G protein), alpha stimulating activity polypeptide 1) gene, usually at codon 201 (R201C and R201H), are present in ~75 % of IPMNs [7–9]. *GNAS* mutations appear to be more common in IPMNs with "intestinal" differentiation than they are in IPMNs with "pancreatobiliary" or "gastric-foveolar" differentiation [9,21]. A *GNAS* mutation and/or a *KRAS* gene mutation are seen in >90% of IPMNs [8,9]. The *GNAS* gene codes for a protein which forms a protein complex that activates adenylate cyclase.

Several studies integrating *GNAS* and *KRAS* mutational analyses with tissue pathology have provided insight into IPMNs biology and clinical behavior. For example, IPMNs have historically been defined pathologically as lesions >1 cm, while smaller precursor lesions (<0.5 cm) are categorized pathologically as pancreatic intraepithelial neoplasia (PanIN) [22]. This leaves a large unclassified grey zone for lesions between 0.5 and 1.0 cm. PanINs have not been shown to harbor *GNAS* mutations, while IPMNs do. Matthaei and colleagues therefore examined 21 lesions in the size grey zone (0.5 cm–1.0 cm) for *KRAS* and *GNAS* mutations [23]. *GNAS* mutations were identified in seven (33%) of these lesions, helping to define them as small ("incipient") IPMNs rather than large PanIN lesions [23]. As a result the new pathologic classification system for precursor lesions in the pancreas now includes the new term "incipient IPMN" for lesions ≤1.0 cm with histologic or genetic features of a larger IPMN [24]. Matthaei and colleagues also used *KRAS* gene mutational and LOH analyses to establish that grossly multifocal IPMNs are, in some cases, genetically multiclonal, too [25].

The *PIK3CA* (phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit alpha) gene codes for a protein that forms the catalytic subunit of the phosphatidylinositol 3-kinase (PI3K) enzyme. This enzyme activates a number of downstream functions that in turn promote cell proliferation and migration, and ultimately cell survival and tumorigenesis. *PIK3CA* gene mutations have been reported in 10% of IPMNs [9]. These mutations are, as was true for *GNAS* mutations, more common in IPMNs with intestinal differentiation.

Inactivating mutations in the *RNF43* gene are present in 30–70% of IPMNs [7,9]. The *RNF43* gene codes for a ubiquitin ligase protein that functions in the Wnt/β-catenin signaling pathway [26,27]. As will be discussed later in this chapter, the presence of genetic alterations of the *RNF43* gene in some IPMNs suggests that Wnt/β-catenin signaling is a potential therapeutic target for invasive carcinomas that arise from *RNF43* mutant IPMNs [26,28].

*SMAD4*, *p16/CDKN2A*, and *TP53* are all tumor suppressor genes that have been reported to be inactivated in IPMN [7,9]. The *p16/CDKN2A* gene, which encodes CDKN2A, an important regulator of the cell cycle, is inactivated by intragenic mutation, usually a deletion or an indel, of one allele coupled with LOH of the second allele in 10–30% of IPMNs, and in additional cases by hypermethylation of the gene's promoter [7,9,29]. Mutations in this gene can be seen in IPMNs with both low- and high-grade dysplasia. By contrast, *SMAD4* and *TP53* inactivation appear to be late genetic events, and are found in IPMNs with high-grade dysplasia and in invasive carcinomas that arose in association with an IPMN [7,9].

Studies of the genetic alterations present in the noninvasive and invasive components of IPMNs have shown that the invasive and noninvasive components virtually always harbor identical mutations [7,9]. This finding helps establish that invasive carcinomas can arise from IPMNs (they are not chance coincidental lesions).

The expression of a number of microRNAs is dysregulated in IPMN. These microRNAs may have important biologic functions in the neoplasms, and some may be useful clinical markers [30–34]. For example, Matthaei and colleagues compared the expression of 750 microRNAs in a series of microdissected IPMNs to their expression in normal ductal epithelium and identified a panel of microRNAs that have the potential of being used to distinguish IPMNs with low-grade dysplasia from IPMNs with high-grade dysplasia [30]. Similarly, Caponi and colleagues found that miR-21 and miR-155 are upregulated in IPMNs with an associated invasive carcinoma, as compared with IPMNs without an invasive carcinoma, and, conversely that miR-101 levels are higher in IPMNs without an invasive component than in IPMNs with an invasive component [34]. Going a step further, Matthaei and colleagues also identified a panel of microRNAs that could help distinguish IPMNs from other types of cysts in the pancreas [30]. Of note, microRNAs can be identified in cyst fluid samples, suggesting that quantifying microRNA levels in cyst fluid aspirated at the time of endoscopy could be used to improve the clinical classification of pancreatic cysts [30,32].

A number of alterations in protein and glycoprotein expression have also been reported in IPMNs [35–40]. As is true for microRNAs, several proteins and glycoproteins are differentially expressed in IPMNs with low-grade as compared to IPMNs high-grade dysplasia, and most are detectable in cyst fluids [35–37]. Pandey and colleagues have established a useful on-line resource that summarizes many of proteins whose expression is altered in invasive pancreatic cancer, and the expression of many of these proteins is also altered in IPMNs [38].

## Mucinous Cystic Neoplasm

Mucinous cystic neoplasms are mucin-producing and cyst-forming neoplasms that contain a characteristic ovarian-type stroma [10]. In contrast to IPMNs, the cysts of MCNs almost never communicate with the main duct system of the pancreas [10]. As is true for IPMNs, only a fraction of MCNs progress to invasive carcinoma.

Many of the genes targeted in IPMNs are also targeted in MCNs [7]. These genes include *KRAS*, *RNF43*, *PIK3CA*, *p16/CDKN2A*, *SMAD4*, and *TP53* [7,41]. The major difference is that, in contrast to IPMN, the *GNAS* gene is rarely, if ever, targeted in MCNs. The function of these genes is described in detail earlier in the section on IPMNs.

Just as the genetic alterations found in IPMNs have proven useful, so too have a number of groups attempted to use the genetic alterations in MCNs clinically. As noted earlier, oligocystic serous cystadenomas can mimic MCNs, and, as a result, some benign serous cystic neoplasms are surgically resected [10]. There is therefore a great clinical need to distinguish between these two entities. The initial clinical results using molecular approaches to distinguish between serous cystic neoplasms and MCNs are not as promising as they are with IPMNs [42]. For example, Singhi and colleagues tested 546 pancreatic cyst fluid samples obtained by fine-needle aspiration at the time of endoscopic ultrasound (EUS) for *KRAS* gene mutations and found that although *KRAS* mutations had a specificity of 100% and a sensitivity of 54% for mucinous differentiation (IPMNs and MCNs), the sensitivity was only 14% when limited to MCNs [42]. However, with improvements in methodology, addition of more genes, and new algorithms the sensitivity of detecting MCNs has increased significantly [7,11].

The patterns of microRNA expression in MCNs have been studied, and as is true for the genetic mutations, there is some overlap with IPMNs [32]. For example, mir-21 is elevated in MCNs [32].

## Solid-Pseudopapillary Neoplasm

Solid-pseudopapillary neoplasms are epithelial neoplasms composed of poorly cohesive, relatively uniform, neoplastic cells [10]. Although all SPNs are now classified as malignant, the vast majority(~90%) of patients with an SPN can be cured with surgical resection [10].

The exomes of a series of well-characterized SPNs have been sequenced, and, quite remarkably, virtually all SPNs harbor a *CTTNB1* (β-catenin) gene mutation, and practically no other genetic alterations [7,43,44]. The *CTTNB1* mutations observed prevent the degradation of the β-catenin protein, which is then translocated from the cytoplasm to the nucleus. In the nucleus β-catenin functions to activate the Wnt (int/Wingless) signaling pathway which in turn mediates gene expression through the lymphoid enhancer-binding factor 1 (LEF1)/T-cell factor transcription complex [45]. Indeed, Singhi and colleagues have shown that *CTTNB1* gene mutations strongly correlate with LEF1 nuclear overexpression in SPNs [45].

Of interest, SPNs are also characterized by alterations in e-cadherin expression, including loss of expression of the extracellular domain of the e-cadherin protein [46,47]. Recently Huels and colleagues have suggested that reduced e-cadherin expression has a synergistic effect with activating mutations in β-catenin in promoting tumorigenesis [48].

Little is known of the changes in microRNA and protein expression in SPNs [49–51]. In large part this is because the normal cell type that corresponds to the neoplastic cells of SPNs is not well defined. Therefore, expression studies are challenged by the absence of a good control tissue/normal cell type. Several immunohistochemical labeling studies using a candidate marker approach have shown that CD99 and CD10 are overexpressed in SPNs, that the β-catenin protein is abnormally localized to the nucleus, and that e-cadherin expression is lost (when antibodies to the extracellular domain are used) or abnormally localized to the nucleus (when antibodies to the intracellular domain are used) [52,53].

## Other Cystic Neoplasms of the Pancreas

For completeness sake we should mention that some typically solid neoplasms of the pancreas can present as cystic masses. For example, pancreatic neuroendocrine tumors (PanNETs) can be cystic, as can some ductal adenocarcinomas [10]. These cystic variants appear to have the same molecular alterations as the solid variants of these same tumors.

## Clinical Applications

Several clinical applications of our growing knowledge of the molecular events that drive the formation of cystic neoplasms of the pancreas have been mentioned earlier, and in this section we focus on what we believe to be the most promising clinical applications close on the horizon.

First, the genes mutated in IPMNs can be used clinically to distinguish IPMNs from other neoplasms, and in so doing prevent unnecessary surgeries [7,8]. For example, as noted earlier, serous cystic neoplasms virtually never harbor *KRAS* or *GNAS* mutations, while one or both of

these mutations is seen in 90–95% of IPMNs [11]. Since mutant DNA present in neoplastic cells is shed into the cyst fluid, endoscopic ultrasound (EUS) aspiration of cyst fluid coupled with sequencing of the fluid for *KRAS* or *GNAS* mutations can be used to distinguish serous cystadenomas from IPMNs [11,42]. Furthermore, the cysts of IPMNs communicate with the pancreatic duct system, suggesting that a similar approach can be taken with sequencing secretin-stimulated pancreatic secretions ("juice") obtained in the duodenum at the time of endoscopy [54,55]. It is hoped that additional markers, such as *SMAD4* and *TP53* gene mutations and patterns of LOH, will be useful in distinguishing IPMNs with low-grade dysplasia from IPMNs with high-grade dysplasia [11].

Second, some of the molecular alterations present in cystic neoplasms that progress to invasive carcinoma are potentially therapeutically targetable. As mentioned previously, a significant fraction of IPMNs and MCNs harbor *RNF43* gene mutations that are predicted to activate the Wnt signaling pathway [7,26,56]. A number of new agents, including selective inhibitors of the porcupine protein in the Wnt pathway, are being developed that could be effective in treating invasive pancreatic cancers that have *RNF43* mutations because they arose from a precursor IPMN with an *RNF43* mutation [26].

The *PIK3CA* gene functions in the mTOR pathway and *PIK3CA* is targeted in ~10% of IPMNs [9]. A number of agents targeting PIK3CA have been developed, and again, these agents could be effective in treating invasive pancreatic cancers that have *PIK3CA* gene mutations because they arose from an IPMN precursor with a *PIK3CA* gene mutation.

## Implications for Families

Several familial cancer syndromes are associated with an increased risk of developing a pancreatic cystic neoplasm. Perhaps the greatest risk is seen in patients with the Peutz–Jeghers syndrome (PJS) [57]. Patients with PJS have a 130-fold increased risk of developing invasive pancreatic cancer, and Su and colleagues have demonstrated that some of these invasive cancers arise from noninvasive IPMN precursor lesions [58]. This suggests that patients with PJS may benefit from screening for early curable pancreatic neoplasms (noninvasive IPMNs) [59–61].

Although not strictly a "familial genetic syndrome," the McCune-Albright syndrome is caused by *GNAS* mutations acquired very early during embryogenesis [62,63]. Affected individuals harbor mosaic *GNAS* mutations, and ~15% of individuals with the McCune-Albright syndrome, in addition to the characteristic skin and bone changes, develop IPMNs, some of which progress to invasive carcinoma [62,63]. Of note, Parvanescu and colleagues screened 272 patients operated on for an apparently sporadic IPMNs and found a patient with polyostotic fibrous dysplasia and café au lait spots suggestive of McCune-Albright syndrome [62].

Finally, as noted earlier, germline *VHL* gene mutations cause the von Hippel–Lindau syndrome (VHL), and patients with VHL frequently develop serous cystadenomas of their pancreas [12]. Fortunately, these are virtually always benign.

## Conclusions

It is clear that there is a clinical need to better classify cysts preoperatively. Current guidelines do not appear to be adequate [64]. Molecular analyses of cystic neoplasms of the pancreas have helped validate the existing histologic classification of these cysts, and have provided new opportunities to improve the clinical management of patients with a cystic tumor of the pancreas.

# Clinical Presentation of Cystic Neoplasms

*Susumu Hijioka, Kazuo Hara, Nobumasa Mizuno, Nozomi Okuno, and Kenji Yamao*

*Department of Gastroenterology, Aichi Cancer Center Hospital, Aichi, Japan*

## Introduction

Pancreatic cystic neoplasms comprise intraductal papillary mucinous neoplasms (IPMN), mucinous cystic neoplasms (MCN), serous cystic neoplasms (SCN), lymphoepithelial cysts, epidermoid cysts, and the cystic degeneration of solid tumors including solid-pseudopapillary neoplasms (SPN) and cystic pancreatic neuroendocrine neoplasms (cystic PanNET) [1,2]. The varied clinical manifestations of cystic neoplasms of the pancreas are important to recognize for several reasons. First, the clinical manifestations can be nonspecific, and if clinicians are not familiar with them, the symptoms caused by a clinically important cystic neoplasm can be misinterpreted as secondary to a benign etiology such as back strain. Second, the clinical manifestations of a cystic lesion in the pancreas can provide a clue as to the type of cyst. For example, some clinical manifestations such as those of pancreatitis, suggest the diagnosis of an IPMN over an SCN. Finally, some clinical manifestations, such as jaundice, are suggestive of an associated invasive carcinoma, and can help guide the management of a cystic lesion in the pancreas [3]. Therefore, accurate diagnosis is imperative as management is guided by symptoms and risk of malignancy. Here, we describe the clinical presentation of PCN.

## Classification

Fig. 76.1 shows a general classification of pancreatic cystic neoplasms. True cysts can be neoplastic or nonneoplastic. Neoplastic true cysts include SCN, MCN, and IPMN. Nonneoplastic cysts comprise cystic fibrosis, as well as retention, lymphoepithelial, and epidermoid cysts. Cystic degeneration of solid tumors, including cystic PanNET and SPN, can also produce cystic lesions, as can nonneoplastic pseudocysts.

Typical patient characteristics are shown in Table 76.1.

## General Clinical Presentation of Pancreatic Cysts

Most pancreatic cysts are asymptomatic, and the cysts are discovered incidentally on imaging for another indication. The symptoms of pancreatic cysts mainly depend on their size. Larger pancreatic cysts can cause abdominal discomfort (abdominal/back pain, loss of appetite, nausea, and vomiting). Pancreatic pseudocysts should be considered in patients with chronic pancreatitis and when a patient has persistent abdominal pain after an episode of acute pancreatitis. If pancreatic cysts, such as IPMN, communicate to the pancreatic duct, pancreatitis can be seen due to mucin or bleeding inside the cyst. If the pancreatic cyst has an associated invasive carcinoma, and begins to invade the surrounding tissues, it may lead to the same symptom as pancreatic ductal cancer.

## Clinical Presentation and Characteristics of Serous Cystic Neoplasms

Serous cystadenomas (SCA) account for about 16% of resected cystic tumors of the pancreas [3]. Four-fifths of SCN are asymptomatic and are found incidentally. Even when symptomatic, the symptoms are mostly vague and nonspecific nausea, abdominal discomfort, and weight loss. These symptoms are caused by mass effects or compression of the main pancreatic duct, resulting in

| Age | 50–70 | 40–60 | 50–70 |
| Gender | Male > Female | Female | Female > Male |
| Location | Head > Body/tail<br>Multifocal | Body/tail | Body/tail > Head |
| Symptom | Yes<br>Acute pancreatitis | Size dependent (mass effect) | Size dependent (mass effect) |
| Malignant potential | Yes | Yes | No (rare) |

obstructive pancreatitis. Clinical symptoms are observed more commonly in large(>4 cm) compared to smaller (<4 cm) SCN (72% vs.22%, $P < 0.001$) [4]. Jaundice is rarely seen in patients with an SCN, but may occur when an SCN located in the head of the pancreas has enlarged and occluded the common bile duct.

SCN occur in 35–75% of patients with von Hippel–Lindau(VHL) disease, and in these patients SCN are often multifocal and can diffusely involve the pancreatic gland [5]. Pancreatic cysts can be the first manifestation of VHL.

On imaging, the typical SCN is composed of many tiny microcysts with a honeycomb appearance lined by a cuboidal, glycogen-rich epithelium. Microcystic SCN typically appear on CT and MRI as isolated, lobulated multilocular lesions with well-defined margins in clusters of (usually >6) small cysts separated by a thin septum [6]. Each small cyst is usually <2 cm. Microcysts can occasionally appear as a solid mass on CT, but high signal intensity is evident on T2-weighted MRI. Microcyst structures can be further defined using endoscopic ultrasound (EUS). The septa are usually thin, and typical microcystic SCN have a calcified central fibrotic scar [7,8]. The macrocystic type of SCN without a microcystic component requires differentiation from MCN, or branch-type IPMN.

## Clinical Presentation and Characteristics of Mucinous Cystic Neoplasms

Mucinous cystic neoplasms (MCN) are relatively uncommon neoplasms that comprise about 25% of all resected cystic neoplasms of the pancreas [3]. MCN arise in the distal pancreas (>95%) almost exclusively (>95%) in women with a peak incidence in the fifth decade [7]. In a Japanese multicenter study, only 1 of 156 patients with MCN had the tumor in the head of the pancreas, and the median age of diagnosis was between 45 and 48 (range, 16–84) years [8]. Unlike branch duct (BD)-IPMN, MCN are almost always solitary lesions [3]. They are often large, measuring 8–10 cm, but rare examples can be as large as 25 cm [9–11].

Most patients present either incidentally or with vague symptoms, and the clinical presentation depends on tumor size. Symptoms include a palpable mass in the upper abdomen reported 12% with MCN patients [3], and rarely general fatigue and weight loss. Ten (6.5%) of 153 patients in one series presented with acute pancreatitis. In patients with MCN, the presence of clinical symptoms (especially back pain, jaundice, or systemic

manifestations) should increase the suspicion for underlying associated invasive carcinoma [12]. Communication with the main pancreatic duct is very rare in MCN.

Sperti et al. [13] reported two patients with MCN whose first presentation was an acute attack of pancreatitis and pointed out the possibility of misdiagnosing MCN as a pseudocyst in such patients. MCN should be considered when acute pancreatitis has occurred in nonalcoholic women with no gallstones and has resulted in a cyst formation in the body and tail of the pancreas.

## Clinical Presentation and Characteristics of Intraductal Papillary Mucous Neoplasms

IPMN of the pancreas represent 60% of cystic pancreatic lesions and occur more frequently in elderly men [5]. They are classified as main-duct (MD-IPMN), or BD-IPMN arising from branches, or as mixed IPMN arising in both the main duct and side branches.

Of all the cystic neoplasms of the pancreas, IPMN most commonly produce clinical manifestations. Main-duct IPMN are more often symptomatic than are branch-duct IPMN. Some IPMN, especially those of the main duct, can produce copious amounts of mucin. This mucin may occlude the pancreatic duct, causing acute pancreatitis manifested as epigastric discomfort, episodes of severe pain, and hyperamylasemia. These symptoms can recur repeatedly for many years, but they become less frequent with time because of loosening of the papillary orifice caused by repeated passage of mucin, and as the pancreas itself atrophies from the damage caused by the repeated episodes of pancreatitis. Approximately 25% of patients reportedly have had symptoms of pancreatitis. The presence of symptoms is an independent risk factor for malignancy in multivariate analysis assessing the relationship between clinical features and malignancy [9,14,15].

## Clinical Presentation and Characteristics of Solid-Pseudopapillary Neoplasms

SPN are uncommon cystic lesions of the pancreas, accounting for <4% of resected pancreatic cystic lesions [3]. SPN are much more common in women than in men (>80%) and most occur in the third or fourth decades of life [16]. SPN can occur throughout the pancreas but usually occur in the pancreatic body or tail, and usually present with nonspecific symptoms such as abdominal discomfort, increased abdominal girth, and poor appetite and nausea from tumor compression of adjacent organs [16]. With the increased use of abdominal imaging, more and more SPN are being discovered incidentally [3]. In a recent systematic review of SPN, the most common presenting symptom was abdominal pain or discomfort, which was present in 65% patients. Patients also presented with a palpable abdominal mass, nausea or vomiting, and weight loss. Pancreatitis and jaundice were relatively rare, occurring in 5.0% and 10.3% of patients, respectively. Almost 40% of the patients were asymptomatic. In rare cases, the SPN can rupture producing an acute abdomen.

## Clinical Presentation and Characteristics of Cystic Pancreatic Neuroendocrine Neoplasms

Cystic pancreatic neuroendocrine neoplasms (CPanNET) account for approximately 8% of resected PCN [3,11] and 10–15% of resected pancreatic neuroendocrine tumors [3,11]. Most are found incidentally and are nonfunctioning. They occur equally in men and women, are usually diagnosed between 60 and 70 years of age [3], and are more prevalent in the body and tail of the pancreas [17]. CPanNET are more common in patients with multiple endocrine neoplasia type 1 (MEN-1), with one study finding MEN-1 to be 3.5 times more likely in CPanNET than in solid tumors [18].

## Introduction

Pancreatic cysts are incidentally detected in 2.6% of computed tomography (CT) and 3–13% of magnetic resonance imaging (MRI) studies [1,2]. Pancreatic cysts represent a range of etiologies from benign cysts such as pseudocysts or serous cystadenomas, those with the potential for progressing to invasive carcinoma (IC), such as intraductal papillary neoplasms (IPMN), and mucinous cystic neoplasms (MCN), as well as those that are by definition malignant, including solid-pseudopapillary neoplasms (SPN) and cystic degeneration of a neuroendocrine tumor (NET). The four most common types of pancreatic cysts seen are pseudocysts, IPMNs, MCNs, and serous cystadenomas (SCAs), which account for over 90% of pancreatic cysts seen [3].

Imaging plays two critical roles. First to identify the type of cyst, and second to identify features associated with the presence of high-grade dysplasia (HGD) or invasive carcinoma (IC) in patients with IPMNs and MCNs, in whom surgical resection should be considered [4]. In this chapter, we review the imaging features of different types of pancreatic cysts using CT, MRI, and endoscopic ultrasound (EUS).

## Low-Risk Pancreatic Cysts

### Pseudocyst

Pancreatic pseudocysts are inflammatory collections related to trauma, acute or chronic pancreatitis. They are well defined, and found either within, or adjacent to the pancreas, and can be single or multiple. Initially the wall is thin but may thicken as the pseudocyst matures. Pseudocysts appear as low-attenuation fluid collection on CT. On T1 weighted (T1W) images, they have a hypointense center, with an enhancing wall. Blood products, necrotic or proteinaceous debris are commonly present in postnecrotic collections associated with necrotizing pancreatitis (walled-off pancreatic necrosis) and are seen as areas of increased signal on T1W images [5]. On T2 weighted (T2W) images pseudocysts appear hyperintense due to their fluid content. Similarly areas of decreased signal may be seen in postnecrotic collections or walled-off pancreatic necrosis due to the presence of debris [5]. In acute pancreatitis, peripancreatic fluid and stranding may be present, which correlates with the degree of inflammation present on the T2W fat-suppressed images [6]. On EUS, they appear as a well-defined, anechoic lesion. The wall may appear thickened, and debris can appear as irregular, echogenic material within the cyst (Fig. 77.1). Differentiating pseudocysts from IPMNs can occasionally be difficult, as highlighted by surgical series in which pseudocysts account for between 3–6% of resected cases, and cyst fluid analysis can be helpful in these cases [3,7]. A very low cyst fluid amylase of <250 U/L excludes 98% of pseudocysts [8]. A CEA of <5 ng/mL has a high specificity (98%), but low sensitivity (50%) for a pseudocyst [8].

### Serous Cystadenoma

SCAs are typically unifocal lesions, and can occur in any location in the pancreas. The exception to this rule is von Hippel–Lindau disease, in which multiple SCAs occur. Two-thirds occur in women, with a median age of presentation of 58 years [9]. They carry an exceptionally small risk (0.1%) of transformation into a cystadenocarcinoma [9]. Thus, differentiating these

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

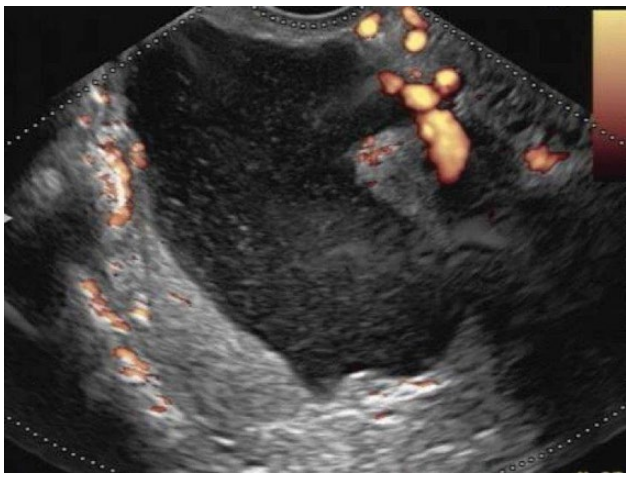

**Figure 77.1** Pseudocyst. The features of a well-defined pseudocyst seen on EUS, with hyperechoic material within the cyst consistent with debris. *Source:* Copyright AML, by permission of the author.

very low-risk cysts from other types of neoplastic cysts is extremely important for appropriate clinical management. Classical teaching is that SCAs have a non-dilated main pancreatic duct, which does not communicate with the cyst. However, 10% of pathologically proven SCAs had evidence of communication on ERCP on preoperative imaging, while main-duct dilation is found in between 11–50%, and a stricture identified in 37.5% [9,10]. The presence of a central scar, with or without calcification, is found in between 11–30% of SCAs and is very specific [10]. A microcystic, or honeycomb, appearance is found in 45–58% of SCAs, 32–35% have a macrocystic, 18–28% a mixed macro- or microcystic appearance, and 5–6% have a solid appearance (Fig. 77.2a–d) [9,10]. On CT, the most common appearance is a conglomeration of small cysts that are greater than six in number, measure up to 2 cm and may exhibit a central scar with or without calcification [11]. On MRI they have a low intensity on T1W

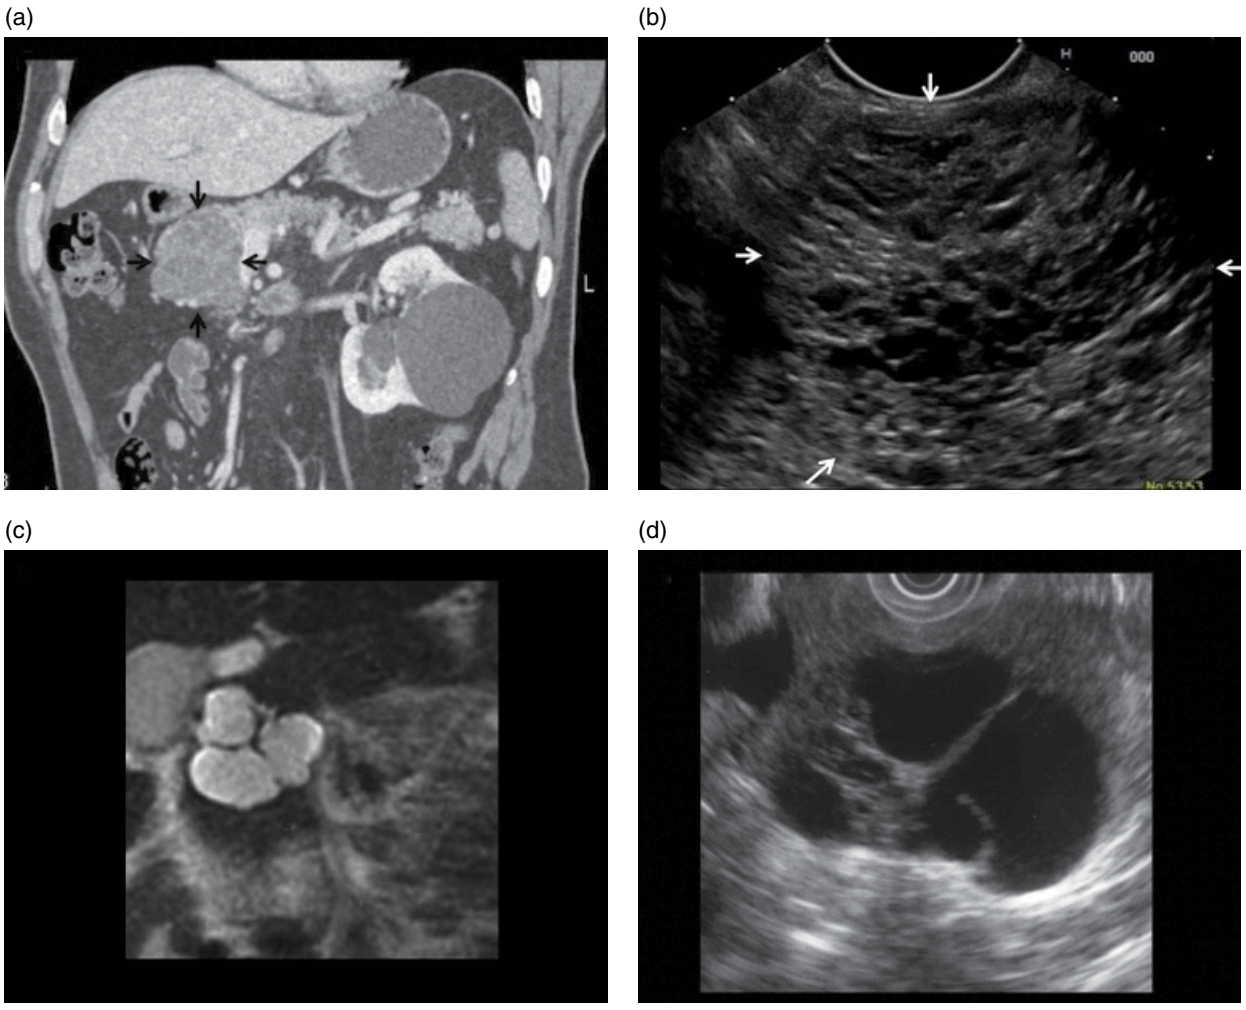

**Figure 77.2** Serous cyst. Serous cysts (arrows) have a range of appearances including microcystic (a,b), macrocystic (c), mixed macro and microcystic (d). They can occasionally have a solid appearance (e,f). In these cases MRI/MRCP is helpful in confirming the cystic, rather than solid nature of the cyst (g). *Source:* (a,b) Copyright AML, by permission of the author.

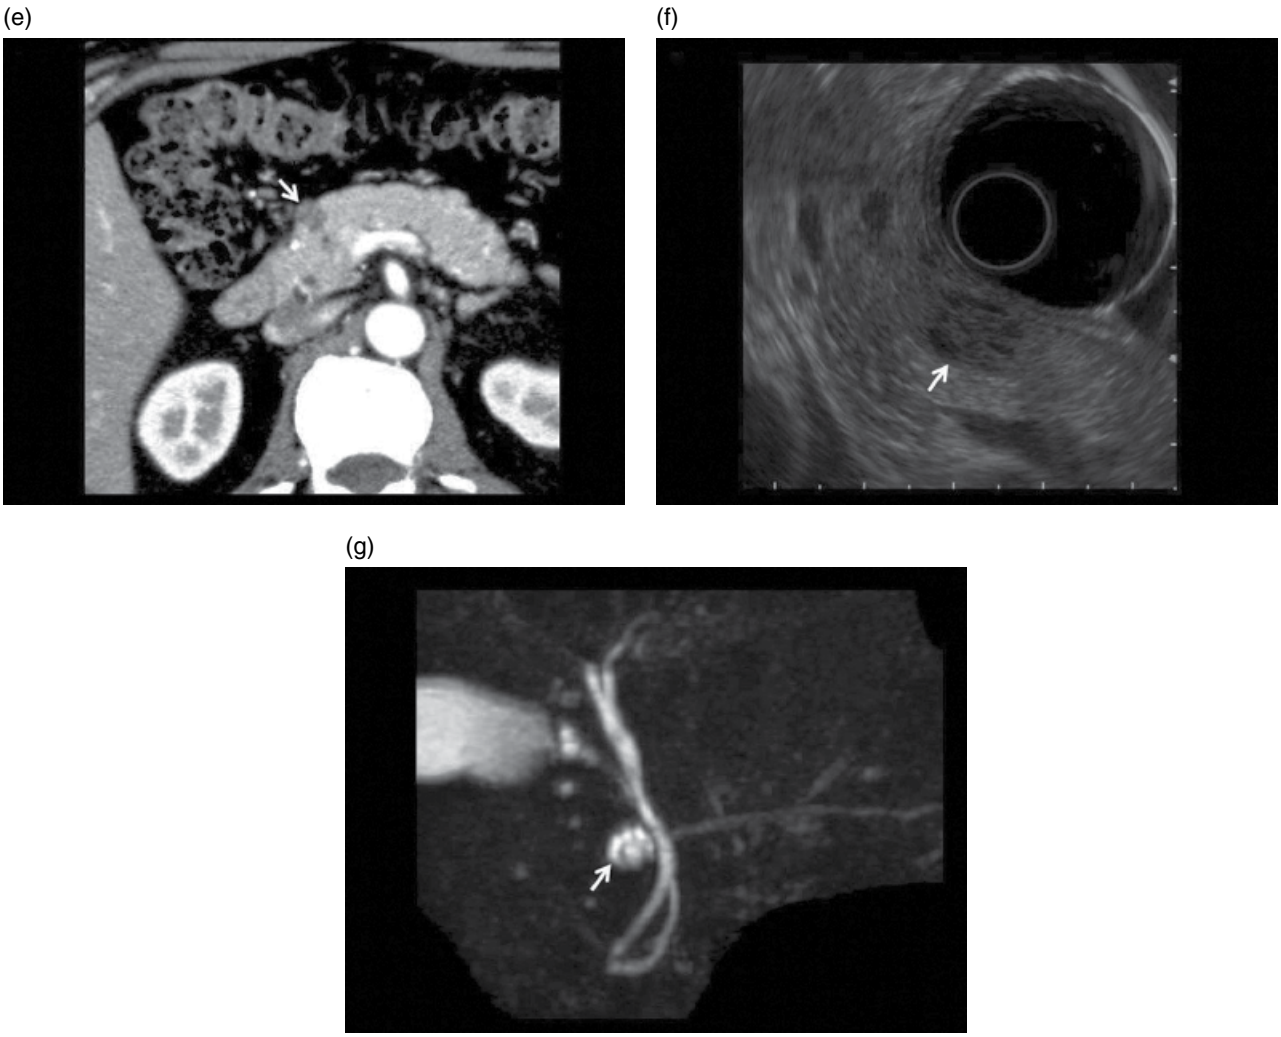

**Figure 77.2** (Continued)

imaging, high signal on T2W imaging, with enhancement of the septations on contrast-enhanced T1W imaging with or without a central scar. In solid appearing SCA, MRI and magnetic resonance cholangiopancreatography (MRCP) are useful for confirming the cystic, rather than solid nature of the cyst (Fig. 77.2g). EUS can be useful in these cases in which classic imaging features are absent. It is superior for identifying a classic microcystic appearance to either CT or MRI [10], while the vascular nature of SCAs is often seen with Doppler, or with contrast-enhanced EUS. A very low cyst fluid CEA, of <5 ng/mL, has 95% specificity, and 50% sensitivity for a SCA [8]. Almost 70% of SCA harbor a mutation in the Von–Hippel Lindau (*VHL*) gene or loss of heterozygosity (LOH) of chromosome 3 where the *VHL* gene is located. The presence of either of these findings, and the absence of mutations in *GNAS*, *KRAS*, or *RNF43* has 100% sensitivity and 91% specificity for a SCA [12].

## Lymphoepithelial Cyst

Lymphoepithelial cysts are rare, benign pancreatic cysts, which occur predominantly in middle-aged men (82%), with a mean age of presentation of 55 years [13]. They are single cysts, with almost 70% found adjacent, or outside of the pancreas [14]. Sixty percent are multilocular. The main pancreatic duct is normal, and unlike IPMNs or pseudocysts, there is no communication between the cysts and the duct. Lymphoepithelial cysts typically have a mixed solid and cystic appearance, with a purely cystic or mainly solid lesion occurring in only 14% and 16% of cases, respectively (Fig. 77.3a,b) [13]. Lymphoepithelial cysts are low-attenuation cystic lesions on CT. On MRI, they may be hyperintense on T1W imaging, and heterogeneous on T2W imaging due to the presence of fluid (high signal) and high keratin content (low signal) [13]. These features are not classically seen in other cysts and may be helpful in identifying these lesions [13]. On EUS

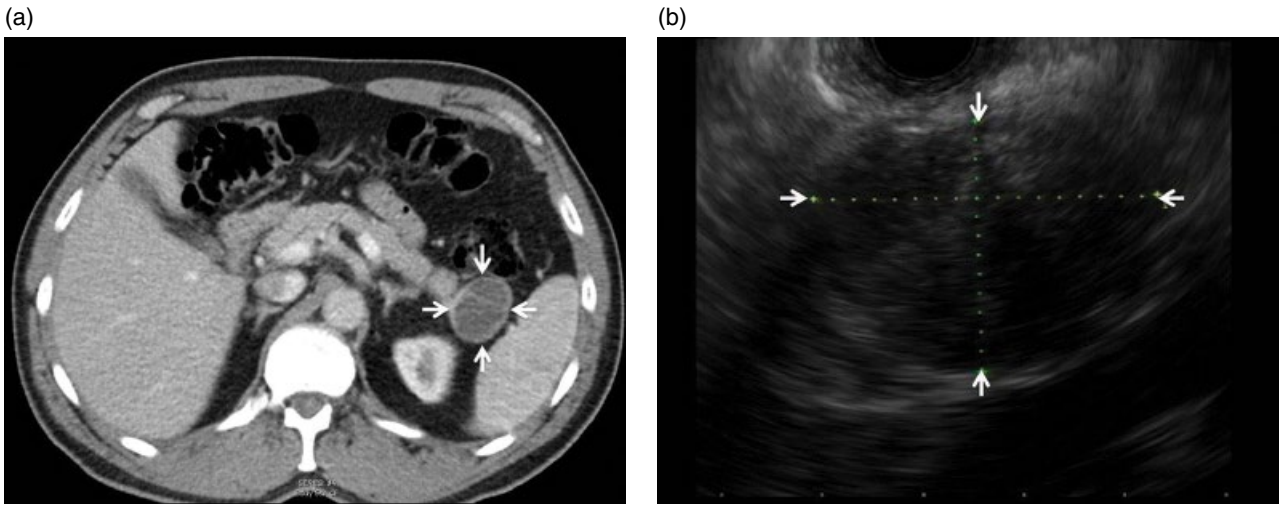

**Figure 77.3** Lymphoepithelial cyst. The CT (a) and EUS (b) appearance. *Source:* Copyright AML, by permission of the author.

they are a solid-appearing, hypoechoic, heterogeneous lesion with posterior acoustic enhancement and may have evidence of debris within the cyst [14]. Cytology can be useful and identified 22% of lymphoepithelial cysts in a large series of 117 patients [13]. Cyst fluid CEA is >192 ng/mL in a third of patients [13].

## Pancreatic Cysts with Malignant Potential

### Mucinous Cystic Neoplasm

Mucinous cystic neoplasms (MCNs) are unifocal lesions, which occur almost exclusively in women (20:1 ratio), with a mean age of presentation of 53 years [15]. Just over 90% of MCNs are located in the body or tail of the pancreas. Although MCNs do not involve the main pancreatic duct, abnormalities can be found. Main pancreatic duct dilation is found in 17% of MCNs, which increases to 43% in the presence of HGD/IC. The absence of communication between the cyst and the main pancreatic duct is a classic feature used to differentiate a MCN from an IPMN; however, a study of 156 MCNs found communication between the MCN and the pancreatic duct in 18% of cases [16]. Almost 40% of MCNs are multilocular, and may have slightly thickened septations. The classic appearance of a MCN is a thickened wall, which enhances on contrast-enhanced CT and MR imaging. This thick wall, or capsule, often has a "cyst within a cyst" appearance, which resembles an orange on CT or MRI (Fig. 77.4a,b). On EUS the cyst is unilocular with the "cyst within a cyst" seen within the wall (Fig. 77.4c). Calcification is located at the edge of the cyst creating an "eggshell" type appearance (Fig. 77.4d,e). In large surgical series between 15–25% of MCNs have a mural nodule, increasing to 54–100% in MCNs with HGD/IC [16,17]. This is seen on CT and MRI as intracystic enhancing soft tissue, or a hypoechoic, irregular area on EUS (Fig. 77.4f). Cyst fluid CEA (>192 ng/mL) and amylase are elevated. *KRAS* mutations are present in 50% of MCNs [12].

### Intraductal Papillary Mucinous Neoplasm

IPMNs can involve the main pancreatic duct (MD-IPMN), branch-duct (BD-IPMN), or both, in which case it is termed a mixed-type IPMN (Fig. 77.5a–c). This classification is important, as it determines the risk of malignant transformation, and the management of patients with IPMNs. IPMNs have an equal distribution in men and women, with a median age of presentation of 66 years [18]. They have a slight preponderance for the head of the pancreas, but can occur anywhere. Just over a third of individuals with IPMNs will have multifocal cysts [18]. One of the classic features used to identify BD-IPMNs from other types of cysts is the presence of communication between the IPMN and the main pancreatic duct (Fig. 77.5b). This is best assessed with either MRI or EUS, which have a 100% and 89% sensitivity, respectively [19]. MRCP with secretin has been shown to improve the detection of ductal communication in some, but not all, studies. Cysts are usually well defined, with thin walls, can be unilocular or multilocular, and calcification is rarely present. Main-duct involvement, which occurs in MD-IPMN or a mixed IPMN, is defined as focal or diffuse dilation of the main pancreatic duct to >5 mm. On endoscopy a gaping "fish-mouth" papilla extruding mucus is occasionally seen.

IPMNs have the potential to progress to HGD or IC. There are a number of imaging features that are

**Figure 77.4** MCN. Classic "cyst within a cyst" appearance of a MCN on CT and MRI (a,b). On EUS the cyst is unilocular, with the "cyst within the cyst" seen in the wall (c, arrow). A classic appearance of a MCN (a) with calcification at the edge (d, arrowheads). The EUS appearance showing calcification at the edge (e, arrowhead) with a thickened, irregular wall (f, arrowheads). *Source:* (c–f) Copyright AML, by permission of the author.

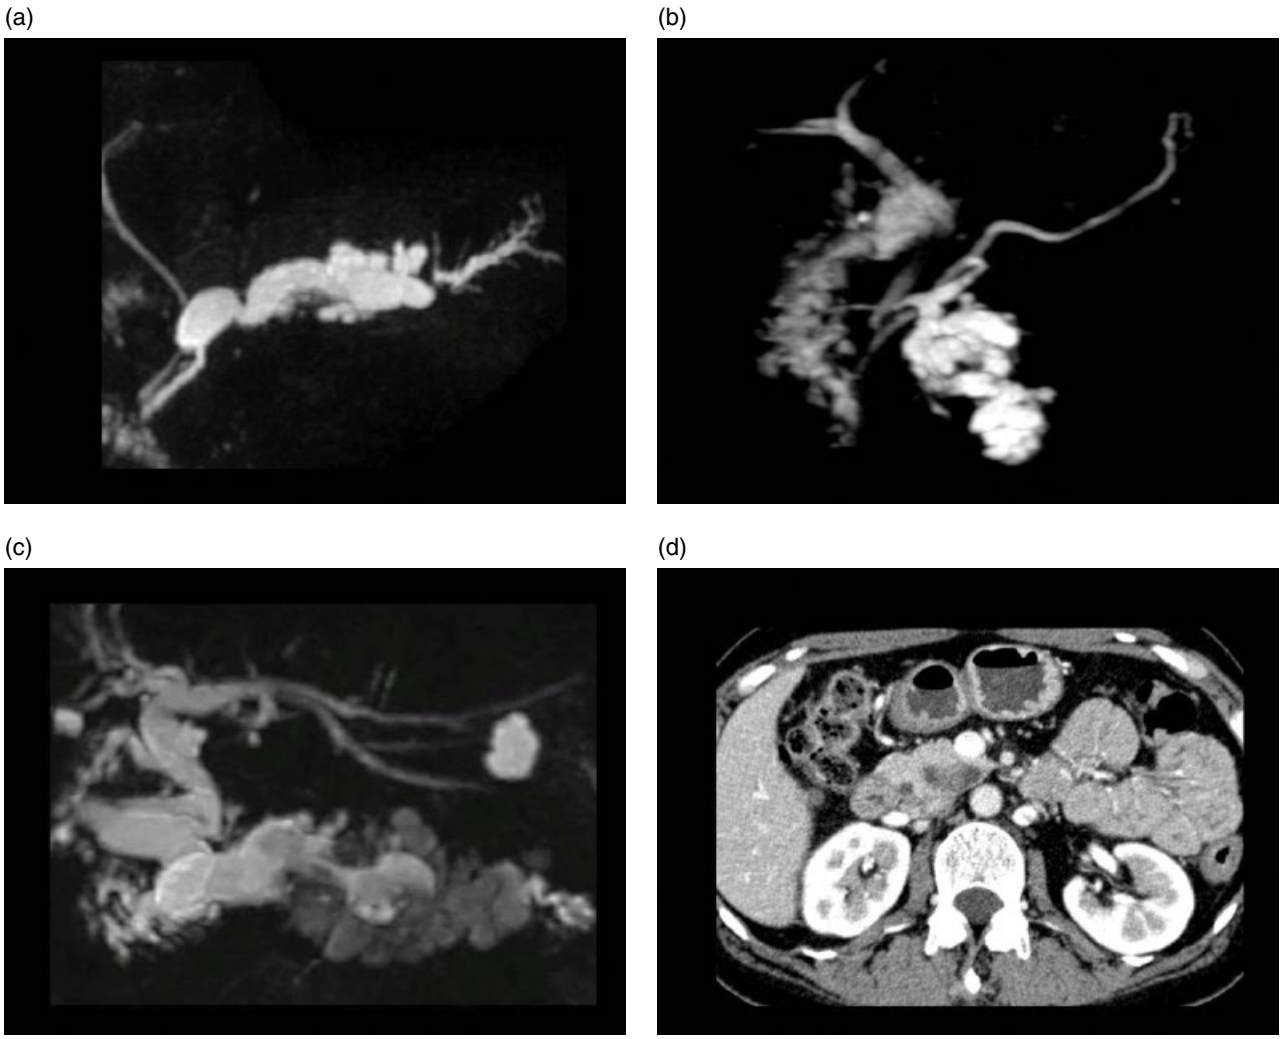

**Figure 77.5** IPMNs. The classic dilated main pancreatic duct seen in main-duct IPMN (a). In comparison there is a cyst but a normal pancreatic duct in a BD-IPMN (b,c), and a dilated main pancreatic duct and a cyst in a mixed-type IPMN (c). Mural nodules appear as soft tissue mass with contrast enhancement on CT and hyperechoic protruded lesion on EUS (d,e). Tissue harmonic echo (THE) shows a superior imaging compared with B-mode (f,g).

associated with an increased risk of HGD or IC including cyst size >3 cm (odds ratio (OR) 2.97), dilation of the main pancreatic duct (OR 2.4), and the presence of a solid component, or mural nodule (OR of 7.7) [20].

On CT and MRI, a mural nodule appears as a soft tissue nodule protruding into a mucin-filled dilated duct or cyst, with enhancement following administration of intravenous contrast. On EUS, a mural nodule appears as a hyperechoic, irregular lesion (Fig. 77.5d,e). The size of the mural nodule is associated with the risk of IC; however, the exact size is unclear and varies in studies from ≥3 mm to >10 mm, with the latter associated with IC in almost 90% of patients in one study [21,22]. Mucin appears as a hypoechoic lesion, with a hyperechoic, smooth rim on EUS, and is non-enhancing on CT or MRI. Contrast-enhanced EUS (CE-EUS) may demonstrate vascularity in mural nodules and is useful for differentiating a mural nodule from a mucin ball. A prospective study found that CE-EUS correctly identified 75% of mural nodules with HGD or IC. Tissue harmonic echo (THE) imaging is a further development in EUS. Preliminary studies appear promising, and show superior image visualization of mural nodules compared with normal B-mode imaging (Fig. 77.5f,g) [23]. Individuals with IPMNs can develop concomitant pancreatic adenocarcinoma in a region separate to the cyst, highlighting the importance of inspecting the entire parenchyma and not just the cyst. The cyst fluid analysis

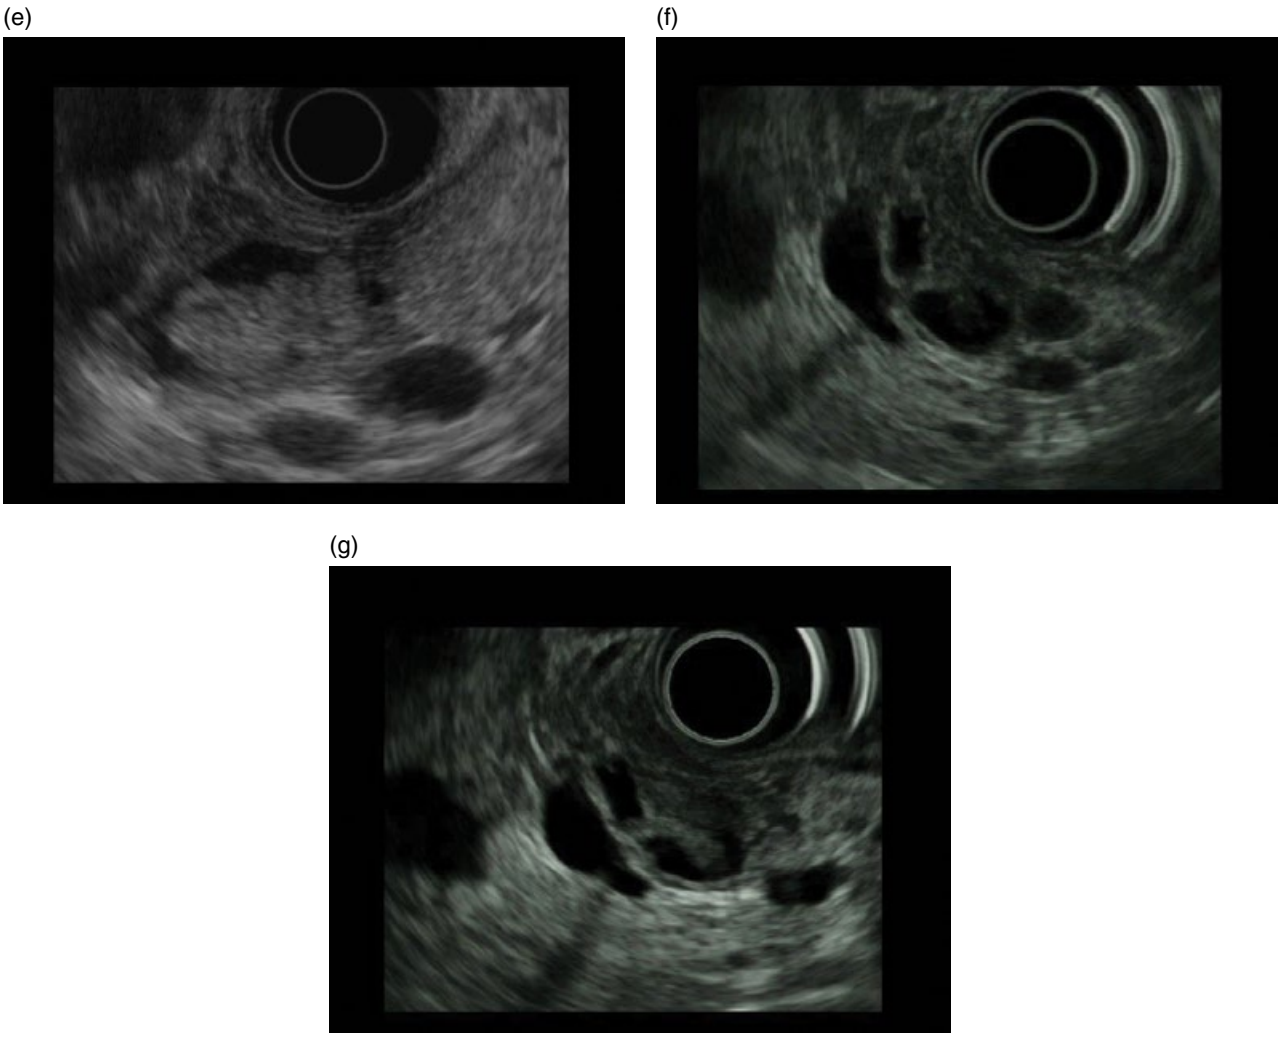

**Figure 77.5** (Continued)

shows a high CEA (>192 ng/mL), and high amylase. A *GNAS* or *KRAS* mutation is present in 91% of IPMN.

## Solid-Pseudopapillary Neoplasm

SPNs are single cysts, with 60% located in the body or tail of the pancreas. Almost 90% occur in women, presenting at a mean age of 29 [24]. The main pancreatic duct is normal, and does not communicate with the cyst. The cysts are well circumscribed, round or oval, with calcification present in almost half the cases [25]. In ~70% of cases, the imaging appearance is of a cystic and solid lesion, in 30% they are predominantly solid, and in rare cases are entirely cystic (Fig. 77.6a) [24,25]. The imaging appearance varies due to the cystic and solid nature of these neoplasms with areas of fluid appearing as low attenuation on CT and high signal on T2W imaging with weak enhancement within the solid components [26]. Areas of increased signal may be seen on the precontrast T1W imaging due the presence of hemorrhage within the lesions.

## Cystic Neuroendocrine Tumor

Cystic degeneration of neuroendocrine tumors is rare, occurring in less than 20% of cases [27]. There is an equal distribution between genders, with a mean age at presentation of 53 years. These cysts are predominantly solid, with the cystic component due to degeneration of the tumor. They are round, usually well defined, with a rim of tissue which enhances on the arterial phase CT and MR imaging. On EUS they appear as a well-defined, round, hypoechoic lesion, with an anechoic cystic area (Fig. 77.6b,c). They often have a vessel running around the edge of the lesion. Cyst fluid CEA and amylase levels are low.

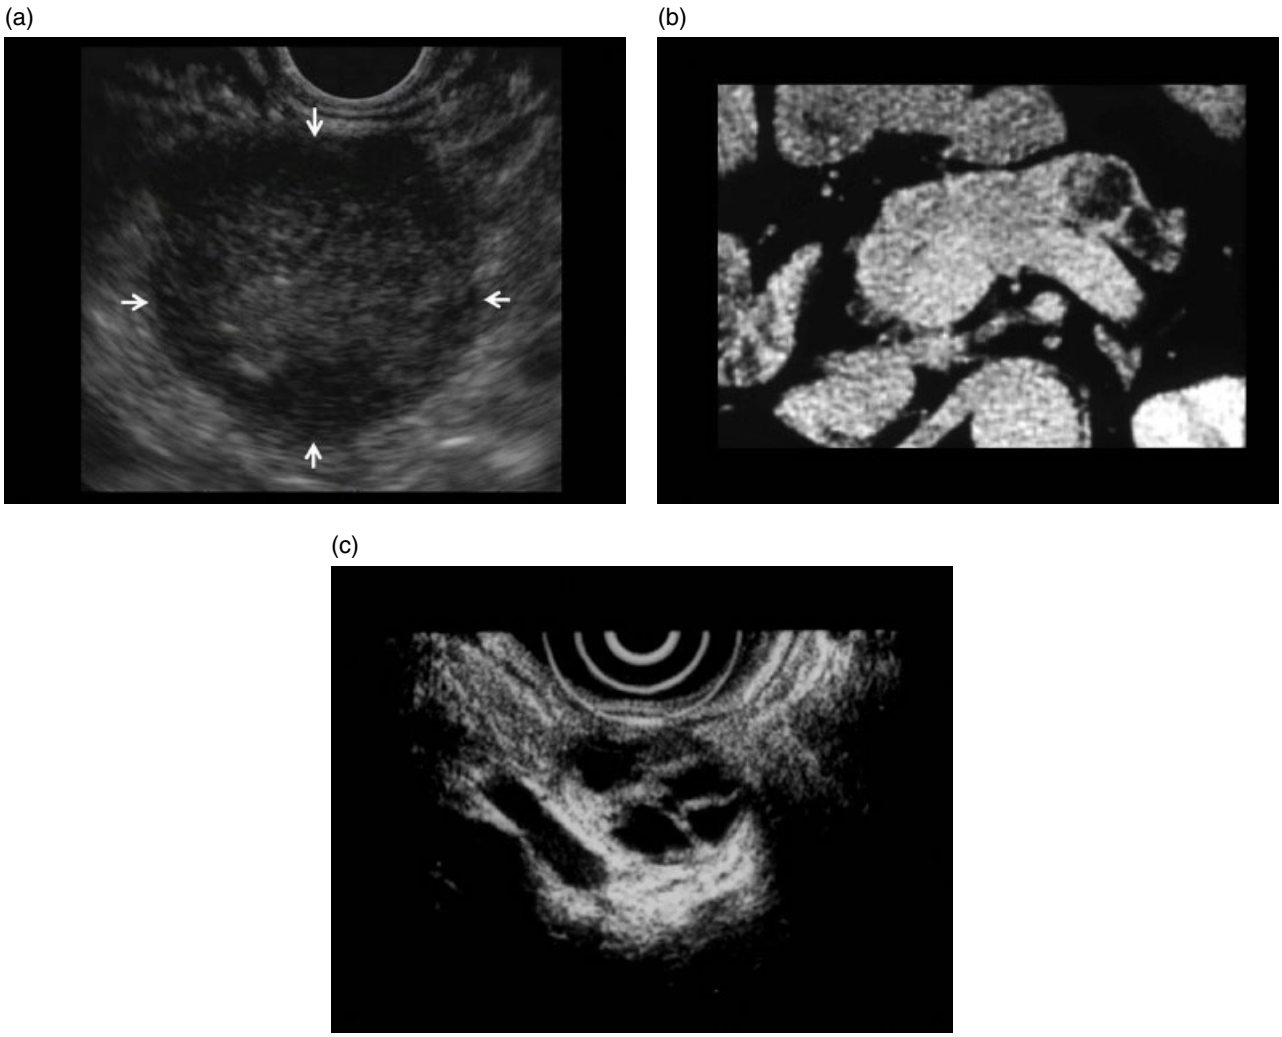

**Figure 77.6** SPN and PanNET. Solid appearing SPN (a). Cystic PanNET showing enhancement of the rim and septum on CT (b). On EUS the appearance is of a solid component with cystic areas (c). *Source:* (a) Copyright AML, by permission of the author.

## Future Technology

A number of promising new techniques have been developed to evaluate pancreatic cysts. Diffusion-weighted MRI imaging has shown promise in differentiating pancreatic cancer from mass-forming focal pancreatitis; however, its role in identifying cyst type is unclear, with conflicting results from different studies [28–31].

A new area under investigation are disease-specific ligands, such as antibodies. These have been developed and can be attached to a microbubble surface, or gadolinium (III)-containing micelles and liposomes, and then injected into a patient where they bind to their target and can be visualized with CE-EUS in the former, or MRI in the latter case. Preliminary studies in pancreatic cancer animal models have demonstrated feasibility and are promising [32–34].

Needle-based confocal endomicroscopy (nCLE) is a relatively new technology in which a very thin microscope is passed through a 19-gauge EUS-FNA needle into a cyst and creates a real-time optical biopsy of the cyst. Initial studies found that different types of cysts had specific imaging features, such as a superficial vascular network in SCAs, and identify cyst type with 59–80% sensitivity and 100% specificity [35,36]. A fiberoptic probe can also be passed through a needle into a cyst, with good or excellent visualization achieved in 70% of cases, and 71% sensitivity and 100% specificity for identification of IPMNs and MCNs in one study [36]. The initial results from both of these techniques are promising; however, there are limitations in the studies published to date and further larger, prospective studies are required to fully evaluate their potential and role.

# Cytologic Evaluation of Cystic Neoplasms

*Martha Bishop Pitman*

*Department of Pathology, Massachusetts General Hospital; Harvard Medical School, Boston, MA, USA*

## Introduction

The management of patients with a cystic lesion of the pancreas balances the benefits of surgically resecting a curable precursor lesion with the risks of overtreating a patient with an entirely benign lesion [1,2]. Cytohistology (fine needle aspiration biopsy with direct smears and cellblocks of small tissue fragments from needle rinsings and/or microbiopsies) is a critical tool in determining cyst type and the risk of malignancy. While cytology alone can be readily diagnostic, the diagnosis of cystic neoplasms often requires a multidisciplinary and multimodal approach for accurate interpretation [3,4]. Table 78.1 outlines the clinical, imaging, and cyst fluid characteristics of primary cystic neoplasms most commonly encountered in clinical practice.

## Cytology of Neoplastic Cysts

### Serous Cystadenoma

Aspirates of serous cystadenoma (SCA) produce variable amounts of cyst fluid depending on the size of the cysts. Microcystic SCA generally yield scant bloody specimens on fine needle aspiration (FNA) whereas macrocystic (oligocystic) variants often produce relatively abundant bloody or clear, thin, nonviscous fluid. Aspirates contain few cells and most cells do not survive the mechanical forces of direct smearing during slide preparation. Cyst fluids also rarely contain many intact cyst lining cells. As such, most FNAs are nondiagnostic.

When present, intact serous cells are small cuboidal cells with round, regular nuclear membranes and inconspicuous nucleoli [5,6] (Fig. 78.1a). Cytoplasm is scant, pale, and finely vacuolated, glycogen-rich and nonmucinous [5,7]. Given the high vascularity of the septae, which can bleed, hemosiderin-laden macrophages may be noted and these cells may serve as a surrogate marker for the diagnosis [5]. Microbiopsies may procure small diagnostic tissue fragments (Fig. 78.1b).

#### Ancillary Studies

The absence of thick mucin, mucinous epithelial cells, and high-grade cytologic atypia, coupled with low cyst fluid amylase and carcinoembryonic antigen (CEA) levels are characteristic findings that support the diagnosis. Periodic acid–Schiff (PAS) stain performed on formalin-fixed paraffin-embedded tissue will highlight the cytoplasmic glycogen and diastase will remove it (Fig. 78.2a,b). Molecular analysis may detect the *VHL* gene mutation or loss of heterozygosity on chromosome 3p, either of which would also support the diagnosis.

### Mucin-Producing Cysts

The distinction between intraductal papillary mucinous neoplasm (IPMN) and mucinous cystic neoplasm (MCN) as specific diagnoses is often not possible on cytology alone. Cytologic analysis may be able to ascertain that the cyst is mucin-producing, however, and determine whether there are any cells suggestive or diagnostic of malignancy [8].

The volume of fluid aspirated from mucinous cysts is highly variable, obviously dependent on the size of the cyst(s) accessible to the needle. Visibly "thick and viscous fluid" indicates a mucin-producing cyst. Smears of grossly thick, viscous mucin correlates with colloid-like, thick extracellular mucin, which is not characteristic of gastrointestinal contamination, and is a finding that supports the diagnosis of a mucin-producing cyst (Fig. 78.3). The presence of degenerated cells and debris floating in

BD, branch-duct; CEA, carcinoembryonic antigen; HR, high risk; MPD, main pancreatic duct.

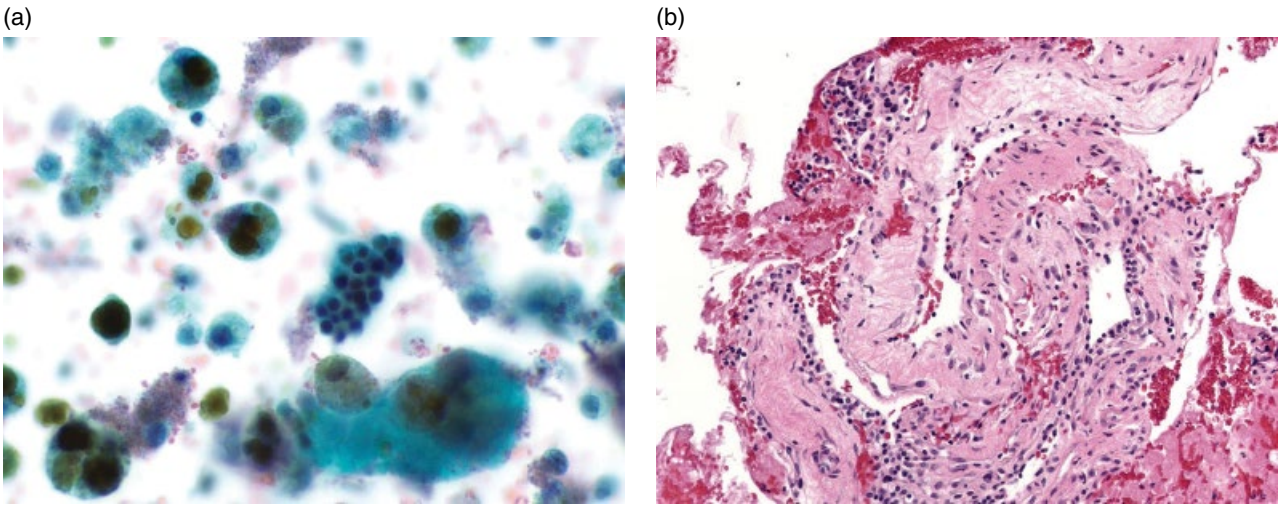

**Figure 78.1** Serous cystadenoma. Cyst lining cells are nonmucinous cuboidal cells with benign round nuclei and finely vacuolated cytoplasm rich in glycogen and many are associated with hemosiderin-laden macrophages, which is not an uncommon finding given the highly vascular septa of this neoplasm (a). Cellblock or core biopsy provides tissue for diagnosis and ancillary testing (b). ((a) SurePath preparation; Papanicolaou test; (b) cellblock, hematoxylin, and eosin).

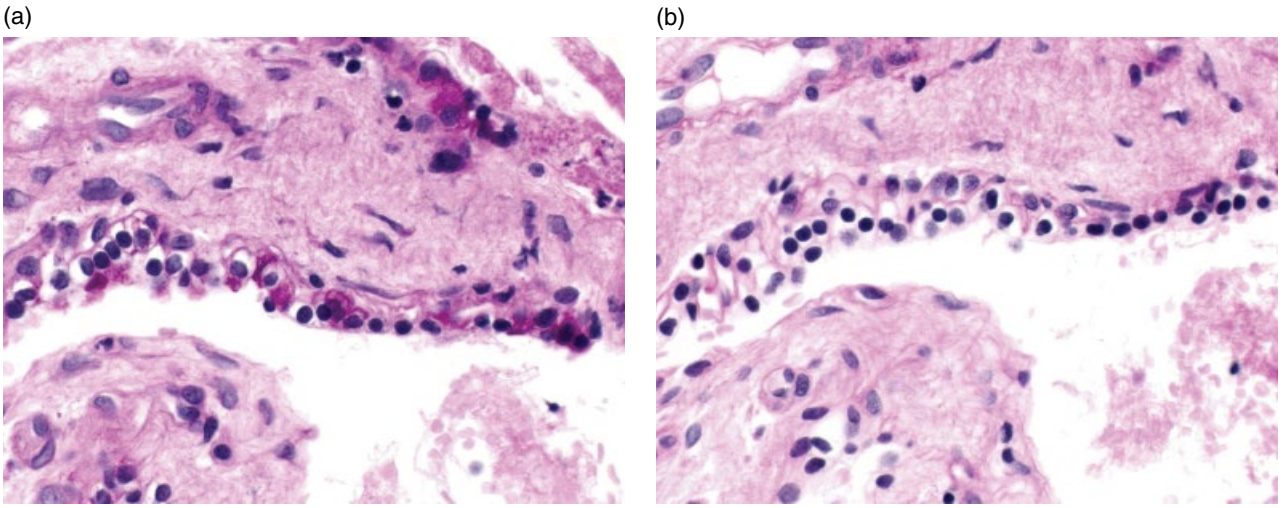

**Figure 78.2** Serous cystadenoma. The glycogen-rich cytoplasm of the cyst lining cells is highlighted by a PAS stain (a), which, in contrast to mucin, is removed with diastase (b). (Cellblock; (a) periodic acid–Schiff; (b) periodic acid–Schiff with diastase).

the mucin is a finding that also supports origin from the cyst rather than contamination. The absence of an epithelial component in colloid-like mucin should not lead to a nondiagnostic report, but instead, a report of a neoplastic mucin-producing cyst [9].

Cytologic features associated with various grades of dysplasia (low, intermediate, and high) have been described for IPMN [10–15]. These findings are similar for MCN, although most MCN are low grade even when quite large [16,17]. IPMN are associated with four distinct types of lining epithelium, but specifying the cell type is not necessary on cytology. The most important cytologic interpretation is to report whether the cells are low risk (low-grade or intermediate-grade dysplasia, e.g., low-grade atypia) or high risk (high-grade dysplasia or invasive carcinoma, e.g., high-grade atypia) for malignancy [9].

Cytologic features associated with grades of dysplasia are as follows:

- Low grade

*Low-grade dysplasia* (Fig. 78.4): Low-grade mucinous epithelial cells are gastric-foveolar type epithelial cells, which are columnar cells with basal nuclei and mucinous

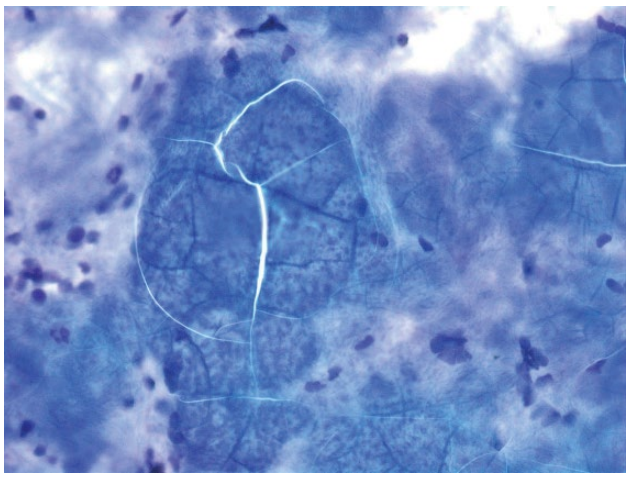

**Figure 78.3** Mucinous cyst. Thick, colloid-like extracellular mucin is not consistent with gastrointestinal contamination and supports the diagnosis of a mucinous cyst, regardless of the presence of an epithelial component. (Direct smear; Diff-Quik).

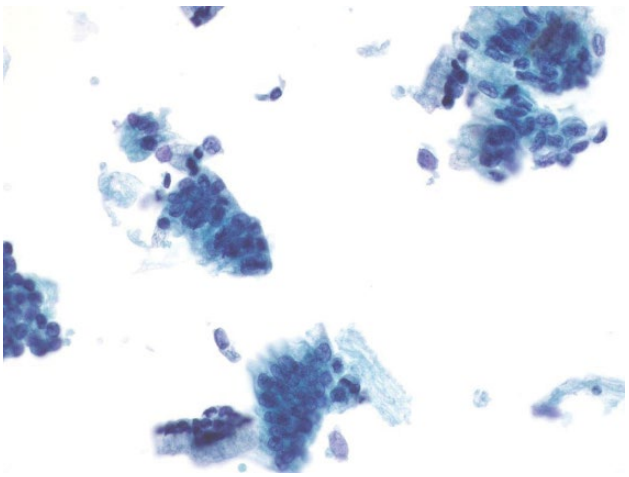

**Figure 78.5** IPMN with intermediate-grade dysplasia. Cells show stratification of the nuclei and moderate cytologic atypia with mild anisonucleosis and slight loss of polarity. (Cytospin; Papanicolaou).

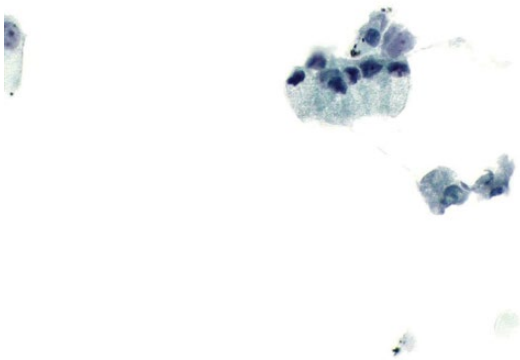

**Figure 78.4** IPMN with low-grade dysplasia. Columnar mucinous epithelial cells show abundant mucinous cytoplasm and minimal nuclear atypia. (Cytospin; Papanicolaou).

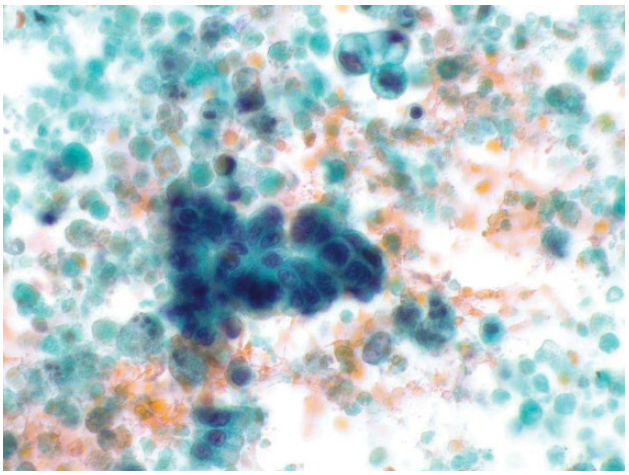

**Figure 78.6** IPMN with high-grade dysplasia. Cells are small (<12 micron duodenal enterocyte), often in small clusters and singly, with abnormal chromatin and typically associated with background necrosis. (Cytospin; Papanicolaou).

cytoplasm. Aspirated cells are present as two-dimensional cell groups, sheets of mucinous cells, and single cells.

*Intermediate-grade dysplasia* (Fig. 78.5): Intermediate-grade dysplastic cells are either intestinal type epithelial cells or gastric-foveolar type epithelial cells with stratification and tufting, crowding, and some loss of polarity. The cells demonstrate increased nuclear to cytoplasmic ratio and may also demonstrate mild nuclear atypia including inconspicuous nucleoli and membrane irregularity. Mucinous cytoplasm is still present in many but not all cells.

- High grade

*High-grade dysplasia* (Fig. 78.6): High-grade dysplasia may be pancreaticobiliary type, oncocytic type, or high-grade dysplastic gastric or intestinal type cells. High-grade atypical cells are noted in large to small bud-like clusters and single cells. These cells are usually smaller than a 12 μm duodenal enterocyte. They will have increased nuclear to cytoplasmic ratio, abnormal chromatin (hypochromasia or hyperchromasia), some have irregular nuclear membranes, and the cytoplasm is variably vacuolated. In addition, background necrosis is usually present [15].

*Adenocarcinoma* (Fig. 78.7): Cellular atypia diagnostic of malignancy (i.e., "positive" aspirates) is not very

**Figure 78.7** IPMN with invasive carcinoma (adenocarcinoma). Cells show irregular spacing in a sheet with nuclear crowding and overlap, anisonucleosis of 4:1, and irregular nuclear membranes. (Cytospin; Papanicolaou).

common unless the imaging features are also those of a high-risk lesion. Cells are present in three-dimensional groups and single cells with variable anisonucleosis (variation in nuclear size) of at least 1:4 in a single sheet, irregular nuclear membranes, prominent nucleoli, and variably vacuolated cytoplasm, usually present in a background of necrosis [18].

#### Ancillary Studies

Establishing that the cyst is mucin-producing is accomplished by detection of extracellular mucin either grossly, microscopically, or with special stains, documentation of cyst fluid CEA elevation (generally above 192 ng/mL) [19,20], or molecular analysis documenting *KRAS, GNAS*, or *RNF43* mutations [21–24]. Grading atypia requires cytologic analysis of the cells. Detection of mutations known to occur late in progression to malignancy such as *TP53* or deletion of *SMAD4* supports malignancy [23,24].

### Secondarily Cystic Solid Neoplasms

Secondarily cystic neoplasms include solid-pseudopapillary neoplasm, neuroendocrine tumor, acinar cell carcinoma, and conventional ductal adenocarcinoma. These usually solid neoplasms may form complex cysts more often with the solid component greater than the cystic component. Rarely do typically solid neoplasms mimic primary cysts of the pancreas, but this does occur. Endoscopic ultrasound (EUS)-FNA targeting of the solid component produces cellular aspirates and should provide sufficient tissue for cellblocks, which is a goal of the FNA to ensure tissue for ancillary testing. The cytomorphologic characteristics recapitulate those of their solid counterparts. The two more commonly encountered neoplasms are described in the following section. The ancillary studies used to distinguish these neoplasms are outlined in other chapters specific to each neoplasm.

### Solid-Pseudopapillary Neoplasm

Solid-pseudopapillary neoplasms (SPN) produce cellular aspirates with many discohesive single cells as well as branching and papillary cell groups (Fig. 78.8a). The cells have a high nuclear to cytoplasmic ratio, bland nuclei with round to oval shape, even chromatin, and frequent nuclear grooves or indentations, which yields a "coffee bean appearance." The cytoplasm is typically scant and ill-defined but may show large clear perinuclear vacuoles or well-defined hyaline globules that are PAS positive (Fig. 78.8b) (both best highlighted on air-dried Romanowsky stain) [25–27]. Fibromyxoid stroma separates the cells from the vessels. Cellular smears and cellblocks of needle rinsing typically contain sufficient small tissue fragments to make a morphologic diagnosis (Fig. 78.8c).

### Cystic Neuroendocrine Tumors

The cytologic features of cystic pancreatic neuroendocrine tumors (PanNET) are similar whether the aspirate is from a solid tumor or a cystic lesion [28–31]. Cystic PanNET often produce yellow cyst fluid that has low CEA and amylase levels [31,32]. The neoplastic cells are usually small clusters or individual cells with coarse, stippled chromatin and a plasmacytoid appearance caused by the eccentrically located nucleus (Fig. 78.9). Nucleoli may be prominent.

## Summary

The cytopathologist plays a pivotal role in the management of patients with pancreatic lesions. It cannot be overemphasized that the accurate diagnosis of pancreatic cysts depends upon a multimodal team approach that combines the clinical and radiologic patient information with the cytologic impression and the results of ancillary studies. The gastroenterologist and pathologist must understand the optimal methods of tissue handling and processing of cyst fluid and the pathologist must be familiar with pancreatic histopathology and the nomenclature of pancreatic cytology for accurate diagnosis and consistent, standardized reporting [8,9,33].

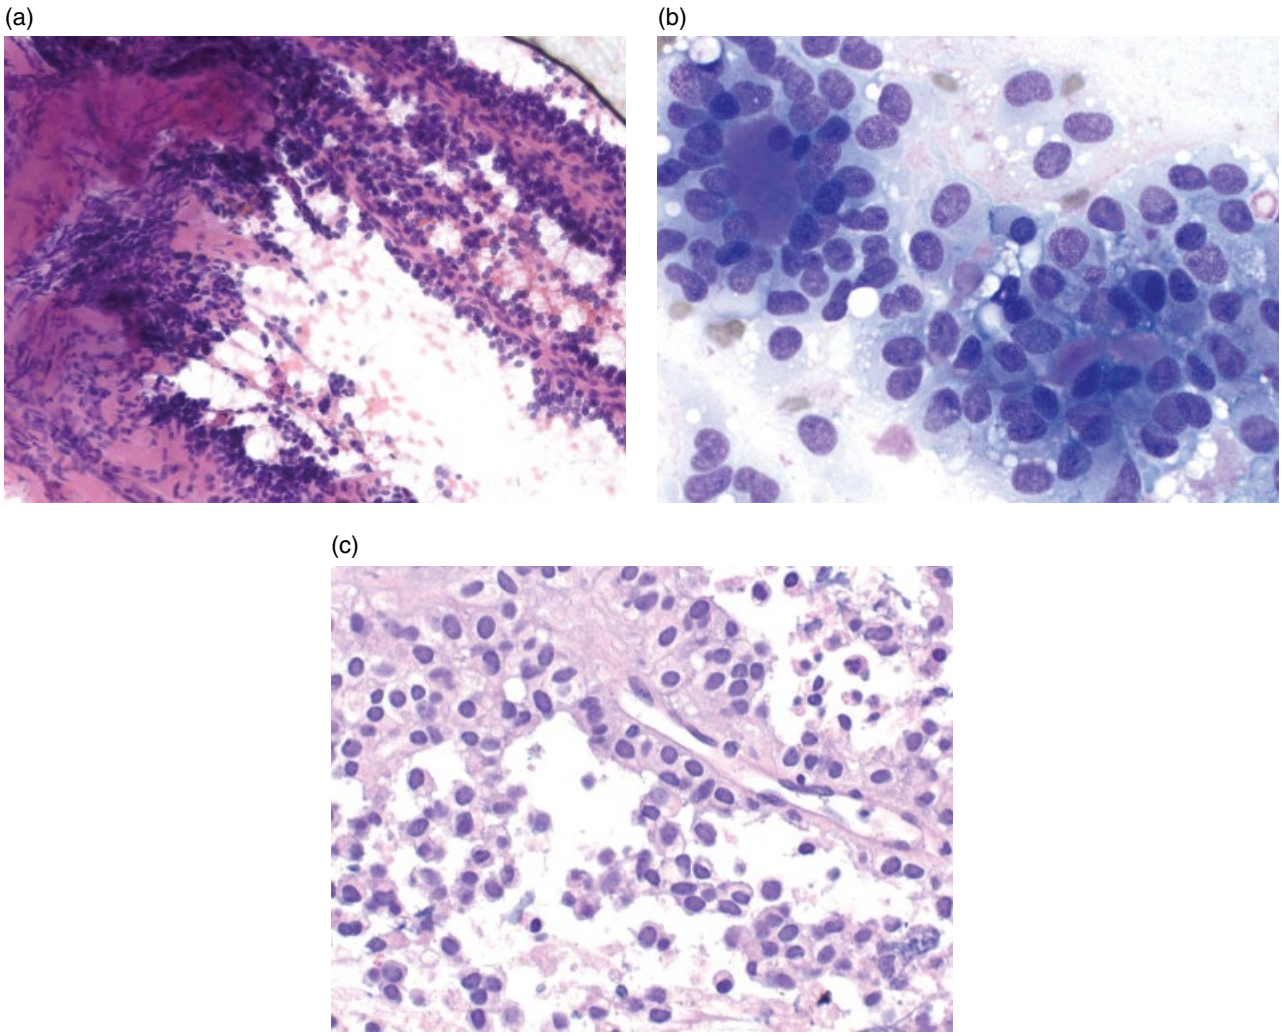

**Figure 78.8** Solid-pseudopapillary neoplasm. Smears are cellular with fibromyxoid stroma and thin, branching, papillary groups (a). The cells are bland with a high nuclear to cytoplasmic ratio, round to "coffee bean" shaped nuclei, and perinuclear cytoplasmic vacuoles or hyaline globules (b). Cellblocks provided tissue for morphology and ancillary studies ((a) Direct smear; hematoxylin and eosin; (b) direct smear; Diff-Quik; (c) Cellblock; hematoxylin and eosin).

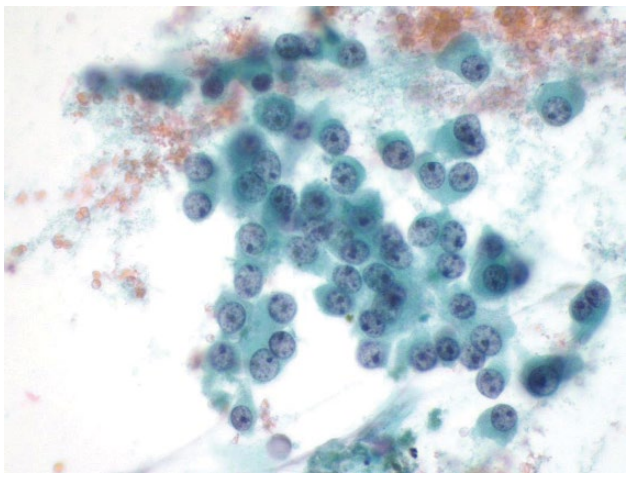

**Figure 78.9** Cystic neuroendocrine tumor. The neoplastic cells are typically individual cells with coarse, stippled chromatin and a plasmacytoid appearance typical of solid tumors. (Cytospin; Papanicolaou).

# Natural History of Cystic Neoplasms: IPMN, MCN, SCN, and SPN

*Anna-Katharina Stadler[1], Thilo Hackert[1], Stefan Fritz[2], and Markus W. Büchler[1]*

[1] *Department of General, Visceral and Transplantation Surgery, Heidelberg University Hospital, Heidelberg, Germany*
[2] *Department of General, Visceral, Thoracic and Transplantation Surgery, Hospital Stuttgart, Stuttgart, Germany*

## Introduction

In recent years, cystic lesions of the pancreas have been identified with rising incidence owing to the extended use of modern abdominal imaging modalities, and therefore have gained increasing awareness [1,2]. Any type of cystic lesion or pancreatic branch-duct alteration can be found frequently in the general population, increasing to a 50–70% prevalence in people aged >70 years [3,4].

For adequate diagnosis and management of cystic pancreatic lesions, it is crucial to correctly differentiate between pancreatic pseudocysts and pancreatic cystic neoplasms. In the past, inflammatory pseudocysts were considered to account for the majority of all cystic pancreatic lesions. With the increasing use of modern abdominal thin-slice imaging, it has become clear that neoplastic pancreatic cysts are far more common than pancreatic pseudocysts, particularly in patients without previous history of pancreatitis. While pseudocysts are benign residual lesions that occur after acute or recurrent chronic pancreatitis, pancreatic cystic neoplasms display a certain potential for malignant transformation. The most common cystic neoplasms of the pancreas are intraductal papillary mucinous neoplasms (IPMN), mucinous cystic neoplasms (MCN), serous cystic neoplasms (SCN), and solid-pseudopapillary neoplasms (SPN).

## Intraductal Papillary Mucinous Neoplasms

Intraductal papillary mucinous neoplasm is the most frequent entity of cystic pancreatic neoplasms comprising approximately 35% of all tumors. IPMN are characterized by the production of mucin as well as intraductal and papillary growth of the duct epithelium. According to their location in the pancreatic duct system, they can be subclassified into main-duct (MD), branch-duct (BD), or mixed-type IPMN, involving both the main duct and its major side branches [1,5]. To date, it remains controversial whether the mixed-type arises from the main pancreatic duct or from side branches, or whether it represents a distinct subtype of IPMN [6]. Beside pancreatic intraepithelial neoplasms (PanIN), IPMN are the best-described precursors to ductal adenocarcinoma of the pancreas [7].

MD- and mixed-type IPMN are characterized by a dilation of the main pancreatic duct >5 mm, segmentally or diffusely, without any sign of external obstruction [8]. The neoplastic epithelial cells produce abundant mucin with a high viscosity that cannot be sufficiently drained, which leads to an internal obstruction and secondary dilation of the affected parts of the duct system [9]. In contrast, BD-IPMN are characterized by cysts >10 mm communicating with the pancreatic main duct without its dilation (Fig. 79.1) [2]. Although most IPMN are fundamentally noninvasive, they progress over time following an "adenoma-carcinoma" sequence via four grades (low-grade, intermediate-grade, high-grade dysplasia, and invasive cancer).

Four major aspects determine the natural history of IPMN patients:

- morphologic type (MD-, BD-, or mixed-type IPMN);
- age at time of diagnosis and time course of the disease;
- histologic subtype (intestinal, pancreaticobiliary, oncocytic, gastric differentiation);
- grade of dysplasia (low-grade, intermediate-grade, high-grade dysplasia, invasive cancer).

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

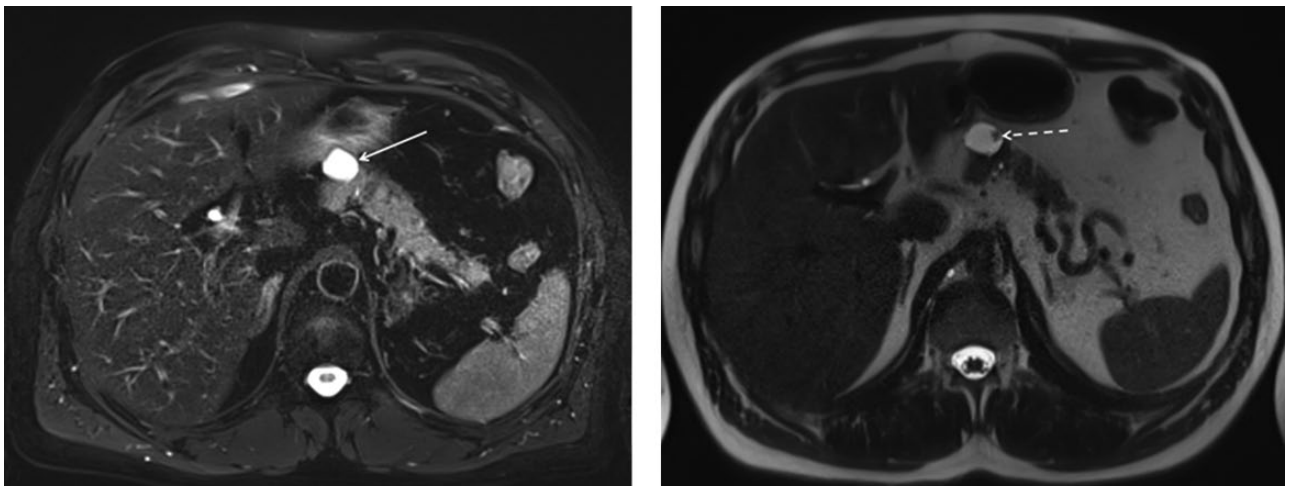

**Figure 79.1** Natural history of branch-duct IPMN. Fifty-four-year-old male patient with initial MRI finding of a BD-IPMN, serum CA 19-9 negative, no worrisome or high-risk features, diameter 22 mm (white arrow, left side). MRI control 8 months later with development of a mural nodule (broken white arrow, right side). Indication for laparoscopic distal pancreatectomy, histopathology: BD-IPMN, oncocytic subtype, pTis, N0 (0/12), R0.

## Morphologic Type (MD-, BD-, or Mixed-Type IPMN)

In a recent meta-analysis MD- and mixed-type IPMN have been identified as invasive carcinoma in about 43%, whereas the rate of invasive BD-IPMN is only about 17% [2]. Lesions with high-grade dysplasia (previously called carcinoma *in situ*) can also be regarded as "malignant" lesions because within a very short time they may progress to invasive cancer [10–12]. Together with high-grade dysplasia lesions, MD-IPMN harbor an ~60% risk of malignancy, whereas BD-IPMN show malignant transformation in around 20–25% of cases at the time of resection. Mixed-type IPMN seem to be associated with the highest risk of malignancy, estimated to be ~70% in larger study populations [2,13]. To date, the dynamic of progression for the different morphologic IPMN types is not completely understood, especially for MD- and mixed-type IPMN—which are generally resected by the time of diagnosis—and no reliable data are available (Fig. 79.2). Furthermore, radiologically defined findings of BD-IPMN may reveal as mixed-type lesions in the histologic workup when they are resected [14]. This underlines the difficulty in evaluating an individual patient's risk on the basis of morphologic characteristics.

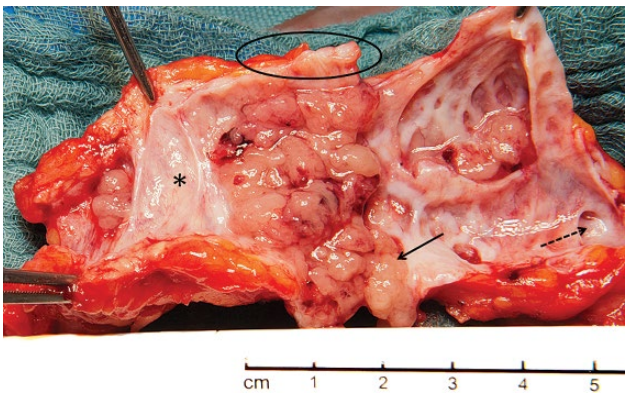

**Figure 79.2** Mixed-type IPMN of the pancreatic head and body (resection specimen) showing typical findings and stages of IPMN. Dilated main duct without dysplasia (black star), branch duct component (broken black arrow), papillary changes in the main duct with borderline dysplasia (black arrow), and progression to invasive cancer arising from the main duct component (black circle). Histopathology: IPMN with invasive cancer based on mixed-type IPMN, pT1, N0 (0/17), R0.

## Age at Time of Diagnosis and Time Course of the Disease

Significant differences in the median age of patients presenting with benign IPMN compared to malignant IPMN have been reported in cohort studies of 140 resected MD- and mixed-duct IPMN by Salvia et al. [15] as well as in another study by Sohn et al. with 136 resected MD-IPMN patients [16]. From both studies, the mean time of progression to invasive IPMN can be estimated at 5–6 years as patients with benign IPMN showed a median age of 61 and 63 years, compared to 67 and 68 years for patients with malignant findings [16]. This can be regarded as a surrogate parameter for an already longer subclinical course of preceding IPMN development by the time of diagnosis, which might be an indirect indicator for disease progression and malignant transformation over time [15,16]. Another corresponding observation is the correlation between duct diameter and the risk of malignancy in MD-IPMN, underlining

that a potentially longer course of the disease reflected by the increased duct size leads to a higher proportion of malignant findings [17].

Time-dependent progression rates in patients with BD-IPMN, who were mostly observed due to the lack of any worrisome features, have been reported in larger studies by Sahora et al. [18] and Maguchi et al. [19]. Among 411 and 349 patients respectively, signs of progression occurred in 18% during a median follow-up time of 26 months and 44 months, respectively. Malignant histologic features after resection were found in 9% and 15% of these patients. Furthermore, both studies demonstrated the development of "remote" lesions—both IPMN as well as separate and independent PDAC—distant from the index lesion during the observation. This underlines the hypothesis that IPMN-bearing pancreata may harbor a "field defect" of the entire gland [20]. Another aspect in this context is the synchronous occurrence of multiple BD-IPMN [21]. As patients with these multifocal lesions are generally older than those with solitary IPMN findings, the "field defect" theory seems reasonable and the progression from solitary to multifocal IPMN can be regarded as the natural course of this disease [21]. Although multiple lesions are likely to increase the long-term risk of malignant transformation, it remains controversial whether multifocal IPMN have a higher risk of malignancy compared to unifocal lesions [21]. The additional risk for IPMN patients of developing concomitant PDAC ranges between 3% and 9% over a 10-year period [22,23]. In what respect the IPMN might play an indirect promoting role in the development of PDAC remains unclear and prognosis of the long-term outcome of these patients is almost always determined by the PDAC component. It is supposed that some kind of pancreatic genetic field defect might lead to multifocal neoplastic changes over time.

## Histologic Subtypes

The differentiation of histologic subtypes (intestinal, pancreaticobiliary, oncocytic, and gastric type [24]) has a relevant prognostic impact. The intestinal subtype reveals a phenotype that resembles villous polyps of the colon with neoplastic epithelial cells expressing MUC2, MUC5AC, and CDX2. A recent study focused on 173 patients with MD-IPMN could show that most MD-IPMN were of intestinal type with invasive components in 50% and overall invasiveness of 39% [22]. Invasive carcinomas that arise in association with an intestinal-type IPMN are usually colloidal carcinomas and show a better median survival compared to patients with PDAC (107 vs. 20 months) [9,25,26]. The pancreatobiliary subtype is composed of branched papillary epithelia with high-grade atypia. In the immunohistochemical examination it is positive for MUC1 and MUC5AC, and 90% of all cases show an associated invasive component. The associated invasive tubular adenocarcinomas are very similar to PDAC in morphology and prognosis [9,27,28]. The oncocytic subtype is characterized by eosinophil cytoplasm, goblet cells, and complex branched papillary epithelia expressing MUC1 and MUC6. This subtype is rare as well as a malignant transformation into an oncocytic carcinoma, which shows a prognosis similar to patients with a colloid carcinoma [26–28]. BD-IPMN usually are of the gastric subtype. The typical morphology is multiple small cysts with foveolar gland epithelium, similar to the glands of the gastric antrum. A tubular adenocarcinoma can eventually arise from these IPMN and is associated with a rather poor prognosis with a mean survival of only 45 months [9,29].

## Grade of Dysplasia (Low-Grade, Intermediate-Grade, High-Grade Dysplasia, Invasive Cancer)

Data on outcome with referral to the grade of dysplasia are available from various larger cohorts of surgical patients [5,22,30]. As these results always reflect the grade of dysplasia at the time of resection, a valid estimation on the time intervals between the distinct grades remains difficult. Patients with resection of IPMN harboring noninvasive IPMN with a range of low-grade to high-grade atypia show an excellent overall and disease-specific survival prognosis of 95–100% in a follow-up of 10 years in both MD- and BD-IPMN [5,22]. In invasive IPMN poor prognosis is closely related to disease stage, positive resection margins for invasive IPMN, and N1 status [22,30]. While early stages including pT1 and pN0 show a much more favorable prognosis compared to sporadic PDAC, this advantage vanishes in more advanced stages (pT2–pT4), and also positive lymph nodes in any stage result in a prognosis that is similar to PDAC [30].

As all types of IPMN must be considered as a chronic and life-long disease—unless a total pancreatectomy has been performed—the natural course of these entities requires surveillance and postoperative follow-up. Surveillance and management strategies have been determined in the IAP consensus guidelines published in 2006 and updated in 2012 [2,8], as well as in the 2013 European guidelines [31] and the 2015 AGA guidelines [32]. These guidelines are partly conflicting not only with regard to surgical and nonsurgical management but also regarding surveillance, follow-up diagnostics, and intervals after resection of IPMN. Lately, published follow-up data from surgical IPMN patients showed that 17% of 381 patients after resection of invasive and noninvasive IPMN had a recurrence of IPMN after a median of 17 months [23]. Within this study, 33 patients had only

partial resection of the multifocal disease with mixed-type as well as BD-IPMN. The residual BD-IPMN with a median size of 10 mm at the date of resection grew within a follow-up of on average 5 years to a median size of 13 mm. In another cohort of 130 patients who had undergone partial pancreatic resections for noninvasive IPMN, He et al. showed that 17 % of the patients developed lesions suspicious for new or progressive IPMN within a median time of 46 months [33]. Within this disease progression cohort some patients developed high-grade dysplasia and invasive cancer. Another 12% of the cohort showed neither new IPMN nor progression in known residual IPMN. Although within the literature the recurrence rates vary between 8% and 57% [15,23,33,34], even patients with noninvasive IPMN might have an estimated average recurrence rate of 25% of remote IPMN and 7% for developing pancreatic cancer within 5 years after resection, which underlines the necessity of a structured and long-term follow-up.

## Mucinous Cystic Neoplasms

Mucinous cystic neoplasms (MCN) generally occur in perimenopausal women with a median age of 48 years. MCN are often located in the distal body or the tail of the pancreas (>90%) with a mean size of 6.5 cm in diameter at diagnosis. Macroscopically, MCN show a uni- or multicystic pattern with a thick wall and potentially solid components without any communication to the pancreatic duct system. An ovarian-like stroma is typical and pathognomonic for the histology of MCN [35,36].

Similar to IPMN, most MCN are noninvasive, but show a risk of an "adenoma-carcinoma" sequence over time. In 15–20 % of all resected cases, MCN harbor at least focally an invasive component [37]. As data show that patients with an invasive MCN are significantly older (median 3–10 years) than those with a noninvasive MCN, a time-dependent tumor-progression is suggested, comparable to that in IPMN [2,38,39]. It has been suggested that ectopic ovarian stroma in the pancreatic tail might release hormones and growth factors that stimulate endodermally derived epithelium to progress and form cystic pancreatic neoplasms [40]. This hypothesis is supported by the fact that rapid growth of pancreatic MCN was seen in women during pregnancy. It has been reported that mural nodules on imaging, lesion size >6 cm and calcification of the cyst wall are associated with the presence of a tubular-type invasive carcinoma very similar to PDAC [38,41–43]. Since nearly all reported MCN have been resected, the natural history of MCN is still unknown and recommendations are based on findings from resection specimens revealing the aforementioned malignancy rates. Once a MCN is diagnosed, a distal pancreatectomy is indicated in most cases due to the young age of the patients and the present inability to differentiate securely between a benign and a malignant lesion. For most patients with noninvasive MCN complete resection means curative therapy as these lesions are solitary and show no recurrence or second neoplasms [2]. A postoperative surveillance is not mandatory and would require life-long high-resolution imaging associated with high costs without any advantage to the patient [2,31]. In contrast, follow-up after resection of invasive MCN should be performed similar to PDAC [31]. The 5-year survival of patients presenting with invasive MCN has been described to be as high as 62%, being worse for elderly patients and for patients with more advanced tumor stages [44].

## Serous Cystic Neoplasms

Serous cystic neoplasms (SCN) are typically located in the pancreatic body and tail and show no significant potential for malignant transformation. The incidence of SCN is higher in women than in men with a peak at the age of 60 years. In abdominal imaging, SCN have a micro- or macro-cystic appearance with a spongy structure. In some cases, they also present with a solid growth pattern. On histopathology, they typically are composed of cysts lined by a single layer of cuboid epithelial cells filled with glycogen [36,45]. A preoperative distinction of SCN from MCN is feasible in most cases due to significant differences in imaging. SCN are usually sporadic, but some arise in patients with von Hippel–Lindau (VHL) syndrome. In patients with VHL syndrome, SCN are commonly multiple. These patients show a loss of heterozygosity of the *VHL* gene [46,47,48]. Sporadic SCN have a somatic mutation of the *VHL* gene in up to 50% with an inactivation of the VHL tumor suppressor protein [46–49] and often show a mutation in the *TBC1D3* gene, also known as PRC17, but no mutations in the genes typically mutated in mucin-producing neoplasms, such as KRAS, RNF43, or TP53 [47,49].

At time of diagnosis, micro- and macro-cystic SCN have a mean size of 4–6 cm and approximately 50% of all patients are asymptomatic [45,50]. Depending on the localization and size of the lesion, symptoms including abdominal pain, discomfort, jaundice, or fatigue are reported. Malignant transformation of SCN with the occurrence of a serous cyst adenocarcinoma is very rare and has only been described in a few case reports [51]. Thus, for asymptomatic patients with a SCN of <4 cm in diameter and without criteria for malignancy on preoperative imaging, surveillance is indicated instead of surgical resection. The natural course of SCN is characterized by a gradual increase in diameter (0.6 cm per year on average).

The growth rate seems to be dependent on initial tumor size as small SCN (<4 cm) show a significantly slower growth rate of 1–2 mm per year than larger lesions (>4 cm) in which annual growth rates of up to 2 cm can be observed [50]. Consequently, besides the size itself, growth rate during surveillance may have an influence on the decision for surgery to avoid local complications due to compression. Following resection, recurrence risk is extremely low and no structured follow-up is recommended [31].

## Solid-Pseudopapillary Neoplasm

The solid-pseudopapillary neoplasm (SPN), also known as Frantz tumor, was first described in 1959. SPN are rare cystic neoplasms that account for approximately 1–2% of all pancreatic tumors [52]. They usually occur in women with a median age of 30 years and are most frequently located in the tail of the pancreas. SPN are classified as malignant due to the potential of lymphatic spread, recurrence, and distant metastases [53]. As all reported series include mainly patients who underwent resection, the natural history of SPN without resection (i.e., growth dynamics) cannot be addressed sufficiently. Anecdotal reports on nonsurgical treatment have shown that both courses—long-term survival with locally limited tumor manifestation, and also aggressive systemic spread with short survival times—are possible [54].

At diagnosis, SPN have a mean size of 8 cm and are located in the body and tail of the pancreas in 60% of patients [53,55,56]. Their macroscopic morphology varies from pure solid to entirely cystic [57]. Tissue analysis of resection specimen has shown that characteristic mutations in exon 3 of the β-catenin gene occur in 83–100% SPN [58,59]. Moreover, especially the absence of other common mutations, such as KRAS, SMAD4, or TP53, distinguishes SPN from other neoplasms of the pancreas [59,60].

Following complete surgical resection, the long-term outcome of SPN is excellent although approximately 6% of the patients show locally advanced tumors (vascular involvement, lymph node metastases) and 8% present with distant metastases [53]. The most comprehensive review including 2.285 resected patients showed that 95.6% of the patients are disease-free during long-term observation. The time to recurrence in the remaining 4.4% of the patients is more than 4 years and final tumor-related mortality is 1.5% [53]. Despite this overall favorable prognosis, SPN must be considered as a tumor entity with a basically malignant course and complete surgical resection is indicated in all patients who qualify for a respective operation. Furthermore, a life-long follow-up (i.e., annually) is mandatory [31].

# Surveillance or Surgical Treatment in Asymptomatic Cystic Neoplasms

*Klaus Sahora and Carlos Fernández-del Castillo*

*Department of Surgery, Massachusetts General Hospital, Harvard Medical School, Boston, MA, USA*

## Introduction

Our knowledge regarding cystic lesions of the pancreas has evolved tremendously over the last few decades, and currently we can offer a safe and individual approach to most patients. In cystic neoplasms, such as solid pseudopapillary neoplasms, mucinous cystic neoplasms, cystic neuroendocrine tumors, and main-duct intraductal papillary mucinous neoplasms (IPMN), the accepted approach is surgical resection if the patient is a suitable candidate [1,2]. Otherwise, observation of serous cystic neoplasms and branch-duct intraductal mucinous neoplasms has proved to be safe [3]. However, in a majority of patients with small lesions, identification of the cyst subtype is either not feasible or uncertain. Based on observational data, several treatment algorithms have been proposed for these unclassified cystic lesions, facilitating the decision whether to operate or observe [4–6]. Most of these recommendations are based on the presence of the patient's symptoms and morphologic cyst characteristics. Symptomatic patients per se should strongly be considered for surgery, while in the absence of symptoms, observation is recommended in lesions without suspicious morphologic features. Further aspects such as age, comorbidities, quality of life, and assumption of costs by the local healthcare system should also be considered when counseling a patient with an asymptomatic cystic lesion of the pancreas.

## Rationale for Surveillance or Surgery in Asymptomatic Cystic Neoplasms

After an early period of radical resection of all pancreatic cystic tumors, growing evidence from larger case series caused a transition towards a more selective and observational approach. The rationale behind the selective surveillance in asymptomatic patients with a pancreatic cyst is: (i) some cystic lesions, such as serous cyst-adenomas of the pancreas, never progress into malignant tumors; (ii) in others that can become malignant, an adenoma–carcinoma transformation takes many years; and (iii) cystic lesions with malignant potential normally exhibit suspicious features that can distinguish them from those that are benign. Overall, it can be assumed that the risk that a cystic lesion is malignant at the time of diagnosis is not exceeding 0.01% and for cystic neoplasm >2 cm the risk is a maximum of 0.21% [7]. Further estimation based on collective data from large case series suggests that the percentage of patients developing an invasive carcinoma is approximately 0.24% per year, with a lifetime risk of <1% if the cyst has no worrisome features at presentation [5]. While this direct relation between cyst size and the risk of malignancy has been investigated and described in numerous studies, the relative meaning of cyst size change over time has been given less attention. Certainly, rapidly growing cystic lesions should be generously resected in young patients or observed in very short intervals by EUS and/or MRI (3–6 months). Kang and colleagues showed in a cohort of patients with BD-IPMN that malignant cysts grew by a greater percentage (69.8% vs. 19.4%; $P = 0.046$) and at a greater rate (4.1 mm vs. 1.0 mm/year; $P = 0.001$) [8]. At our institution we strongly recommend surgery if cyst size changes more than 25% within one year. In the common scenario that a patient presents with multiple cystic lesions (25–41% of all BD-IPMN), overall no greater risk of malignancy has been described and decisions about resection or observation should be made on an individual lesion. If symptoms are present or the cystic lesion exhibits suspicious morphologic changes, resection should be recommended to all surgically fit patients.

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

Ideally, patients should only be recommended pancreatic surgery if this is to prevent death from pancreatic cancer or if resection is required for relief of symptoms. In patients with a high comorbidity burden (measured by a Charlson comorbidity score of ≥7), an analysis from our institution demonstrated that the absolute majority of patients with unsuspicious cystic lesions, assumed to be branch-duct (BD)-IPMN, died from causes other than IPMN carcinoma [9]. Therefore, the question could be raised about whether further surveillance should be limited to those patients who would benefit from major pancreatic surgery if the lesion develops features that cause concern.

## Treatment Guidelines for Asymptomatic Cystic Neoplasms

Presently, the International Association of Pancreatology (IAP) guidelines for the management of IPMN and MCN of the pancreas [4,6] or the American Gastroenterological Association (AGA) guidelines on the management of asymptomatic neoplastic pancreatic cysts [5] have been adopted by most physicians. There are several differences between these proposed algorithms. Primarily the AGA guidelines have been designed for asymptomatic mucinous cysts in general, while the IAP algorithm focuses on the management of BD-IPMN. Both of them established a list of concerning or worrisome features on which further diagnostic workup, surveillance or surgery is recommended (AGA: main-duct dilation, size ≥3 cm, solid component, concerning cytology; IAP: main-duct dilation, size ≥3 cm, solid component, concerning cytology, thickened cyst wall, abrupt change of main-duct diameter). The IAP recommends further evaluation by endoscopic ultrasound (EUS) ± fine needle aspiration (FNA) if one of these features is present, while the AGA requires two or more of them. If a definitive mural nodule/solid component, and/or main-duct involvement is confirmed by EUS, surgery should be considered in all fit patients according to the IAP guidelines. These guidelines also recommend surgery if the EUS shows concerning features or the cytology shows high-grade dysplasia or more. The AGA guidelines, by contrast, only recommend surgery if two concerning features are present and the cytologic analysis of the fluid or cyst wall (obtained by EUS) is either malignant or suspicious for high-grade dysplasia. For further surveillance, the AGA proposed an annual interval once after diagnosis, followed by a two-year interval, and end of surveillance after 5 years. Diversely, the IAP surveillance frequency is based on cyst size: <1 cm, 2–3 years; 1–2 cm, yearly for 2 years, then longer if no change; 2–3 cm, EUS in 3–6 months, then longer interval alternating magnetic resonance imaging (MRI) with EUS as appropriate; ≥3 cm, close follow-up with EUS every 3–6 months. At the Massachusetts General Hospital, surveillance of asymptomatic cystic neoplasm of the pancreas is conducted according to the AIP guidelines. The flowchart in Fig. 80.1 shows our recommended approach at the Massachusetts General Hospital. Observing cystic lesions with a solid component carries an eightfold risk of harboring malignancy and for main-duct dilation we assume a similar probability. Therefore, in surgically fit patients we consider resection if a single worrisome feature is suspected by imaging studies and confirmed by EUS.

## Quality of Life, Surgery Versus Surveillance

The major objective in treating a patient with an asymptomatic und unsuspicious cystic neoplasm is preventing or detecting the development of an invasive pancreatic carcinoma. Repeating imaging studies, invasive diagnostic procedures and many-times major pancreatic surgery are indispensable requirements to maintain this aim.

Yet, the majority of case series and actual guidelines often neglect issues relating to quality of life, patient preference, or postsurgical functional status. In a unique analysis, Weinberg et al. used decision analysis with Markov modeling to compare competing management strategies in a patient with a pancreatic head cyst [10]. In their study they found that surgery remains the superior strategy for maximizing quality of life in patients who are between 65 and 75 years of age with cysts ≥3 cm, but concluded that patients >85 years have improved quality of life when managed with surveillance. They assume that poor quality of life experienced postoperatively often outweighs the minimal benefit derived from surgery in this population. Analogous consideration has been reported regarding prostate cancer in the elderly, where "watchful waiting" is often more appropriate than radical prostatectomy [11]. Van der Gaag et al. reported that, after cyst resection, long-term quality of life is equal to healthy references and concludes that the excellent long-term overall outcome justifies proceeding with surgery once an indication for resection has been made [12]. Equally, evaluation of Italian patients with BD-IPMN under observation revealed that their quality of life did not deviate from the normal population. Further psychological questionnaires conducted at basal evaluation and during the follow-up demonstrated that the majority of patients showed no signs of anxiety or depression [13].

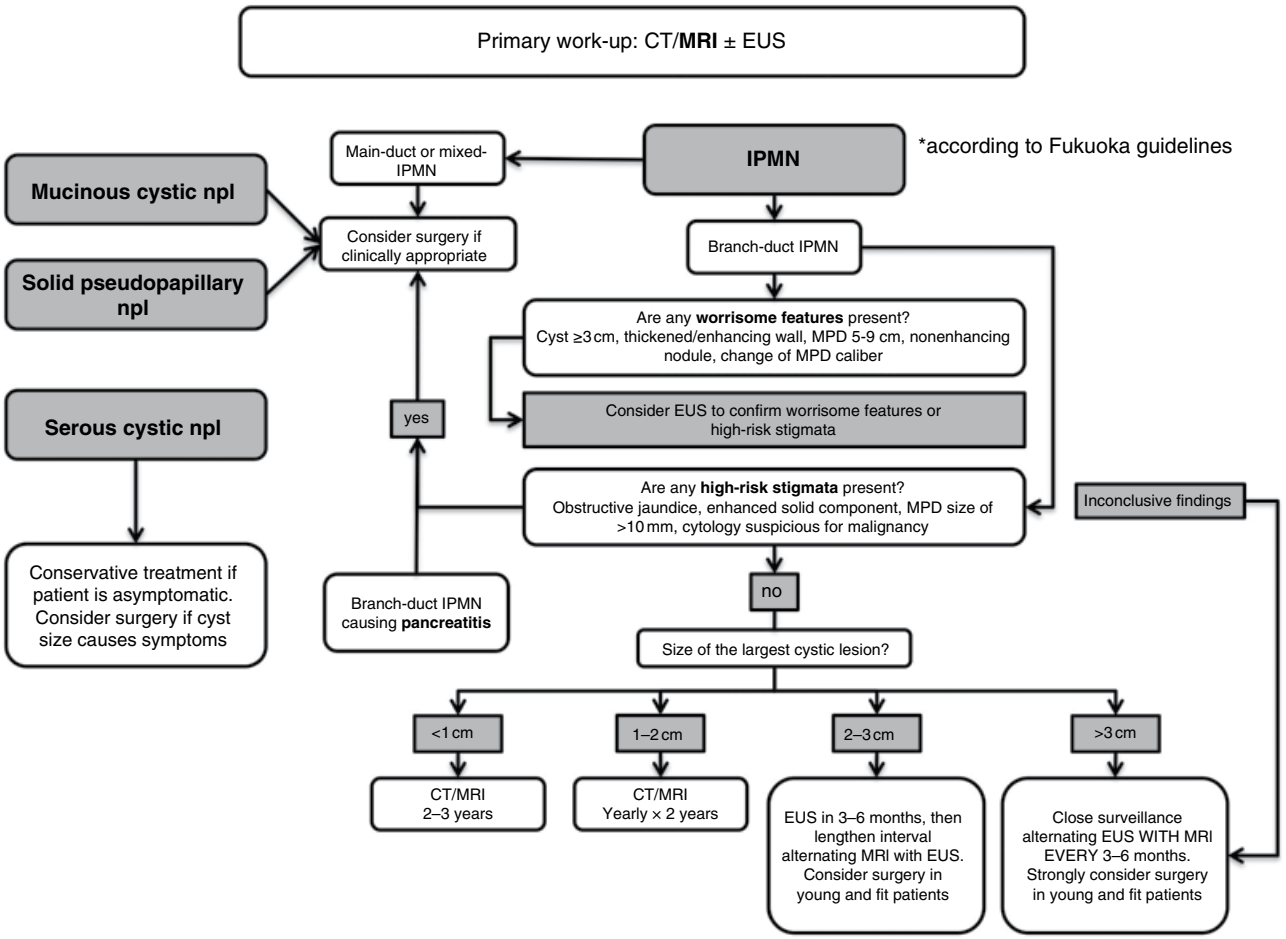

**Figure 80.1** Recommended approach in patients with cystic neoplasms. IPMN, intraductal papillary mucinous neoplasms; npl, neoplasm; EUS, endoscopic ultrasound; CT, computed tomography; MRI, magnetic resonance imaging.

## Cost-Effectiveness of Each Approach

In light of continuously increasing healthcare costs and a restrictive compensation policy by insurance companies, an optimal cost-effective management of asymptomatic pancreatic cystic neoplasm has become relevant. Repeated costly MRI imaging studies for patients under surveillance must be weighed against a more aggressive surgical approach and follow-up with any innervation or stop of surveillance in selected patients. Yet, only a few studies have focused on cost-effectiveness in the management of pancreatic cystic neoplasm. Das et al. used a Markov model with a third-party-payer perspective, comparing follow-up without any specific intervention versus an aggressive surgical approach and initial EUS with FNA with cyst fluid analysis for risk stratification and resection of all mucinous cysts [14]. The strategy based on risk stratification of malignant potential by EUS with FNA and cyst fluid analysis was the most cost-effective strategy and yielded the highest quality-adjusted life years. Researchers from our institution reviewed the cost-effectiveness of the IAP consensus guideline implementation in the management of BD-IPMN [15]. Three scenarios based on 60-year-old patients with branch-duct IPMN were analyzed: surveillance using consensus guidelines for surgical resection (surveillance strategy), surgical resection based on symptoms without surveillance (no surveillance strategy), and immediate surgery (surgery strategy). Surveillance according to the IAP guidelines is a cost-effective strategy in the management of branch-duct IPMN in the head of pancreas when compared to no surveillance and immediate surgery. However, given the large number of patients who are found to have incidental pancreatic cysts, and the lack of endpoint in surveillance, there is a clear need for additional triage strategies that hopefully will identify groups of patients with higher risk and those with negligible risk, where potentially surveillance could be stopped early on. These potential strategies include analysis of cyst fluid for

unique markers and identification of circulating tumor cells, exosomes, or free DNA. For example, mAb Das-1, a monoclonal antibody against a colonic epithelial phenotype investigated at our institution, showed high reactivity, both in EUS-FNA cyst fluid samples (sensitivity of 89%, specificity of 100%) and histologic specimens from resected high-grade IPMN (sensitivity of 85%, specificity of 95%) [16].

# Local and Standard Surgical Treatment of Cystic Neoplasms

## 81

## Duodenum-Preserving Partial or Total Pancreatic Head Resection

*Hans G. Beger*[1] *and Bertram Poch*[2]

[1] *c/o University of Ulm, Germany*
[2] *Center of Oncologic, Endocrine and Minimal Invasive Surgery, Donau-Klinikum, Neu-Ulm, Germany*

### Background

Standard surgical treatments for benign cystic neoplasm of the pancreas are presently multiorgan resections; pancreatoduodenectomy (PD) for tumors of the pancreatic head and a left-sided pancreatic resection, either spleen-preserving or with splenectomy, for tumors in the body and tail. Many of the cystic neoplasms are benign and small (tumor size <4 cm) at the time of diagnosis. The question arises, why a surgical treatment with radical resection of the tumor-bearing pancreas, unnecessarily sacrificing duodenum, pancreatic biliary and gastric tissue, is applied for a benign lesion? Although not performed as standard, parenchyma-sparing, local resection procedures for pancreatic tumors have the potential for low procedure-related postoperative morbidity and preservation of exocrine and endocrine pancreatic functions [1,2].

### Classical Pancreatoduodenectomy or Local Extirpation for Cystic Neoplasms of the Pancreatic Head?

The standard treatment for a benign cystic neoplasm in the pancreatic head is currently the Kausch-Whipple resection. PD is a multiorgan resection associated with considerable loss of functional pancreatic and extrapancreatic tissue, including the stomach, duodenum, and biliary tree. PD is associated with a considerable rate of severe postoperative complications, including pancreatic fistula, disruption of anastomosis, surgical side abscess, intra-abdominal hemorrhage, and a severe form of delay of gastric emptying, requiring reoperation and/or reintervention in 5–12% of cases [3,4]. Hospital mortality after PD in high-volume institutions ranges below 3–5%. However, 30-day mortality rates as high as 4–8% have been reported [4–6]. Postoperatively, new diabetes mellitus develops in 12–20% of patients after surgical resection of a benign or premalignant pancreatic lesion [7–11]. In total, 30–40% of the preoperative diabetic patients display postoperatively an escalation of the adjustment of diabetic glucose metabolism [11]. Following PD, the exocrine pancreatic functions are significantly reduced in 30–50% of cases [12]. The duodenectomy of the Kausch-Whipple operation induces long-lasting dysfunctions of secretion of gastrointestinal hormones and gastrointestinal motility disorders [13–16] (Table 81.1).

In contrast to the Kausch-Whipple resection, duodenum-preserving total pancreatic head resections for benign pancreatic head lesions are associated with low postoperative surgery-related morbidity and a very low hospital mortality [18]. A recently published meta-analysis on functional changes before and after DPPHR and PD revealed that exocrine and endocrine pancreatic functions following DPPHR were unchanged, in contrast to PD [8]. Despite the resection of pancreatic head tissue, total duodenum-preserving pancreatic head resection maintains endocrine functions as reflected by $HbA_{1c}$ levels, glucose tolerance testing, and the frequency of postoperative new-onset diabetes mellitus [8]. The same is true for exocrine pancreatic functions. DPPHR preserves the exocrine functions, whereas after PD there is often a significant decrease, requiring enzyme

supplementation. The probability of developing endocrine and exocrine pancreatic insufficiency 1 year and 5 years after PD was found to be 32% and 85%, respectively [19].

## Rationale for Local Pancreatic Head Resection

The rationale for a local resection of a benign tumor in the pancreatic head is based on: (i) preserving the duodenum, distal biliary duct, and gall bladder as well as distal stomach and pylorus; (ii) maintaining the functional integrity of the duodenum regarding coordination of digestive, metabolic, and motility functions of the pancreas, liver, and stomach, respectively; (iii) conserving a maximum of the pancreatic tissue; (iv) protecting the patient against metabolic and nutritional long-term persisting GI-tract disorders of glucose metabolism and disturbances of carbohydrate, fat, and protein digestion.

The goals of limited, parenchyma-sparing pancreatic head resection are: (i) application of a procedure with a low risk for surgery-related severe complications and hospital mortality, which are superior to the standard surgical procedure; (ii) maintenance of the quality of life of patients aged below 50 years when referred for surgical treatment in the case of IPMN, MCN, SCN, and pancreatic neuroendocrine tumors; (iii) prevention of fear of suffering pancreatic cancer.

## Duodenum-Preserving Total Pancreatic Head Resection With or Without Segmental Resection of the Peripapillary Duodenum and the Intrapancreatic Common Bile Duct

Tumor size and location, radio-morphologic type, and histopathology of the neoplasm being resected determine whether a total or partial pancreatic head resection should be undertaken (Table 81.2).The surgical technique of DPPHR is almost identical to the standard PD procedure except for dissection of the pancreatic head along the duodenal wall and the conservation of the intrapancreatic common bile duct (CBD), and in some instances resection of a 2 cm segment of the peripapillary duodenum. To preserve the duodenum and the intrapancreatic CBD, a total pancreatic head resection (DPPHR-T) entails complete resection of the pancreatic head, including the uncinate process (Fig. 81.1). Duodenum-preserving total pancreatic head resection with segment resection of the peripapillary duodenum (DPPHR-S) comprises total pancreatic head extirpation and resection of the segment of the peripapillary duodenum and the intrapancreatic CBD, while preserving the pancreatic neck (Fig. 81.2). Three anastomoses are to be performed to ensure postoperative GI integrity. An excluded jejunal loop or the stomach is used for anastomosis of the left pancreas. Partial

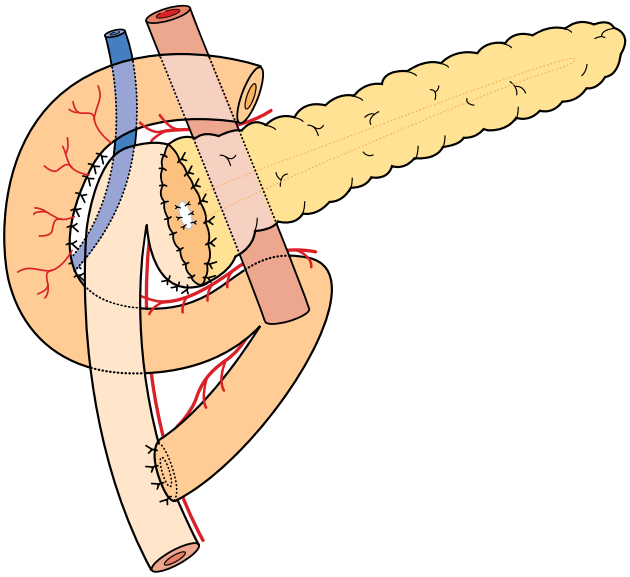

**Figure 81.1** Duodenum-preserving total pancreatic head resection conserving the duodenum and the CBD.

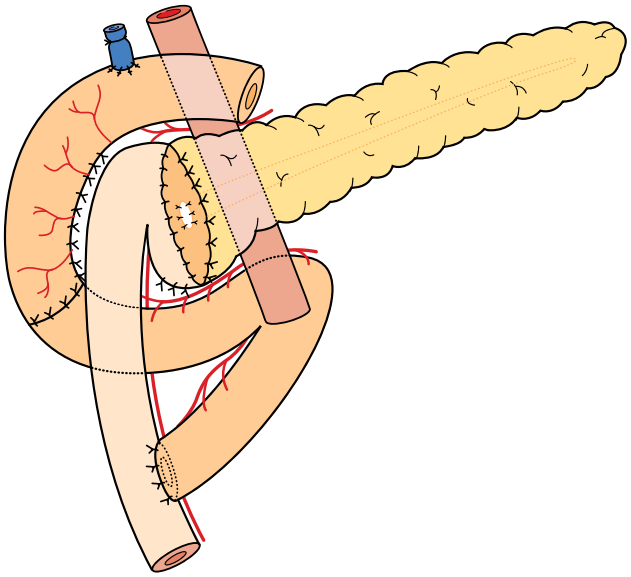

**Figure 81.2** Duodenum-preserving total pancreatic head resection including resection of peripapillary duodenum and CBD.

pancreatic head resection is performed by extirpating the tumor-bearing tissue from the pancreatic head or by resecting of the uncinate process (Fig. 81.3a,b). The application of a duodenum-preserving total pancreatic head resection with preservation of the peripapillary duodenum and the intrapancreatic CBD is associated with a higher frequency of local complications in the area of the peripapillary duodenum and the intrapancreatic CBD [18]. Two additional steps are needed to perform a lymph node (LN) dissection in association with DPPHR. Harvesting the anterior head LN is part of total head extirpation. The access to LN left of the superior mesenteric artery (SMA) and the LN along the hepatic and celiac arteries as well as in the hepatoduodenal ligament are performed in the same way as in the classical PD. Sampling the posterior head LN necessitates an additional step.

Duodenum-preserving total or subtotal pancreatic head resection has been applied in two-thirds of patients with a unifocal cystic neoplasm of the head of the pancreas (Table 81.3). Most total head resections have been performed for an IPMN, followed by SCA; in one third of cases a partial, subtotal head resection was performed, whereas in two-thirds of cases a total, parenchyma-sparing head resection was executed. Approximately 10% of the cystic neoplasms resected by local head resection have been reported to contain high-grade dysplasia or a minimal invasive cancer. The procedure-related morbidity includes: severe complications (Clavien-Dindo >3) 12.7%; POPF B + C 13.6%; reoperation 2.7%; rehospitalization 3.2%; 90-day mortality 0.4%. After a mean follow-up time of 62 months, a recurrence was observed in 2.9% of cases [18].

**PNET, low-risk $T_1$ periampullary cancer, inflammatory/biliopancreatic malfunction.

## Conclusion

For surgical treatment of benign and low-risk cystic neoplasms of the pancreatic head, the application of a local, parenchyma-sparing head resection offers major benefits to the patient by maintaining the quality of life. The advantages of the duodenum-preserving total or partial pancreatic head resection compared to PD are a low surgery-related early postoperative morbidity and a very low hospital mortality. Local pancreatic head resections are associated with an almost complete conservation of the endocrine and exocrine pancreatic functions in contrast to the metabolic consequences following PD. The risk of recurrence after local head resection of cystic neoplasms, including high-grade dysplasia and minimal invasive carcinoma, is very low provided frozen section investigation is used to exclude an advanced cancer.

# Pancreatic Middle Segment Resection

*Calogero Iacono*

*Department of Surgery, Unit of Hepato-Pancreato-Biliary Surgery, University of Verona, School of Medicine, Verona, Italy*

## Introduction

Pancreatic middle segment resection (PMSR; the Dagradi-Serio-Iacono operation) is a parenchyma-sparing operation allowing the removal of benign and low-grade malignant lesions from the neck and the proximal body of the pancreas (Fig. 82.1) [1]. Compared to pancreaticoduodenectomy (PD) and distal pancreatectomy (DP), PMSR is associated with a lower risk of postoperative diabetes and exocrine insufficiency. This operation also spares the spleen, with lower infective and thromboembolic complications, as well as the upper digestive and biliary tract, which is not possible in PD.

The first PMSR was performed in 1982 by Dagradi and Serio resecting a neuroendocrine tumor (insulinoma) located in the neck of the pancreas and was reported in the "*Enciclopedia Medica Italiana*" [2]. Subsequently, Iacono validated PMSR with endocrine and exocrine functional tests [3]. These findings were reported in several international reports demonstrating that there is almost no postoperative impairment of endocrine and exocrine functions when appropriate indications and technique are respected [2–4].

Furthermore, in the last decades, several authors have reported clinical series on patients who underwent PMSR demonstrating that this operation has become a standardized technique commonly applied in the surgical treatment of pancreatic diseases [2,4–9]. Currently, PMSR is performed worldwide either by traditional open surgery [2,4–9] or by using minimally invasive or robotic approaches [2,4,10–12].

## Indications

The prerequisites allowing PMSR include:

1) Benign lesions between 2 and 5 cm in size, when a simple enucleation entails risk of injury to the main pancreatic duct;
2) Cystic lesions not suitable for enucleation: symptomatic serous cystadenoma (Fig. 82.1), mucinous cystadenoma, solid cystic pseudopapillary tumors, selected cases of intraductal papillary mucinous neoplasm (IPMN);
3) Small tumors deeply located in the gland and therefore not eligible for simple enucleation (i.e., functioning endocrine tumors);
4) Focal chronic pancreatitis with isolated short stenosis of the pancreatic duct;
5) Solitary metastases in the pancreatic neck (i.e., from kidney cancer);
6) Metastatic pancreatic endocrine tumors in a multimodality program treatment.

## Contraindications

Contraindications include:

1) A distal pancreas stump of less than 5 cm in length;
2) Distal body–tail atrophy;
3) Malignant tumors (i.e., pancreatic ductal adenocarcinoma);
4) Neoplastic involvement from other organs (stomach, transverse colon);

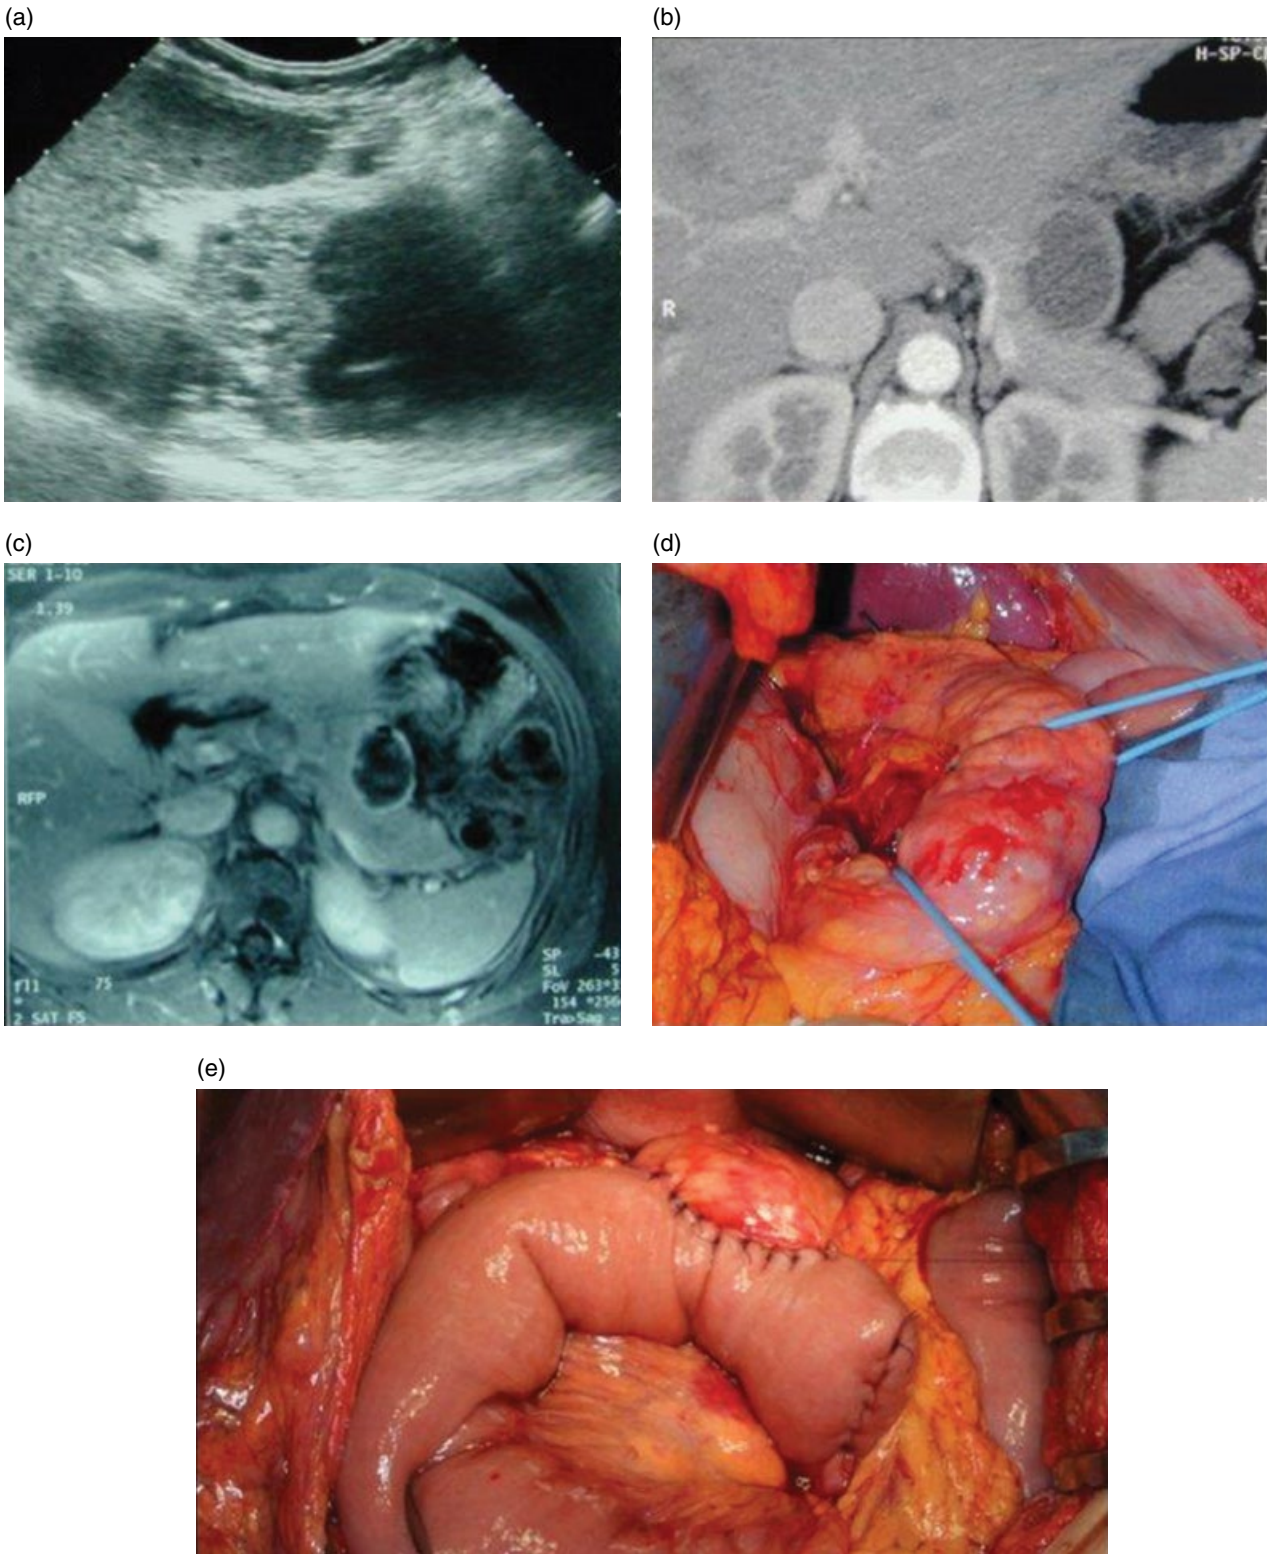

**Figure 82.1** A young patient with a symptomatic serous cystadenoma. Ultrasonograhy (a), computed tomography (b), and magnetic resonance imaging showing a cystic lesion at the neck of the pancreas (c). (d) Intraoperative aspect with evidence of the lesion localized at the pancreatic neck. (e) Final aspect of PMSR, the cephalic stump is sutured and the distal stump is anastomized by duct-to-mucosa pancreaticojejunostomy with a Roux-and-Y jejunal loop.

5) Diffuse or focal chronic pancreatitis not involving the central part of the gland;
6) When the arterial supply for the body–tail of the pancreas is exclusively from the transverse pancreatic artery (left branch of the dorsal pancreatic artery; type III according to Mellière and Moullé) [1].

## Technique

PMSR requires two steps, the first phase to resect the central pancreatic segment (isthmus, and/or proximal body) (Fig. 82.1d), followed by a second phase that includes reconstructive suture of the cephalic stump and performing digestive anastomosis with the distal stump (Fig. 82.1e) [1,3,13,14].

### Resection Step

PMSR requires a midline incision. Access to the lesser sac is achieved by division of the omentum from the transverse colon (the preferred procedure of the author) or of the gastrocolic ligament. The pancreatic gland is widely exposed by dividing the adhesions between the posterior surface of the stomach, retracted upward, and the pancreas.

This is followed by the intraoperative diagnostic workup performed with pancreatic ultrasonography to better identify the lesion or with fine needle biopsy for those cases with uncertain diagnosis.

Incision of the posterior peritoneum along the superior and inferior margin of the gland is carried out. The posterior surface of the pancreatic segment including the lesion is carefully dissected from the portomesenteric axis and the splenic vein and artery avoiding vessel injury.

This phase could be simplified by performing first a proximal dissection of the pancreas (mobilizing the pancreatic stump towards the left) and then exposing all the thin pancreatic veins, which can be more easily divided.

The identification of a large dorsal pancreatic artery might suggest that the left pancreatic blood supply is exclusively maintained by the transverse pancreatic artery. This vascular variation is, as previously mentioned, a clear contraindication to PMSR. Occasionally, it is necessary to isolate and mobilize the common hepatic artery to divide those branches originating from it (i.e., the dorsal pancreatic artery) that supply the central pancreas.

The extent of the resection of the central segment is limited on the right by the gastroduodenal artery and on the left so as to leave at least 5 cm of normal pancreatic remnant.

After stay sutures are placed in the superior and inferior pancreatic margins to indicate the proximal and distal limits of division, the pancreatic cephalic end is transected using either a scalpel or a stapler. For the distal side, the resection should be performed with a scalpel in order to avoid damage to the splenic artery or vein.

The resected pancreatic specimen is then sent to the pathologist to verify that the resection margins are adequate and to confirm the diagnosis by frozen sections. In the presence of malignancy, a PD or left splenopancreatectomy with lymphadenectomy should be performed.

Hemostasis of the two raw surfaces is achieved with interrupted 4/0 or 5/0 nonabsorbable stiches, and the integrity of the main pancreatic duct on the distal stump is preserved by the insertion of a small catheter.

In the presence of IPMN, a pancreatoscopy might be performed just after the resection of the main pancreatic duct in both stumps to rule out other ductal lesions.

### Reconstructive Step

When not stapled, the duct of Wirsung of the cephalic stump is sutured selectively with figure-of-eight nonabsorbable stitches; a row of interrupted, overlapping stitches of the mattress type is placed through the entire length of the stump and tied.

The distal stump is reconstructed using several techniques commonly applied in PD, which include an end-to-end telescopic or invaginated pancreaticojejunostomy (PJ), end-to-side PJ anastomosis, double PJ for both stumps, side-to-side PJ, duct-to-mucosa, using a Roux-en-Y jejunal loop isolated and brought up through the mesocolon; and pancreaticogastrostomy.

In the author's original report, a telescopic PJ with a double-layer suture was performed, while subsequently, an end-to-end invaginated PJ was carried out with a single layer of interrupted stitches. The posterior and anterior parts of the anastomosis was closed with stitches that were tied one after another. To avoid any damage to the duct of Wirsung, a small catheter was introduced before the stitches were inserted and was removed just prior to the stitches being tied. Currently, the author prefers to perform a duct-to-mucosa with a plastic transanastomotic catheter (Fig. 82.1e).

The operation is concluded with the construction of an end-to-side jejunojejunostomy with a double layer of absorbable stitches, about 50 cm distal to the pancreatic anastomosis. Finally, two soft drains are placed close to the head pancreatic stump and the pancreatic digestive anastomosis and pulled through the right and left flanks.

In a recent systematic review, the distal stump was usually dealt with by a PJ in about two-thirds of cases and by a pancreaticogastrostomy in another third of cases.

In the majority of patients, the proximal stump was closed by sutures with or without specific ligation of the main pancreatic duct [4].

## Results

Iacono et al. reported that between 1988 and 2010, 94 studies described 963 patients who underwent PMSR; among these a minimally invasive approach (laparoscopic or robot-assisted) was performed on 30 patients. In a sensitivity analysis considering only studies involving more than 10 patients, short-term postoperative morbidity was recorded in 45.3/% of patients, pancreatic fistula was the most frequent complication in about 40% of patients with only a minority of patients (~10%) presenting with a grade C fistula according to the International Study Group on Pancreatic Fistula (ISGPF) classification [4]. Other surgical complications were intraperitoneal abscess and fluid collections (often related to pancreatic fistulae), splenic vein thrombosis with secondary infarction of the spleen, abscess, pancreatitis, delayed gastric emptying, wound infection, and intestinal obstruction. Less than 5% of patients had an early reoperation for abdominal bleeding, pancreatic fistula, intra-abdominal collections, pancreatitis of the distal stump, or intestinal obstruction [4].

The in-hospital mortality rate was less than 1% and causes of death were heart disease, pancreatic fistula associated with portal vein thrombosis, hepatic failure, respiratory failure, and delayed hemorrhage.

Exocrine and endocrine insufficiencies were observed in about 10% and 5% of patients, respectively.

Disease recurrence after PMSR was about 3%, mainly because of IPMN or inappropriate indications; when the correct indications were respected the rate of local recurrence was almost zero [4].

More importantly, in a meta-analysis comparing PMSR to DP, PMSR was associated with longer operating times and hospital stay but less blood loss during the surgical procedure. Nearly half of the patients who underwent PMSR suffered from postoperative morbidity, in contrast to less than one third of those who underwent DP. Overall morbidity was significantly higher after PMSR, as was the incidence of pancreatic fistula. Despite increased morbidity, PMSR was associated with a significant reduction in the risk of reoperation and with similar in-hospital mortality rate. Interestingly, the incidence of long-term complications was lower after PMSR than DP for both endocrine and exocrine failures [4].

## Conclusions

PMSR assures that the functional parenchyma is preserved as much as possible, and avoids the infective and thrombotic complications commonly associated with splenectomy. Despite the high risk of pancreatic fistula, PMSR has demonstrated low rates of postoperative reoperation, and endocrine and exocrine insufficiency. Following precise anatomic and pathologic indications, PMSR is a consistent and precise surgical technique for the treatment of benign and low-grade malignant pancreatic disease, especially in young patients.

The open approach is still the standard for CP, but minimally invasive surgery, especially the robotic approach, has an emerging role in experienced centers.

It is the author's opinion that PMSR should be included in the technical skills of a modern pancreatic surgeon, but to achieve safety and good results, adherence to the proper indications and experience in pancreatic surgery are recommended.

## Introduction

Cystic neoplasms of the pancreas are increasingly diagnosed due to improvements in modern imaging modalities [1]. Nearly 3% of all patients undergoing abdominal computed tomography (CT) will have an incidentally detected pancreatic cystic lesion. This number varies significantly according to the size of the cyst and the threshold of radiologists to report them. While some of these cysts are benign, most carry some risk of malignancy, and all have the potential to cause symptoms. Diagnosis is often unclear despite multiple strategies including CT, endoscopic ultrasound (EUS), magnetic resonance cholangiopancreatography (MRCP), endoscopic retrograde cholangiopancreatography (ERCP), and fine needle aspiration (FNA) with cytology and cyst fluid biochemical and DNA analysis. A definitive diagnosis may be difficult without surgical resection. Treatment of these lesions must therefore balance the diagnostic and therapeutic benefit against the significant morbidity and potential mortality of surgical resection. If patients require surgical treatment, techniques associated with lower morbidity must be considered. In select cases, cyst enucleation is an effective option with lower morbidity and mortality than pancreatic resection [2–6].

## Indications

A major challenge of pancreatic cyst enucleation is appropriate patient selection. Careful characterization of the cyst is necessary to determine if an indication exists for enucleation. Selection can be done with thorough preoperative evaluation. The first step is cross-sectional imaging (CT or MRI-MRCP with thin slices). Additional diagnostic tests may help in diagnosis and oncologic risk stratification, including EUS with FNA for cyst fluid cytology and biochemical/DNA analysis. Fig. 83.1 shows MRCP of a branch-duct intraductal papillary mucinous neoplasm (BD-IPMN) eligible for cyst enucleation. Radiographic and biologic workup must take place in order to rule out malignancy [6], vascular involvement, and metastases [7], as these are all contraindications to enucleation.

Many lesions amenable to resection also may be amenable to enucleation. Patients who are symptomatic or have signs of malignant/premalignant pancreatic lesions generally should undergo surgical resection. Symptomatic pancreatic cysts should be resected, not only to alleviate symptoms, but also because of the increased risk of malignancy associated with symptomatic lesions [8]. If evidence strongly suggests the lesion is malignant, an oncologic resection should be performed without consideration of enucleation. Findings consistent with malignancy include lymphadenopathy, distant metastases, mural nodules, and solid components [6]. Lesions with uncertain diagnosis or lesions that are premalignant may be appropriate for cyst enucleation. When no oncologic need exists for traditional pancreatic resection, enucleation can avoid unnecessary sacrifice of pancreatic parenchyma minimizing the risk of pancreatic exocrine and endocrine insufficiency [9,10].

Although pancreatic neuroendocrine tumors (PanNET) are the most common lesion removed via cyst enucleation, many other cysts types also are suitable for this method of resection [11]. These cysts include, but are not limited to, mucinous cystic neoplasms (MCN), BD-IPMN [12], serous cystic neoplasms (SCN), and

**Table 83.1** Indications for pancreatic cyst enucleation.

| Pathology | Criteria |
|---|---|
| Nonfunctional PanNET | <2 cm, N0M0 |
| Functional PanNET | if technically feasible |
| MCN | if likely benign; <4 cm; no mural nodules |
| BD-IPMN | rapidly increasing size; high-grade atypia; mural nodules |
| SCN | only if symptomatic |
| SPN | if technically feasible and no evidence of malignancy |

solid-pseudopapillary neoplasms (SPN) [5,13]. Table 83.1 lists criteria for enucleation based on specific pathology. Cyst enucleation is considered the procedure of choice for most functional PanNET as long as technically feasible [6,14]. The prohibiting factor is often size, defined as greater than 3–4 cm by multiple authors [15,16]. Nonfunctional PanNET may be enucleated if less than 2 cm and are N0M0 radiographically [6,16,17]. If lymph node involvement is suspected, oncologic resection should be performed. Nonfunctional lesions less than 1 cm may be observed under a structured surveillance program. Some authors argue that size is not prognostic as up to one quarter of nonfunctional PanNET less than 2 cm will have lymph node metastases [18]. This risk may be unacceptably high indicating a need for lymph node sampling in all nonfunctional PanNET [19]. Conversely, other authors have shown no prognostic value of nodal status in an analysis of 3,851 patients with PanNET [20].

The Sendai and Fukuoka guidelines address indications for surgical resection of MCN and BD-IPMN [8,21]. MCN should be removed and may be enucleated if they appear benign on imaging, are less than 4 cm, and do not contain mural nodules. The indications for resection of BD-IPMN are more controversial. These lesions are often observed, but may require resection if high-risk features exist such as rapidly increasing size, high-grade atypia, associated main-duct dilation (early main-duct involved IPMN) and mural nodules. Because SCN carries a very low risk of malignancy, they are generally only resected if the diagnosis is in doubt or if symptomatic. However, if allowed to grow, enucleation may no longer be technically possible. Thus, the decision for surgical management should be made on an individual basis.

If surgical resection is indicated, assessment of patient fitness must be undertaken. This assessment includes evaluation of comorbid conditions, nutritional status, and psychosocial health. Patients should be assessed for fitness for both enucleation and formal resection since the operation may convert to resection based on intraoperative findings. Fitness is not only an important factor in determining patient tolerance of the procedure, but also in determining life expectancy. Patients with limited life expectancy may be more likely to die of alternate causes than cyst-related causes. In this case, a surgical procedure would not extend their life and would put them at undue risk of surgical complications.

## Contraindications

Table 83.2 lists the major contraindications to pancreatic cyst enucleation. Patients with known or suspected malignancy should not undergo enucleation and instead should have an oncologic resection with negative margins and lymph node dissection [11,22]. This includes lesions with high risk of progression to malignancy such as main-duct IPMN (MD-IPMN). Diagnosis of malignancy is based on symptoms, radiographic images, cytopathology, and DNA profile. Despite these multiple diagnostic tools, a definitive diagnosis of malignancy is often difficult to achieve preoperatively. In those cases, consultation with experts and the patient are necessary to determine the best course of action. The surgeon may elect to begin the operation as a parenchymal-sparing enucleation until he/she encounters evidence of malignancy intraoperatively. Malignant cysts can be difficult to dissect due to adherence to surrounding parenchyma. Whether or not the surgeon suspects malignancy,

**Table 83.2** Contraindications to pancreatic cyst enucleation.

| Contraindications |
|---|
| Suspected malignancy or high-risk lesions (i.e., MD-IPMN) |
| Pancreatic duct involvement/close proximity |
| Location in tail |
| Large size |
| Multifocality |
| Poor patient fitness |

intraoperative frozen section pathology confirmation of invasive cancer necessitates conversion to formal pancreatic resection.

The lesion's proximity to the main pancreatic duct is an important technical consideration for enucleation. If the cyst involves the main duct, enucleation cannot be achieved without transection of the duct and, therefore, is contraindicated [17,23]. Additionally, cysts involving the main duct, specifically main-duct IPMN (MD-IPMN), are at a greater risk of conversion to invasive cancer and, thus, require formal resection [8]. Enucleation also may be contraindicated based on the cyst's close proximity to the main duct. Risk of injury and subsequent pancreatic fistula is greatly increased (60%) when the cyst is within 2 mm of the duct [23,24]. Distance of 2–3 mm between the cyst and the main pancreatic duct is safe for cyst enucleation and can be determined with preoperative imaging such as MRCP and EUS [3,25]. During surgery, this safe distance is confirmed with intraoperative ultrasound (IOU). Location of the cyst within the pancreas is also important when considering enucleation. If located in the tail of the pancreas, enucleation does not save much parenchyma compared to distal pancreatectomy and thus, would offer no benefit.

The mean size of enucleated pancreatic cysts is 2.4 cm [11]. This relatively small size is due to the relationship between larger size and higher likelihood of malignancy [26]. Enucleation of larger cysts also may sacrifice too much pancreatic parenchyma for this procedure to be beneficial over formal resection. The size at which enucleation may be safely performed is controversial and differs based on pathology. Four centimeters is arguably the cut-off at which enucleation should be performed due to increased risk of recurrence of lesions greater than 4 cm [3,11,17,23]. Data suggest that this size limit may be increased to 6 cm in SCN and MCN without increasing recurrence, morbidity, or mortality [27]. Multifocality is a relative contraindication due to incremental risk of pancreatic fistula with each enucleation. Similar to size, multifocality of cysts also requires a larger amount of parenchymal resection without benefit over formal resection. Depth of the cyst is a relative contraindication for enucleation. More extensive dissection is required for deeper lesions making their dissection more tedious and at times, making formal resection the more appropriate choice [4,5,22].

## Surgical Technique

Pancreatic cyst enucleation can be performed minimally invasively (laparoscopically/robotically) or open and is based on surgeon preference. Currently, enucleations are being performed minimally invasively in approximately one quarter of cases, and are associated with shorter recovery times and similar morbidity and mortality as open enucleations [11,28,29]. The steps of the procedure remain the same regardless of whether minimally invasive or open techniques are used. After entrance into the abdomen, the liver, hemidiaphragms, and all peritoneal surfaces are surveyed for occult metastatic disease. IOU is used to identify intraparenchymal metastases, thus completing the survey of the liver. The pancreatic cyst is then exposed using the Kocher maneuver for head lesions, and entrance into the lesser sac for body and tail lesions. Ultrasound can aid in both location and careful characterization of the cyst [30]. The distance between the cyst and the main pancreatic duct is calculated to determine safety of performing enucleation. Concerning features such as mural nodules and solid components are identified with IOU. After ultrasound evaluation, enucleation may be aborted due to suspicion for malignancy or duct proximity.

Superficial lesions with extrapancreatic components are the most amenable to cyst enucleation, as significantly less dissection is required to free them from surrounding parenchyma. Ultrasound guidance can assist in locating deeper lesions. Overlying parenchyma is dissected away until the lesion is identified. Frozen section pathology is always performed; and if invasive disease is discovered, lymph nodes must be retrieved and negative margins must be achieved for maximal survival benefit. Parenchyma sparing must be balanced against but never compromise oncologic principals. BD-IPMN have communicating ducts that must be identified and ligated to prevent leaks (Fig. 83.2). After removal of the cyst, the cavity is searched for small vessels and ducts, which are ligated with clips, ties, or tissue coagulation devices. Thermal injury can result from cautery and should be avoided when the main duct is near. Main pancreatic duct integrity can then be evaluated with ultrasound and secretin stimulation. Some surgeons close the pancreatic parenchyma with absorbable suture [31] and many routinely leave surgical drains.

## Postoperative Management

Postoperative management of patients following cyst enucleation is the same as any pancreatic resection. If surgical drains are placed intraoperatively, drain amylase should be followed. Drain amylase should be measured on postoperative day one (POD #1) [6]. Drain amylase elevated greater than three times the serum level indicates a pancreatic fistula [32]. Growing evidence suggests that in patients with low POD #1 drain amylase levels, drain removal by POD #3 dramatically reduces the incidence of a pancreatic fistula [27,28,30,31].

Management of pancreatic fistulas depends on grade and surgeon preference. No standardized management plan exists due to lack of strong evidence. Treatment of diet ranges from continued normal diet, to nothing by mouth with total parenteral nutrition [6]. Other management options include endoscopic pancreatic sphincterotomy. This method has been practiced in patients with prolonged pancreatic fistula and may lead to improved healing time due to the decreased duct pressure [33].

Parenteral octreotide may be used in the immediate postoperative period to decrease the rate of pancreatic fistula [6,12,34]. A Cochrane review revealed decreased rate of fistulas, but no decrease in mortality, hospital stay, or rate of reoperation [35]. Those prescribing prophylactic octreotide endorse 7 days of use. Authors of the Cochrane review recommend routine use in patients undergoing pancreatic resection because the potential benefit outweighs the low risk and low cost of the medication.

## Complications

Pancreatic fistula is the major morbidity following enucleation and occurs in 18–61% of cases (see Table 83.3). However, the majority of the fistulas are Type A without clinical significance. Postoperative pancreatic fistulas can be difficult to treat because of their many associated problems. Intra-abdominal infection and/or hemorrhage, delayed gastric emptying, increased hospital stay, increased readmission, and the need for reintervention have all been associated with pancreatic fistula [4,22]. Specific risk factors for development of pancreatic fistula include soft pancreatic texture with absence of fibrosis, main pancreatic duct (MPD) diameter of less than 3 mm, cyst distance less than 2 mm from the duct, and cyst depth of greater than 3 mm (see Table 83.4) [3,25,33]. New York Heart Association class II or III and procedure time greater than 180 minutes were also recently found to be independent risk factors for fistula formation following enucleation [4]. Multiple studies have attempted to identify methods for decreasing risk of fistula. In addition to the previously described prophylactic octreotide, a study by Kiely et al. demonstrated a decreased fistula rate (50% to 27%) by adding intraoperative ultrasound and closure of the space after cyst removal [31]. Preoperative nasopancreatic stenting is another approach that allows surgeons to palpate and directly visualize the duct, thereby avoiding MPD injury and fistula formation [4,5,36–38]. If injury to the MPD is suspected, a jejunal Roux-en-Y onlay technique can be used to decrease the risk of pancreatic fistula development. This technique can also be used in management of inadequate branch-duct ligation.

## Outcomes

Table 83.3 displays contemporary pancreatic cyst enucleation outcomes from studies conducted since 2007. Six case-control and eight case series reported overall morbidity and mortality of cyst enucleation to be 12–67% and 0–1% (with one 7% outlier), respectively. Although recent, small case-control studies ($n$ = 7–127) show no difference in morbidity and mortality as compared to formal pancreatic resection, a larger analysis by Parikh et al. employing the American College of Surgeons National Quality Improvement Program (ACS NSQIP), reported lower morbidity and mortality of cyst enucleation [39]. Compared to pancreatoduodenectomy and distal pancreatectomy, enucleation had 0.1 and 0.17 times the odds of mortality, respectively. Pancreatic fistula occurs at a similar rate in both enucleation and formal resection. Despite the same number of fistulas, some

**Table 83.3** Pancreatic cyst enucleation case-control/case series studies from 2007–current. Contemporary case-control and case series studies from the last decade are displayed. Outcomes of case-control studies show both the rate of occurrence and an arrow indicating comparison of cyst enucleation to formal resection.

| Distance of cyst from pancreatic duct <2 mm |
| Cyst depth >3 mm |
| NYHA class II or III |
| OR time >180 min |

studies suggest that fistulas after enucleation are less severe and require less intervention than fistulas following formal resection [17]. Patients undergoing enucleation also utilize less healthcare resources. Although length of hospital stay may be comparable between groups, ICU stay, operative time, and pancreatic insufficiency are decreased in cyst enucleation patients. Additionally, oncologic outcomes for premalignant lesions are no different between enucleation and formal resection. This fact is demonstrated by the similar rates of recurrent tumor and 5-year overall survival between groups [17,40].

## Contraindications

Appropriate patient selection is one major challenge in pancreatic cyst enucleation. This procedure is beneficial for a very select group of patients. Indications for enucleation versus close observation or nonparenchymal-sparing pancreatic resection are specific and exclusive. Table 83.1 displays the limited criteria for performing enucleation in contrast with Table 83.2, which lists several excluding factors. Poor outcomes are often attributed to improper patient selection. Pancreatic fistula results in patients with risk factors listed in Table 83.4. Unfortunately, it is often difficult to definitively categorize patients as appropriate for cyst enucleation prior to pathologic evaluation of the surgical specimen. If the evaluation reveals malignancy, the patient must then undergo additional surgical treatment.

## Cyst Ablation

Pancreatic cyst ablation is an alternate treatment option in which cysts are lavaged with ethanol or a chemotherapy solution. Potential candidates for cyst ablation are high-risk surgical candidates or those who refuse surgery [8]. Ablation may also be used as a bridge to surgery when patients are already receiving EUS with FNA for indeterminate lesions [41]. Patients with coagulopathies should not undergo ablation as passage of the needle into the cyst may cause bleeding. Most endoscopists use the cut-off of international normalized ratio (INR) less than 1.5 and platelets greater than 50,000 [41,42].

The procedure begins with a complete endoscopic ultrasound exam. The cystic lesion is located and characterized. Cysts must be greater than 2 cm in order to safely target. Multiple septations are another barrier to ablation. If the cyst contains multiple septations in which not all compartments communicate, complete drainage will not be possible. Unilocular or oligolocular cysts with two to six compartments are therefore the preferred lesion [41]. The MPD should be carefully evaluated to confirm absence of communication with the cyst. The ablative agent will be lost though the communicating duct if the cyst is connected to the main duct [42]. Some authors advocate preoperative ERCP to determine the cyst's ductal relationship [41]. IOU can also serve as a final opportunity to diagnose overt cancers with peripancreatic invasion. Ablation may then be aborted.

Following a complete IOU examination, a 22-gauge needle is passed transduodenal or transgastric into the cyst. This passage is done under direct ultrasound guidance. The cyst is then aspirated until collapse. If the cyst fluid is thick and mucinous, the clinician may be unable to complete cyst aspiration [41]. Formal resection must be considered if ultrasound characterization or cyst fluid analysis is consistent with invasive cancer. With the cyst collapsed, 99% ethanol is injected into the cyst, which is then lavaged for 3–5 min [42–44]. Following lavage and removal of ethanol, some endoscopists advocate the use of paclitaxel injection into the cysts as an additional ablative agent [41]. The volume of paclitaxel used is equal to that of the cyst fluid aspirated. If the cyst is in communication with the main pancreatic duct as previously described, the ablative solution will not remain in the cyst during this time. Acute pancreatitis is a major complication of pancreatic cyst ablation. The ablative agent may trigger acute pancreatitis by extravasation into the parenchyma or exposure of the ductal system via cyst communication.

Existing literature is heterogeneous with varying rates of cyst resolution, 33–79% [41,42,44,45]. Data suggest a higher rate of resolution with the combined use of ethanol and chemotherapy agents. Oh et al. found 62% complete resolution of pancreatic cysts using this method [41]. Additional studies have shown greater decrease in size and higher rates of cyst resolution with multiple ablation sessions [43]. Resolution is most often based on radiographic evidence as shown in Fig. 83.3 [42]. Resolution may be dependent upon cyst type, with mucinous cysts having much lower rates of resolution [45]. Other predictive features include cyst size, fluid volume,

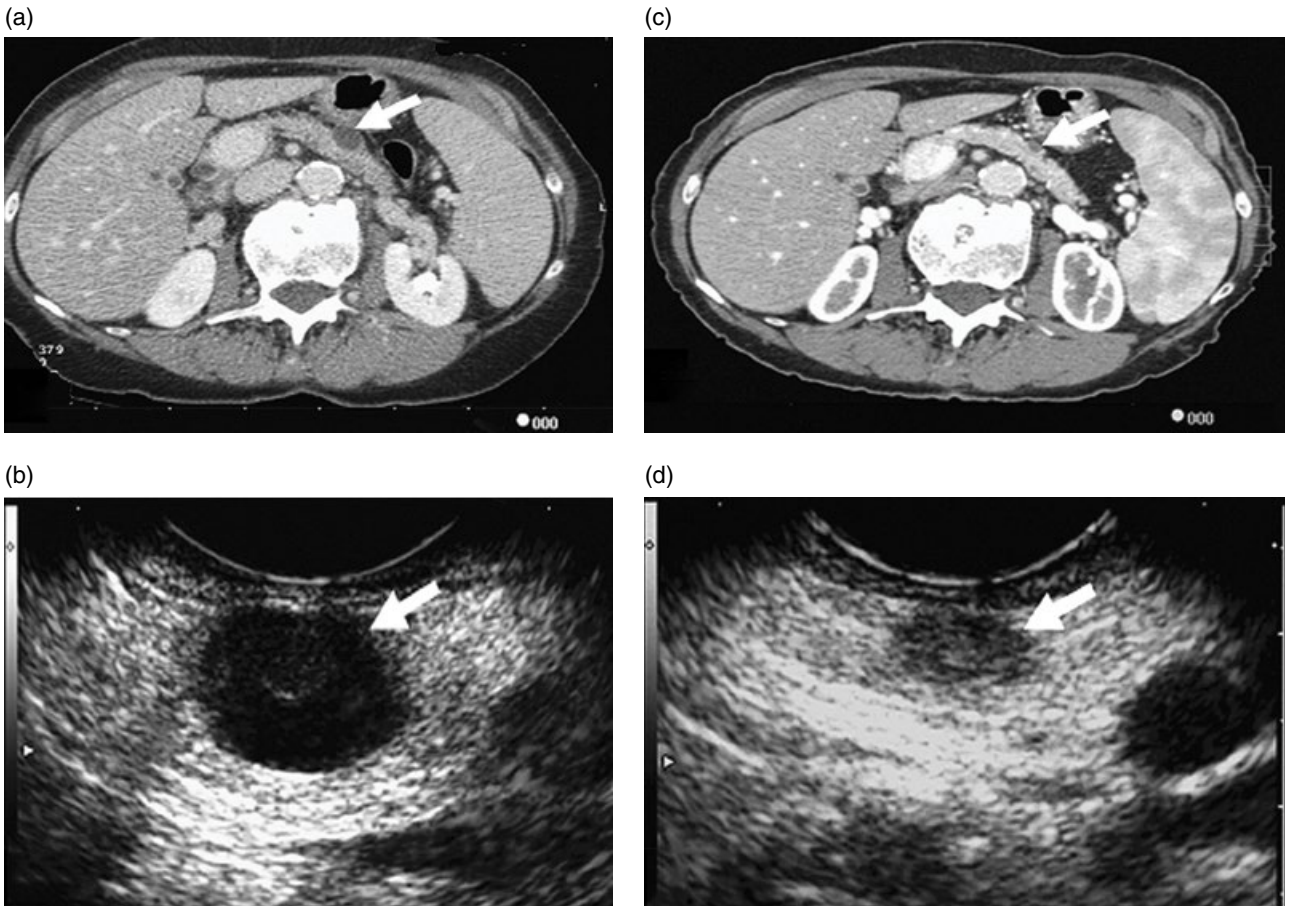

**Figure 83.3** Radiographic evidence of cyst ablation after ethanol lavage. (a) CT scan of the abdomen showing a 13 mm cyst in the body of the pancreas (white arrow). (b) Ultrasound of the same pancreatic cyst. (c) and (d) CT scan and ultrasound of the same patient 3 months after ablation. The cyst measures 8 mm. *Source:* DeWitt et al. 2009 [42]. Reproduced with permission of Elsevier.

locularity, and presence of mural nodules. Less than 14 mL of cyst fluid and less than 3.5 cm diameter on ultrasound examination were specifically shown to be predictive of cyst resolution in recent published data [41]. Of those patients who do achieve complete cyst resolution, data are even less clear as to which patients will have recurrence of their cyst. A small prospective study followed patients 13–39 months after ablation and found no recurrence in any patient who had complete radiographic cyst resolution [46]. Additional studies are needed to better quantify cyst recurrence. Although uncommon, multiple complications have been reported including fever, abdominal pain, and acute pancreatitis. Abdominal pain is reported in up to 20% of patients, and acute pancreatitis occurs in 4.5–10% of cases. Intracystic hemorrhage, bowel perforation, and severe acute pancreatitis are even less commonly reported [41,42,45].

Cyst ablation is considered an experimental therapy and should be performed in a very select group of patients. Additional studies are required to further characterize the utility of this procedure and appropriate surveillance of patients following the procedure. Although multiple studies have shown complete or partial resolution of cyst radiographically, far fewer cysts have been resected post-ablation for pathologic evaluation [42,44,45]. It is therefore unclear as to whether these cysts reach true histopathologic resolution.

## Conclusions

Pancreatic cyst enucleation is an alternate surgical option for small, low-risk cystic lesions. Several factors make each pancreatic cyst more or less optimal for enucleation. Main-duct involvement or close proximity increases the rate of postoperative fistula development. Enucleation of large, multifocal, or tail cysts does not yield significant parenchymal preservation and therefore, is not beneficial to perform. Patients considered for enucleation must receive appropriate preoperative evaluation and must be adequately fit. Postoperative pancreatic fistula is the major morbidity of enucleation

but occurs at the same rate as in formal resection with fewer grade B or C fistulas. Enucleation is associated with less utilization of healthcare resources and similar or lower morbidity and mortality without compromising local recurrence rates or long-term survival. Lastly, cyst ablation is an alternate technique that may be employed in patients unwilling or unable to tolerate enucleation or resection.

## Introduction

Pancreatic cystic neoplasms (PCN) were previously considered rare. With the increased use and improved sensitivity of cross-sectional imaging, PCN are identified more frequently and often diagnosed incidentally [1]. The prevalence of incidental pancreatic cystic lesions identified by multidetector computed tomography and magnetic resonance imaging ranges from 2.4% to 13.5% in asymptomatic patients and increases with age [2–4]. Despite the improved detection of these pancreatic cysts, radiologists fail to document their presence 69% of the time in the radiology report [4]. This underreporting may explain the discrepancy between the current prevalence of pancreatic cysts and an autopsy study reporting that 24.3% of people harbor pancreatic cysts at time of death [5].

The most common subtypes of PCN are intraductal papillary mucinous neoplasm (IPMN), mucinous cystic neoplasm (MCN), serous cystic neoplasm (SCN), and solid-pseudopapillary neoplasm (SPN). These PCN comprise a diverse group of tumors with a wide range of malignant potential, making the management quite challenging. The management of pancreatic cysts is driven by the presumed cyst subtype, which is based primarily on age at presentation, gender, imaging cyst characteristics, and cyst fluid analysis. While together this information is not fully diagnostic, the pancreatic cyst subtype is accurately diagnosed the majority of the time, guiding management of the cystic lesion [6].

The decision between operative resection and surveillance imaging of a PCN involves weighing the risk of surgical resection against the risk of malignant progression (or presence of malignancy). Although pancreatic resection has become safer with a low risk of mortality at high-volume centers, postoperative morbidity continues to remain high at roughly 40% [1,7,8]. While all PCN should be evaluated, surgical resection should only be recommended when appropriate. Most pancreatic cysts are asymptomatic, small (<2 cm), and benign in nature. In these lesions, the risk of surgical resection is generally greater than the risk of malignant progression, making routine surveillance appropriate. In lesions that are symptomatic, have malignant potential, or are concerning for frank malignancy, surgical resection is recommended. In this chapter, we will discuss the standard, open surgical management of each of the PCN subtypes.

## Pancreatic Cystic Neoplasm Subtypes, Surgical Indications, and Operative Intervention

PCN can be broken down into four subtypes: IPMN, MCN, SCN, and SPN. PCN are further classified by the type of cystic fluid they produce: mucin-producing versus nonmucinous. While SCN and SPN are nonmucinous cystic lesions, IPMN and MCN are considered mucinous cystic lesions. Approximately 10% of SPN have metastatic potential and both IPMN and MCN can be precursor lesions to invasive pancreatic cancer or harbor an invasive component. With an increase in the proportion of incidentally discovered PCN over time, the number of pancreatic resections for PCN has also increased. IPMN is the most common pancreatic cystic lesion resected (38%) followed by MCN (23%), SCN (16%), and SPN (3%) [1]. More importantly, the proportion of resected malignant neoplasms has decreased over time, likely reflecting earlier diagnosis and surgical resection of these premalignant lesions [1].

## Intraductal Papillary Mucinous Neoplasm

IPMN is an intraductal mucin-producing neoplasm and precursor lesion to invasive pancreatic cancer, accounting for the majority of PCN resected at roughly 38% [1]. IPMN has a male predominance with a median age of presentation at 67 years old [9]. IPMN is thought to be a precursor lesion to invasive pancreatic cancer, progressing from low-grade dysplasia to high-grade dysplasia to invasive cancer. In addition, IPMN is a "field defect" with the entire pancreatic duct at risk of developing IPMN or pancreatic ductal adenocarcinoma. IPMN can be categorized as main-duct (MD-IPMN), branch-duct (BD-IPMN), or mixed IPMN, which behaves in a similar way to MD-IPMN. The risk of malignancy is much higher with main pancreatic duct involvement, making the classification between MD-IPMN, BD-IPMN, and mixed IPMN clinically significant. MD-IPMN or mixed IPMN are associated with 62.2% and 57.6% risk of high-grade dysplasia and 43.6% and 45.3% risk of invasive cancer, respectively [6,10]. BD-IPMN is associated with a lower risk of high-grade dysplasia (24.4%) and invasive cancer (16.6%) [6,10].

Based on the Fukuoka International Consensus Guidelines 2012, the presence of "high-risk stigmata," including obstructive jaundice in a patient with a cystic lesion in the head of the pancreas, enhancing solid component on cross-sectional imaging, or main pancreatic duct ≥10 mm, warrant surgical resection. The presence of "worrisome features," including cysts ≥3 cm, thickened enhanced cystic walls, nonenhanced mural nodules, main pancreatic duct size 5–9 mm, abrupt change in the main pancreatic duct caliber with distal pancreatic atrophy, and lymphadenopathy, warrant further evaluation with endoscopic ultrasound (EUS) [10]. If EUS identifies a definite mural nodule, main duct features suspicious for involvement, or cytology suspicious or positive for malignancy, pancreatectomy should be performed in patients fit for surgery. If no "worrisome features" are present, no further workup is recommended, but surveillance is required [10].

In the setting of surgical resection for IPMN, pancreaticoduodenectomy (PD) is performed the majority of the time (71%) followed by total pancreatectomy (15%), distal pancreatectomy (12%), and central pancreatectomy (2%) [9]. Operative intervention for IPMN can be complex at times. In the setting of MD-IPMN, if invasive pancreatic cancer is identified at the time of resection, a partial pancreatectomy should be performed to resect only the invasive cancer, as it will dictate survival. If no invasive component is identified, pancreatectomy to resect the main duct component should be performed with intraoperative frozen section to achieve margins free of high-grade dysplasia. Additional margins should be taken if the frozen specimen returns as high-grade dysplasia until achieving at least moderate-grade dysplasia. Occasionally, achieving an adequate margin may require performing a total pancreatectomy. In a younger and relatively healthy patient, a total pancreatectomy should be considered if the MD-IPMN seems to involve the entire gland, as the risk of the remnant developing pancreatic cancer may be quite high. In the setting of BD-IPMN, segmental pancreatectomy should be performed to resect the lesion with the highest oncologic risk, especially in the setting of multifocal BD-IPMN [10]. Unfortunately, clinically significant IPMN recurs in at least 20% of patient undergoing surgical resection [11]. Hence, close postoperative surveillance with cross-sectional imaging is imperative, as surgical intervention may be required in the future.

## Mucinous Cystic Neoplasm

Accounting for 23% of resected PCN, MCN is a mucin-producing cystic lesion of the pancreas and precursor lesion to invasive pancreatic cancer [1]. MCN occurs almost exclusively in females (95%) with the median age of diagnosis in the mid-40s [12–17]. MCN are precursors to invasive pancreatic cancer with carcinoma *in situ* identified in 3.9–6% of resected lesions and invasive cancer present in 4.4–16% of resected lesions [12–15,18]. Malignant transformation from MCN to mucinous cystic neoplasm with an associated invasive component is concerning with older age, larger lesions (≥4 cm), presence of mural nodule, cyst wall irregularity and thickening, and elevated cancer antigen (CA) 19-9 in cyst fluid [10,13,14,18–20]. Malignant transformation is rarely present in MCN <4 cm without mural nodules.

Given the unknown natural history of MCN and the young age of those affected by MCN, surgical resection is currently recommended to prevent progression to invasive pancreatic cancer in patients who are appropriate surgical candidates. The great majority of MCN is located in the pancreatic tail, making distal pancreatectomy with or without splenectomy the most common surgical resection performed for MCN [12,13,15–17]. In patients with small lesions and low risk of malignancy, spleen-preserving distal pancreatectomy is a reasonable option as well [13]. Of note, great care should be taken to prevent rupture of the cyst during surgical resection in order to prevent tumor seeding and spread. The 5-year disease-specific survival for noninvasive MCN is excellent at 100% and lower at 26–76% for those with invasive cancer [12–15,18]. Postoperative surveillance with cross-sectional imaging is not necessary for patients with benign MCN [6]. On the other hand, those with mucinous cystic neoplasm with an associated invasive

component will require routine surveillance with cross-sectional imaging similar to that of patients with pancreatic ductal adenocarcinoma [6].

### Serous Cystic Neoplasm

SCN are benign PCN and have an extremely low risk of malignant transformation to serous cystadenocarcinoma, accounting for roughly 16% of resected PCN [1,21–23]. SCN or serous cystadenomas occur predominantly in females (70–75%) and in the seventh decade of life (mean age 61 years old) [22–24]. While they rarely undergo malignant transformation, SCN can be locally aggressive in nature. Tumor diameter and tumor location in the head of the pancreas have been demonstrated to correlate with a locally aggressive behavior of SCN [23,24]. Large SCN (≥4 cm) are more likely to be symptomatic and have an accelerated rate of growth at 1.98 cm per year compared to lesions <4 cm with a growth rate of 0.12 cm per year [22]. Furthermore, the growth rate of SCN has been demonstrated to increase after the first 7 years of baseline evaluation (0.1 cm per year during the first 7 years after baseline evaluation to 0.6 cm per year after the first 7 years) [25].

Given the benign nature of SCN, surgical resection should be considered when the cystic lesion causes symptoms or is difficult to differentiate from a mucin-producing cystic lesion [26,27]. While SCN can affect any portion of the pancreas, surgical resection largely depends on the location of the lesion, attempting to preserve as much pancreas and pancreatic function as possible. In several large series, patients with SCN underwent PD with similar frequency as distal pancreatectomy with or without splenectomy [22–24]. Surgical resection is considered curative with no postoperative surveillance required.

### Solid-Pseudopapillary Neoplasm

SPN are rare, indolent pancreatic neoplasms with the potential to metastasize, accounting for roughly 3% of resected PCN [1]. SPN occur predominantly in young females (85%) with median age at presentation in the third and fourth decades of life [28–32]. SPN are usually indolent in nature but have the potential for metastatic spread. Approximately 10% of patients with SPN will have locoregional or metastatic spread involving the liver, portal/mesenteric vessels, lymph nodes, or spleen [28,29,31,32]. Tumor size >5 cm, focal discontinuity of tumor capsule on cross-sectional imaging, and Ki-67 positivity have all been noted to be suggestive of metastases [29,33,34].

Surgical resection with negative margins (R0 resection) is recommended for all patients with SPN given the metastatic potential of these tumors. SPN are usually located in the pancreatic tail or body, requiring a distal pancreatectomy and splenectomy [28,29,31,32,35]. Although incomplete gross resection (R2) or incomplete microscopic resection (R1) are associated with a worse outcome, it may still benefit the patient, and long-term prognosis with complete surgical resection of SPN is excellent with 5-year survival at 95% [32]. At times, locally advanced tumors are technically not resectable. However, metastases should not preclude resection as good long-term outcomes can still be achieved with aggressive surgical resection of the primary tumor and metastatic lesions [32].

## Pancreatectomy

The surgical approach to each of these PCN subtypes is dependent primarily upon the location of the cystic lesion. Preoperative evaluation, operative considerations for each of the major pancreatic resections, and postoperative management will be discussed in this section.

### Preoperative Evaluation

Prior to operative intervention, the patient should be evaluated and assessed regarding the medical risks of undergoing a major abdominal operation. Given that PCN range widely in malignant potential, the benefits of surgery should be weighed heavily against the risks, such as patient medical comorbidities, before proceeding to the operating room. In addition, patients should be assessed and treated for pancreatic insufficiency preoperatively, which occasionally occurs in the setting of PCN and requires pancreatic enzyme replacement. When total pancreatectomy is considered preoperatively, the patient should be evaluated by an endocrinologist prior to surgery, both to establish care and set expectations regarding the management of brittle diabetes. Establishing this relationship preoperatively allows for close diabetes management postoperatively.

### Pancreaticoduodenectomy

PD (also known as a Whipple procedure) is performed for PCN involving the head or neck of the pancreas. Given the integral relationship between the head of the pancreas, distal common bile duct, and duodenum, resection of all three en bloc is generally required for a lesion involving the head of the pancreas. A small portion of the distal stomach, the entire duodenum, and the first portion of the ileum just distal to ligament of Treitz (LOT) are resected en bloc with the specimen, referred

to as a classic PD. Alternatively, the pylorus can be left intact also leaving behind a small segment of the first portion of the duodenum, referred to as pylorus-preserving PD.

The reconstruction generally involves using a loop of proximal jejunum to create a pancreaticojejunostomy (PJ), hepaticojejunostomy (HJ), and gastrojejunostomy (GJ). The proximal jejunal loop is passed retrocolic through the transverse colon mesentery or the LOT defect to complete the PJ and HJ anastomoses. The PJ can be performed in a variety of ways with numerous methods described, primarily in an effort to decrease the pancreatic fistula rate [36]. This not only indicates the complexity of the anastomosis but also the lack of a gold standard method for reconstruction. The two most common PJ anastomoses are the duct-to-mucosa anastomosis and the invagination technique. A plastic biliary stent may also be placed with one end partially in the duct of the pancreas and the other end partially in the jejunal limb, in essence creating a controlled fistula. The second anastomosis downstream to the PJ is the HJ, performed as a single-layer anastomosis. The third anastomosis is the GJ, which can be performed in an antecolic or retrocolic fashion. At the conclusion of the operation, the surgeon may choose to place drains near the PJ and HJ.

When performing a PD, special anatomic situations should be taken into consideration. Aberrant anatomy, such as a replaced right hepatic artery, should be noted on preoperative cross-sectional imaging if possible to avoid injuring the aberrant anatomy intraoperatively. However, aberrant anatomy is not always evident on preoperative imaging, and the surgeon should always be cognoscente of the potential for aberrant anatomy at the time of surgical intervention. Another special anatomic consideration to be noted on preoperative cross-sectional imaging is the presence of celiac artery stenosis (CAS) [37]. During a pancreaticoduodenectomy, the gastroduodenal artery (GDA) is ligated in order to resect the head of the pancreas. In the setting of CAS, the proper hepatic artery may be receiving retrograde flow from the GDA via collateral vessels supplied by the superior mesenteric artery. Thus, ligating the GDA during a PD can lead to liver failure and potentially death. The treatment of this is based on the etiology of CAS: atherosclerotic disease or median arcuate ligament (MAL) syndrome. If the etiology of CAS is atherosclerotic disease, preoperative stenting of the celiac artery may be attempted. If the etiology is MAL syndrome, releasing the MAL intraoperatively and reassessing proper hepatic arterial flow is appropriate. This should be done routinely by clamping the GDA prior to ligation and assessing hepatic flow with palpation and/or Doppler signals. If in the rare chance celiac artery stenting or MAL release do not restore proper hepatic arterial flow via the common hepatic artery, a proper hepatic artery bypass may be necessary at the time of PD [37].

## Distal Pancreatectomy

Distal pancreatectomy is performed for PCN involving the tail, body, or even the neck of the pancreas. Splenectomy should be performed in conjunction with distal pancreatectomy when the lesion has malignant potential in order to assess the lymph nodes, which reside in the splenic hilum. While SPN has metastatic potential requiring splenectomy at the time of distal pancreatectomy, splenic preservation can be considered for patients with small MCN lesions, SCN, and BD-IPMN and low risk of malignancy. Spleen-preserving distal pancreatectomy can be technically more difficult than a distal pancreatectomy and splenectomy given the integral relationship between the pancreas and the splenic vessels.

Surgical considerations during a distal pancreatectomy include the method of pancreatic transection and early splenic artery ligation when a splenectomy is also being performed to decrease blood loss during splenic mobilization. Transection of the pancreas can be done with a scalpel or electrocautery, oversewing the pancreatic remnant. Alternatively, the pancreas can be transected with a stapler with or without an absorbable mesh staple-line reinforcement. Regardless of the method, the surgeon may choose to place a drain near the pancreatic remnant.

## Total Pancreatectomy

A total pancreatectomy is rarely performed in any PCN other than IPMN. Given IPMN is a "field defect," occasionally total pancreatectomy is considered in the appropriate patient if the entire gland is involved. While total pancreatectomy can be technically straightforward requiring a PD and distal pancreatectomy/splenectomy with HJ and GJ reconstruction, postoperative brittle diabetes is the major concern in performing a total pancreatectomy. With the entire pancreas removed, the patient no long has autogenous insulin production or, more importantly, autogenous glucagon production. The lack of glucagon puts the patient at risk of life-threatening hypoglycemia. Total pancreatectomy is generally considered for younger patients with extensive IPMN who have a lifetime risk of developing pancreatic cancer and those with IPMN and a strong family history of pancreas cancer. Equally important, total pancreatectomy should only be offered to patients who will be able to reasonably manage their brittle diabetes given the real risk of life-threatening hypoglycemia.

## Central Pancreatectomy

In select patients with a centrally located PCN, central pancreatectomy may be an appropriate surgical option. Central pancreatectomy involves resecting a central portion of the pancreas and reconstructing with either a pancreaticogastrostomy to the posterior stomach or a Roux-en-Y retrocolic PJ to the distal pancreas. The major benefit of central pancreatectomy is preservation of pancreatic endocrine and exocrine function. However, due to two potential sources of pancreatic leak from the proximal pancreatic remnant and the pancreatic-enteric anastomosis, central pancreatectomy has a higher risk of pancreatic fistula ranging 36% to 63% [38–40]. While most of these centrally located PCN can be resected with an extended PD or extended distal pancreatectomy, central pancreatectomy should be considered for young and healthy patients to prevent long-term sequela of pancreatectomy, such as pancreatic insufficiency and diabetes. These patients will also medically tolerate a pancreatic leak or fistula better than an elderly patient or a patient with multiple medical comorbidities.

## Alternative Procedures

An alternative to pancreatectomy is enucleation of the PCN. Enucleation involves removing the lesion in a nonanatomic fashion, preserving as much functional pancreas as possible. Enucleation should be considered only for PCN that have a low risk of malignancy, such as SCN and small MCN. The entire cyst wall should be resected, taking care to prevent rupture of the cystic lesion. The main disadvantage of enucleation is the increased risk of pancreatic fistula, based on proximity of the lesion to the pancreatic duct.

An alternative to open surgical resection for PCN is minimally invasive surgery, including laparoscopy and robotic surgery. Laparoscopic distal pancreatectomy with or without splenectomy has become a standard operation in many institutions. Minimally invasive surgery for PD or total pancreatectomy can be considered for smaller PCN and extensive IPMN with absence of vascular involvement. Minimally invasive surgery for pancreatectomy is currently evolving and increasing in use, but it should be recommended in the appropriately selected patient by a surgeon who is comfortable performing minimally invasive pancreatectomies.

## Postoperative Management

Postoperative, patients undergoing pancreatectomy are slowly advanced on their diets until tolerating a regular diet. While the risk of perioperative mortality is low, the risk of postoperative morbidity is roughly 40%. The major risks associated with pancreatectomy include pancreatic fistula, delayed gastric emptying, diabetes, pancreatic insufficiency, anastomotic leak or stricture, and postoperative bleed.

The most common complication after major pancreatectomy is a pancreatic fistula with rates reported around 10–28% [41,42]. While numerous studies have investigated various operative techniques and pharmacologic measures to reduce the pancreatic fistula rate, no single measure has been demonstrated to be superior across institutions [43–45]. Recently, a somatostatin analog pasireotide administered in the perioperative period has been demonstrated to show significant reduction in the risk and severity of postoperative pancreatic leak and fistula after PD and distal pancreatectomy [46]. Furthermore, in an effort to prevent uncontrolled pancreatic leaks, some surgeons will place drains around the PJ or pancreatic remnant at the time of surgery. The drain output is then checked postoperatively for amylase levels as a marker of pancreatic leak. Drain amylase level <600 U/L on postoperative day one has been reported to be indicative of <1% risk of pancreatic fistula, with recommendations for early drain removal in these situations [47]. In those with high-output pancreatic fistulas, intravenous nutrition and limiting oral intake along with somatostatin analog may be considered. After a distal pancreatectomy, an endoscopic stent may be placed into the pancreatic duct to divert flow of pancreatic fluid from the remnant back through the ampulla and into the bowel.

Delayed gastric emptying (DGE) is another common complications following a PD, ranging from 14% to 61% [7,48]. DGE is diagnosed with an oral contrast study demonstrating delay in emptying contrast from the stomach after a PD. While the pathogenesis of DGE remains unclear, several factors have been studied, such as pylorus-preservation versus classic PD, antecolic versus retrocolic GJ, and the presence or absence of a pancreatic fistula [48,49]. However, none of these factors have been demonstrated to consistently contribute to DGE. DGE is often managed with replacement of nasogastric tube, subsequent removal with decrease in daily output, and slow advancement of diet. Rarely, a patient must have a percutaneous endoscopic gastrostomy tube with a jejunal feeding limb placed to provide enteral nutrition until gastric function returns to normal.

A late post-PD bleed can be a life-threatening complication. An early postoperative bleed (within first 5 days of surgery) indicates a surgical bleed requiring operative intervention. A late postoperative bleed, however, (5 days after surgery or more) occurs most commonly as a pseudoaneurysm bleed in the setting of a pancreatic fistula. Delayed post-PD bleed will present as blood in the

drains, bleeding through the midline incision, gastrointestinal bleed, and/or hemodynamic instability. A delayed bleed requires interventional radiology to embolize the bleeding vessel and rarely surgical intervention. A delayed post-PD bleed significantly increases mortality to 16% and should be addressed immediately [50].

## Conclusion

As a result of the increased use and improved sensitivity of cross-sectional imaging, more people are undergoing pancreatic resection for cystic neoplasms than in the past [1]. Furthermore, the proportion of resected malignant neoplasms has decreased over time, reflecting earlier diagnosis and resection of these premalignant lesions [1]. However, the morbidity of pancreatectomy remains high despite pancreatic resections becoming safer at high-volume institutions over time [1,7,8]. In addition to the immediate perioperative period, some endure the long-term sequelae of pancreatic resection, such as diabetes mellitus or pancreatic exocrine insufficiency.

The wide range of malignant potential between the various subtypes of PCN as well as the lack of ability to accurately characterize all lesions continue to make the management of PCN significantly challenging. Continued efforts are being made to improve accuracy in diagnosis, determine the true malignant potential of each subtype of PCN, and understand the natural history of each of these PCN. With improved knowledge regarding each of these areas, surgical resection can be reserved for highly selective patients harboring PCN that are symptomatic or have the greatest risk of developing pancreatic dysplasia or malignancy in the future.

## Introduction

Surgical approaches to abdominal disease have undergone a sea change in the past three decades driven by the increased use of laparoscopy and other minimally invasive techniques. While Cushieri first reported laparoscopic distal pancreatectomy (LDP) in 1994, adoption of minimally invasive techniques in pancreatic surgery has been slow [1,2]. Barriers to use include a high degree of operative complexity, the high rate of perioperative morbidity in pancreatic surgery, and concerns about oncologic efficacy.

These barriers have started to break down for pancreatic surgery, in part due to work highlighting superior operative outcomes with preserved cost-effectiveness for LDP performed in a variety of healthcare settings [3–16]. With a broad literature review confirming superiority, consensus is growing that a laparoscopic approach to distal pancreatectomy is preferable, particularly in the setting of benign disease [17]. A recent comprehensive meta-analysis even suggests that splenic preservation (with or without vessel preservation), when safe and of negligible oncologic effect, is perhaps best [18]. The increasing utilization of the laparoscope for left-sided resections has led to the adoption of a laparoscopic approach to other procedures, including enucleation, central pancreatectomy, pancreaticoduodenectomy, and total pancreatectomy [19].

The indications for a laparoscopic operation in cystic disease of the pancreas are identical to those for an open operation. The most commonly cited guidelines for resection are derived from consensus opinion of the 14th meeting of the International Association of Pancreatology [20]. Specifically they include: intraductal papillary mucinous neoplasm (IPMN) of the main pancreatic duct, endoscopically visualized dilated papilla with mucin extrusion, or branch-duct IPMN rapidly increasing in size, with mural nodularity, or with high-grade atypia on tissue sampling. Guidelines also recommend resection for mucinous cystic neoplasms, with a stated preference for a laparoscopic approach in those lesions without mural nodularity and less than 4 cm in size. Rarely, other diagnoses may be encountered that are best managed by extirpative therapy, including symptomatic enteric duplication cysts [21] and intrapancreatic accessory spleen with associated epithelial cysts [22,23]. Notably, the presence of a potentially malignant cystic neoplasm should not, in isolation, be viewed as a contraindication to a laparoscopic approach and will be discussed further in this chapter.

## Specific Surgical Considerations and Procedures

Key operative landmarks in pancreatic surgery include the superior mesenteric-portal vein (SMV-PV) confluence (representing the standard margin of transection), the gastroduodenal artery (representing the landmark for selecting resection of the uncinate/head with the lesion versus body/tail) and the splenic vessels (with either preservation or controlled ligation as indicated by disease and operative planning). When possible during a partial pancreatectomy, the site of gland transection is the pancreatic neck [24]. When pathology is located close to the SMV-PV confluence, the site of transection may vary from the neck and recent data demonstrates this is associated with an elevated rate of postoperative pancreatic fistula (POPF). This increased risk for POPF is hypothesized to be due to the increase in gland

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

diameter to either side of the SMV-PV confluence [24]. The specific method chosen for pancreatic transection can vary based on procedure and will be covered in more detail later.

The most commonly performed laparoscopic procedure for cystic lesions is distal pancreatectomy (LDP) [25]. Historically, cystic lesions are overrepresented in retrospective reviews of LPD as compared to open DP, with the proportion of cystic lesions in many LPD series approaching 60% of diagnoses [8,17]. This proportion is higher than those reported in open DP and is most likely biased by concerns about oncologic efficacy [26].

When evaluating patients for distal pancreatectomy, selective splenic preservation can be entertained in the presence of benign etiology [18,27]. In many high-volume centers, LDP for benign indications, such as mucinous cystic neoplasms, serous cystic neoplasms, or branch-duct IPMN, is commonly carried out with preservation of the spleen. When cystic lesions are overtly malignant or carry a higher risk of malignancy (i.e., main-duct or mixed-type IPMN), an en-bloc splenectomy as dictated by standards of lymphadenectomy in pancreatic tail malignancy should be performed [28]. From a technical point of view, there are two commonly employed methods for splenic preservation in the setting of distal pancreatectomy. The first involves careful dissection and preservation of the splenic artery and vein with ligation of the short branches to the distal pancreas. The second involves ligation and resection of the splenic artery and vein along its course near the distal pancreas with careful preservation of the short gastric branches towards the hilum (Warshaw technique) [18,29]. Both techniques for splenic preservation have been demonstrated to be safe, with no clear randomized data for superiority of either. Dissection of the pancreatic body and tail out of its retroperitoneal position can be safely performed using an ultrasonic dissector or vessel-sealing device. A recent meta-analysis comparing ultrasonic to conventional dissection in DP suggests superiority of the ultrasonic approach in terms of postoperative morbidity [30]. The most common method of parenchymal transection during LDP is the application of a stapling device (Fig. 85.1), as sharp transection with suture closure is technically challenging laparoscopically and rates of POPF for staple and suture closure appear similar [31].

Operative morbidity most frequently involves POPF. Reported rates of POPF following LDP range between 20% and 65%, with clinically relevant rates (ISGPS grade B or C) ranging between 10% and 25% [3–16,32]. Efforts to reduce POPF often focus on modifications to stapling techniques, including staple line reinforcement with a bioabsorbable synthetic fabric or glue. Currently, there are no reproducible, high-quality data to recommend any specific modification to a stapled pancreatic transection [33–35]. As rates of POPF remain high, intraoperative drain placement at the resection margin is routine in many centers. Data quantifying blood loss, pain, and speed of postoperative recovery all favor LDP over open DP and suggest that LDP should be the procedure of choice for cystic lesions located in the pancreatic body and tail.

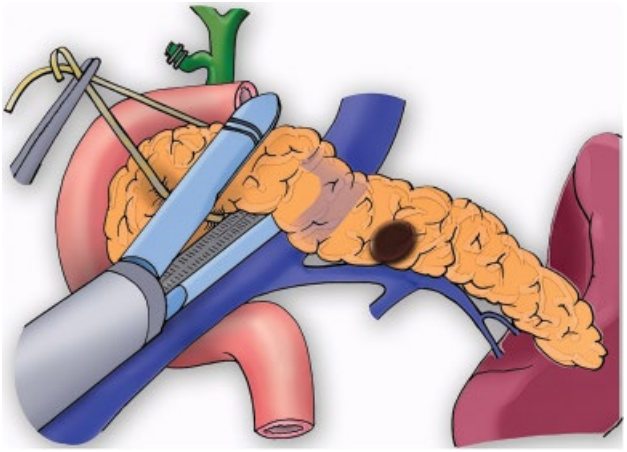

**Figure 85.1** Laparoscopic transection of the pancreas. The technologic refinement of laparoscopic stapling devices allows for simple, safe, and effective transection of the neck of the gland during distal pancreatectomy. Following circumferential dissection of the pancreas at the neck, a stapling device is inserted and closed gently across the gland. The contents in the stapler are inspected from both the left and right sides to ensure there are no inadvertent structures grasped prior to transection. Following staple deployment and transection, hemostasis can be achieved by a combination of electrocautery, suture ligature, and application of clips.

Enucleation of cystic lesions for benign disease, enabling parenchymal preservation, can also be performed laparoscopically. Though the collective experience is not as vast as with LDP, enucleation of cystic lesions in either the pancreatic head or tail is a safe and effective approached in selected pathologies. Importantly, enucleation is associated with significant oncologic limitations that prevent its use in diseases such as IPMN, where diffuse involvement of the ductal system may be associated with small foci of invasive disease. Literature demonstrating the technical feasibility and perioperative safety of enucleation is dominated by case series data and most commonly limited to 5–30 patients [36–38]. Dissection into the pancreas risks two major complications: hemorrhage and postoperative leak. Typically, an electrosurgical or ultrasonic device is used during the gland dissection and care must be taken to ensure adequate hemostasis at the conclusion of the case. Additionally, a gross inspection (at a minimum) of the pathologic specimen after enucleation is required prior to abdominal closure to ensure that it includes the lesion of interest. While a minimally invasive approach to

enucleation may have several potential advantages, it is burdened by a high rate of POPF. Case series data would suggest that these POPF are generally uncomplicated and most frequently not of clinical relevance [36–38]. Operatively placed drains are frequently used after enucleation to mitigate the morbidity that may arise from an uncontrolled pancreatic fistula.

Central pancreatectomy (CP) is another parenchymal-sparing procedure that is often considered for nonmalignant cystic lesions located in the pancreatic body. Originally developed in the 1950s, this operation was first described laparoscopically in 2003 [39]. Similar to LDP, the pancreas is divided at the SMV-PV confluence by stapler and the pancreatic body is mobilized towards the tail with preservation of the splenic vessels. After resection of the pathology-bearing segment, pancreaticoenteric anastomosis of the tail is required. Both pancreaticojejunostomy and pancreaticogastrostomy have been reported in the literature, with pancreaticogastrostomy often favored due to apparent ease in a laparoscopic setting [40–42]. Methods for pancreatoenteric anastomosis vary according to surgeon preference, with the two most common techniques being a duct-to-mucosa or an invagination style. Similar to LDP, the most frequent complication of CP is POPF. As CP leaves the patient with two cut surfaces across the gland, rates of POPF are high in reported series (40–60%). Most of these leaks remain clinically minor and can be managed conservatively with prolonged peritoneal drainage [40–42].

One major advantage to parenchymal preservation (both enucleation and CP), compared to LDP, is maintenance of pancreatic exocrine and endocrine function in the perioperative period. This is highlighted by literature documenting a very low risk for postoperative diabetes mellitus in parenchymal preserving operations as compared to distal pancreatectomy [19,43]. Therefore, when location and extent of cystic pathology lend themselves to a parenchymal-sparing procedure it should be seriously considered. In all laparoscopic approaches, intraoperative ultrasound can be an important tool used to confirm the location of pathology and choose a suitable surgical strategy. Additionally, intraoperative frozen section analysis of both the lesion and the surgical margins should be routinely performed to avoid a return to the operating room due to unanticipated disease or margin involvement.

Though the use of laparoscopy and robotics in pancreaticoduodenectomy (PD) is increasing, it has yet to become routine in most centers. Similar barriers to widespread adoption exist for PD today as they did for distal pancreatectomy 20 years ago, including operative complexity, patient safety, and concerns about oncologic efficacy. Despite these barriers, there are several high-volume centers demonstrating that minimally invasive PD can be achieved safely [44–46]. Typically, four to six ports are required for laparoscopic PD and the approach to the dissection can vary by surgeon preference. Key points in the dissection are identical to those during an open procedure and include mobilization of the duodenum and pancreatic head, confirmation of resectability by assessment of disease spread, isolation and transection of the gastroduodenal artery, development of a retropancreatic tunnel to facilitate safe gland transection, and careful uncinate dissection. Though the key points in dissection are similar, the techniques for exposure and visualization are unique when the head of the pancreas is approached laparoscopically. For liver retraction, for example, both the falciform and the gallbladder can be used as "handles" to manipulate positioning. During laparoscopy, the angle of the operating table can also facilitate bowel "retraction" by allowing it to fall away into the pelvis by gravity alone. Reconstructive techniques in a minimally invasive PD are also similar to those done in an open procedure. For pancreatoenteric reconstruction, for example, both duct-to-mucosa and invagination techniques can be performed. Reports demonstrating similar outcomes for minimally invasive PD and open procedures are now commonplace [44,45,47]. In highly selected patients, outcomes for a laparoscopic approach can even be superior to an open approach [44]. The expansion of minimally invasive PD away from high-volume centers must be approached with caution, however, as data is emerging that suggests mortality may be increased when utilized in low-volume settings [47].

## Future Perspectives

The use of laparoscopy in the setting of pancreatectomy is likely to continue to expand along with advancements in technology, technique, and the understanding of tumor biology. As discussed earlier, recent data is challenging two long-standing barriers to rapid adoption of minimally invasive surgery: technical safety and oncologic effectiveness. The technical challenges are being progressively overcome and the list of relative contraindications to laparoscopy is decreasing as published experience grows with large tumors and tumors located in technically challenging positions [42,48]. Historically, the view that a laparoscopic approach may compromise oncologic effectiveness of resections involving biopsy-proven malignancy is also being challenged. For example, a recent retrospective analysis from French healthcare databases suggests that a laparoscopic approach does not compromise long-term oncologic outcomes in left-sided pancreatectomy [49]. Many thought leaders in surgical oncology are now calling for a large, randomized trial focusing on oncologic effectiveness, defined end-points,

and cost-effectiveness of a laparoscopic approach to pancreatic malignancy [17,26].

As experience with laparoscopic distal pancreatectomy has increased, there has been a shift in patient selection to sicker patients with more proximal tumors and yet similar perioperative outcomes can be achieved [50]. Despite these data, as the use of minimally invasive techniques expands it is important to remember that patient safety must remain paramount. For laparoscopic pancreatectomy, this means that accurate patient selection is a critical component to any surgical practice. Supporting this view, a recent series documented that those patients requiring conversion from laparoscopic to open pancreatectomy were found to have increased rates of perioperative morbidity and pancreatic leak than the cohort with an initial approach via laparotomy [5]. There are several identified risk factors for failure of a laparoscopic approach and increased perioperative morbidity (including body mass index and extent of pancreatic resection) that can help guide surgeons in accurate preoperative assessment [5,51]. In one series, the adoption of a robotically assisted minimally invasive approach to distal pancreatectomy reduced the risk of conversion to an open resection while maintaining equivalent safety outcomes [52].

Descriptions of a laparoscopic-robotic hybrid or purely robotic approaches to pancreatectomy are increasing in the literature. Touted for superior 3-dimensional visualization and hinged instrumentation, the robot may provide a technologic platform for safe completion of more technically demanding operations. Though conceptually familiar to surgeons learning laparoscopy, there is a definite learning curve evident with the adoption of robotic technology [53]. In experiences that extend beyond the period of surgeon learning, the outcomes for robotic and laparoscopic approaches appear to be similar [46,52,54]. Thus, in the face of data suggesting equivalency, it is becoming increasingly apparent that future surgical decision making will be driven in part by patient and surgeon preference for operating platform (open, laparoscopic, or robotic).

Finally, there is increasing awareness of healthcare expenditures both in the United States and abroad. The adoption of novel technologies requires an initial investment by healthcare systems to enable practitioners to offer procedures such as laparoscopy and robotics. From a global health perspective, this initial investment remains beyond the reach of many hospitals and systems. Once acquired, however, the utilization of resources (as measured by cost) may in fact be decreased by the adoption of minimally invasive approaches to pancreatectomy. Similar to other studies of MIS in pancreatectomy, the most mature data to support this view comes from analysis of cost data in LDP. Retrospective reviews of data in both the United States and Britain document an overall cost advantage to MIS pancreatectomy as compared to an open technique [55,56]. One distinct limitation in both these studies is the inability to account for the initial investment costs required to procure the instruments needed to successfully perform these advanced procedures.

## Introduction

In an era of improved cross-sectional imaging, pancreatic resection has been increasingly performed for cystic neoplasms, with intraductal papillary mucinous neoplasms (IPMN) representing more than half of resected cystic neoplasms [1,2]. The natural history of IPMN varies widely, depending on a host of variables including pattern of duct involvement and epithelial subtypes, amongst others [3]. In 2012, the International Association of Pancreatology (IAP) established an updated consensus guideline addressing the appropriate indications of resection based on predictors of malignancy [4]. The follow-up and surveillance strategy for patients after they have had an IPMN resected, however, remains a matter of debate, with no formal evidence-based gold standard. This is in part due to imprecise use of the terms "recurrence" and "progression" in studies attempting to characterize these patterns to inform surveillance strategies.

The term "recurrence" has historically been used in the context of malignancy and implies the return of disease as a result of descendant cells of the original resected lesion on account of residual microscopic disease, mainly in IPMN with an associated invasive cancer. In regard to the natural history of the occurrence of a new IPMN in the pancreatic remnant following resection of noninvasive IPMN, the term "recurrence" when used in this manner only accounts for a subset of disease. In most cases, patients have multifocal disease and have residual IPMN separate from the index lesion not meeting criteria for resection in their remnant gland, or they develop new metachronous lesions that either remain stable or progress. These "recurrences" should be analyzed as a distinct process, as the former (IPMN with an associated invasive cancer) has an overwhelming risk of systemic and local recurrence akin to conventional pancreatic ductal adenocarcinoma [5,6]. With the practice of parenchymal-sparing pancreatectomy for IPMN [7,8], it is ever more important to characterize the progression or development of new lesions in the remnant pancreas to inform postoperative surveillance strategies. In this chapter, we will be focusing on reviewing the current literature that analyzes the natural history of the remnant pancreas after resection of noninvasive IPMN. Mucinous cystic neoplasms are predominantly solitary and complete resection is often curative [9]. Thus, the postoperative surveillance strategies are not applicable and will not be the focus of the chapter.

## Fate of the Pancreatic Remnant

IPMN is a disease associated with a "field defect," with rates of synchronous disease reported to be as high as 83% [10], and risk of developing clinically significant metachronous lesions being about 8% [11]. This field defect predisposes the remnant gland to developing significant neoplasia, even after resection of a primary lesion. Kang et al. reported a recurrence rate of 5.4% in the remnant gland after resection of 298 noninvasive IPMN [12]. More importantly, 10 of the 298 recurred as an invasive lesion. In the largest series to date, Marchegiani analyzed close to 300 patients with noninvasive IPMN and similarly reported a 9% risk of recurrence after resection of a noninvasive IPMN, with six representing invasive recurrences [13]. This is in line with the literature, which reports a recurrence rate ranging from 1% to 20%, and an invasive recurrence

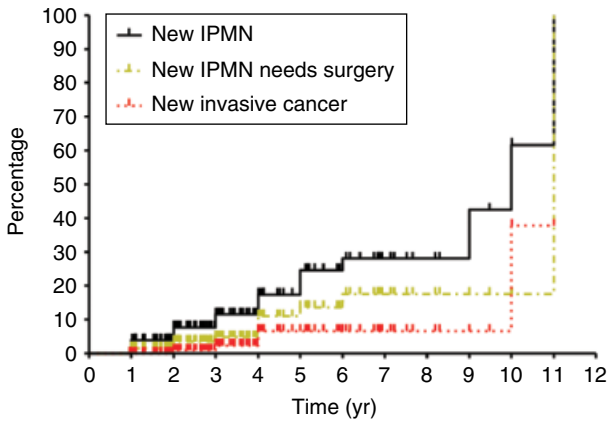
IPMN, intraductal papillary mucinous neoplasm.

rate of 2% to 7.8% [14–22]. Despite this, 5-year survival has been reported to be favorable, ranging from 77% to 100%. The median time to recurrence has been described to range from 22 months to 46 months, suggesting that long-term surveillance is necessary as recurrence can occur up to 4 years after resection of a benign IPMN (Table 86.1).

Perhaps the most comprehensive analysis specifically investigating the natural history of the pancreas remnant after resection of a noninvasive IPMN is that from the Johns Hopkins group. In an analysis of 130 patients who underwent resection of noninvasive IPMN, He et al. reported that the 1-, 5-, and 10-year risks of developing a new IPMN are 4%, 25%, and 62%, respectively, with the subsequent chances of requiring surgery being 1.6%, 14%,and 18%, respectively [22]. Even more importantly, the risk of developing invasive cancer at 1-, 5-, and 10-years is 0%, 7%, and 38%, respectively (Fig. 86.1) [22]. At a median follow-up of 60 months, all patients who were found to have invasive carcinoma on completion pancreatectomy remained alive with no evidence of recurrent disease. This study has two very important implications: (i) after resection of noninvasive IPMN, indefinite surveillance is necessary because of these long-term risks; (ii) management of recurrent IPMN in line with the same resection criteria as the primary IPMN set by the IAP is safe. It is important to point out that there is a possibility that the invasive cancer recurrences could represent concurrent ductal adenocarcinoma that was undetected at the time of surgery instead of the metachronous development of a new invasive adenocarcinoma. Regardless, the implication is that patients who had a noninvasive IPMN resected still require long-term surveillance.



| | 1yr | 5yr | 10yr |
|---|---|---|---|
| New IPMN | 4% | 25% | 62% |
| New IPMN requiring completion pancreatectomy | 2% | 14% | 18% |
| New invasive cancer | 0% | 7% | 38% |

## Predictors of Recurrence

A better understanding of the risk of recurrences can guide resource allocation and maximize the efficiency of postoperative surveillance. The Johns Hopkins series found that patients with a family history of pancreatic cancer were significantly more likely to develop recurrence after resection of a noninvasive IPMN (23% vs. 7%, $P < 0.05$), and family history was the only independent preoperative predictor of recurrence (OR 4.2, 95% CI

1.3–14.1, $P = 0.02$) [22]. The Massachusetts General Hospital group reported an increased incidence of concurrently occurring ductal adenocarcinoma (11.1% vs. 2.9%, $P = 0.02$) and extrapancreatic malignancies (35.6% vs. 20.1%, $P = 0.03$) in patients with a family history of pancreatic cancer [23]. Taken together, patients with a family history of pancreatic cancer represent a high-risk cohort that should not only be followed more intensely after resection of their index lesion, but also encouraged to pursue general age-appropriate cancer screening. Some have even proposed that younger patients with preexisting diabetes and a family history of pancreatic cancer may benefit from total pancreatectomy given that their cumulative risk would be higher, carefully balancing this strategy against potential debilitating metabolic derangements from an apancreatic state.

The impact of surgical margin at the time of surgical resection on recurrence risk, however, is still debated, with conflicting outcomes reported by different centers. The Johns Hopkins (27% vs. 22%, $P$ = ns) [22] and Seoul National University groups (16.7% vs. 10.2%, $P = 0.421$) [12] reported no difference in recurrence rates when margin positive patients were compared with margin negative patients. Conversely, the Memorial Sloan Kettering group reported that dysplasia of any degree at the resection margin was a risk factor for recurrent disease at the remnant gland (OR 2.9, $P = 0.02$), but not for recurrent disease at the resection margin itself [24]. Similarly, the Massachusetts General Hospital group reported a significantly higher rate of recurrence in patients with positive margins (25% vs. 14%, $P = 0.008$), and they found that margin status was one of the most important predictors of survival on multivariate analysis (HR 2.6, $P = 0.0046$) [25]. The discrepant findings are likely to be a result of the retrospective nature of underpowered studies in trying to analyze a small, specific subcohort of patients. The current IAP guidelines recommend that, when present, a low- and intermediate grade IPMN at the resection margin does not require re-resection, whereas high-grade dysplasia or invasive foci are indications for further pancreatectomy to reduce risk of recurrences [4].

High-grade dysplasia in the primary lesion has also been shown to pose a higher risk of recurrence in the remnant pancreas. He et al. reported that 17% of patients with high-grade dysplasia discovered in their primary resected IPMN developed new or progressive disease in their pancreatic remnant [21]. Similarly, the Indiana group reported that 10% of patients with an IPMN with high-grade dysplasia developed a subsequent de novo invasive IPMN despite negative surgical margins [22]. In an analysis of 140 patients, the Johns Hopkins group reported that patients with high-grade dysplasia in their primary resected IPMN were more than eightfold more likely to subsequently develop an invasive cancer (OR 8.82, 95% CI 2.56–30.43, $P = 0.001$) [26]. This specific cohort should be categorized as high risk for recurrence and should undergo close surveillance as well.

## Low-Risk Lesions Left Behind in Remnant

Approximately 7–20% of patients have synchronous IPMN, one or more of which did not meet criteria for resection at the time of index surgery, and were therefore left behind [7,21,27]. The Indiana group reported a 5-year progression-free survival of 88% for these patients, which was no different from the survival of patients who did not have any residual lesion after resection of a noninvasive IPMN (82%, $P > 0.05$) [21]. Similarly, in an analysis of 203 patients who underwent resection, Moriya et al. reported that 14 patients had residual lesions after resection, with no incidence of progression at a median follow-up of 40 months [27]. These patients are not at any higher risk for recurrence or progression, justifying current practices of only operating on IPMN that meet criteria for resection. However, surveillance is still necessary given the similar non-negligible risk of progression and will be discussed in the next section.

## Postoperative Surveillance Strategy

As opposed to conventional adenocarcinoma, early diagnosis of a recurrent IPMN might lead to early surgical intervention that can improve long-term survival. Currently, no published guidelines exist for the management of patients who had a noninvasive IPMN resected. A better understanding of the patterns and mechanisms of recurrence will aid in the development of useful guidelines for follow-up strategies. As noted earlier, several factors appear to correlate with recurrence—family history, a positive resection margin, and high-grade dysplasia in the primary lesion. In these individuals close observation is necessary since the risk of subsequent high-risk lesions or malignancy is high. Moreover, as previously mentioned, the long time periods to recurrence after resection of a noninvasive IPMN implies a lifelong surveillance strategy for these patients, especially in younger patients and high-risk cohorts, that is, patients with high-grade dysplasia at the surgical margin or in the primary lesion, and those with a family history of pancreatic cancer. We feel that the current IAP guidelines recommending history/physical examination and magnetic resonance cholangiopancreatography (MRCP)

surveillance performed at 2- and 5-years following resection, with a gradual lengthening in follow-up interval once there is a pattern of stability may not be sufficient [4]. This is particularly true for patients with risk factors for recurrence. It should be noted that in the He et al. study, the risk of developing a clinically significant lesion is estimated to be over 30% at 10 years. Taken together, these observations argue against reducing the frequency of surveillance once "stability" is determined. In this regard it would appear that the risk of clinically significant lesions increases with time. That said, patients who undergo resection for noninvasive BD-IPMN without the aforementioned risk factors have a very low risk of recurrence, and when they do recur, are rarely invasive [13]. For selected elderly or frail patients with significant comorbidities in whom life expectancy is short or who cannot tolerate a pancreatectomy, follow-up after resection of BD-IPMN could potentially be avoided altogether.

## Conclusions

The recurrence rate after resection of noninvasive IPMN ranges from 1% to 20%, with a little less than half of the recurrences being invasive diseases. The cumulative 10-year risk of developing indications for resection or invasive cancer after resection of a noninvasive IPMN are 18% and 38%, respectively. Because early detection of recurrence or IPMN progression has a positive impact on long-term survival, patients undergoing resection for noninvasive IPMN should be closely surveyed postoperatively. Family history, grade of disease, and resection margins are the only predictors of recurrences after resection, and total pancreatectomy may be contemplated in a highly selected cohort of young patients with preexisting diabetes. Clinical judgment should dictate the need for further surveillance in older patients who have undergone resection for low-grade, noninvasive BD-IPMN.

# Long-Term Outcome of Management of Cystic Neoplasms

## 87

## Long-Term Outcome After Observation and Surgical Treatment: What is the Evidence?

*Giovanni Marchegiani, Giuseppe Malleo, and Claudio Bassi*

*Pancreas Institute, G.B. Rossi Hospital, University of Verona Hospital Trust, Verona, Italy*

### Introduction

Many aspects related to the natural history and outcome of pancreatic cystic neoplasms are poorly understood, because the vast majority of the data are retrospective and uncontrolled, and long-term follow-up is limited. Selective resection of cystic neoplasms seems to be appropriate, balancing the risk of malignancy with those of operation, and—over the years—initial management evolved towards fewer patients undergoing operative resection and fewer benign lesions being resected [1,2]. Patients managed nonoperatively are enrolled in radiologic surveillance protocols, with the aim of finding signs of possible malignant degeneration. Surveillance protocols require periodic cross-sectional imaging and/or endoscopic ultrasound, at a high economic cost for the community. Furthermore, there is no ideal test to diagnose transformed pancreatic cystic neoplasms, and there is not general agreement on the optimum method and timeframe to follow up for these lesions. Long-term results of surveillance protocols have begun to be reported in the literature, especially for lesions amenable to initial observation, such as serous cystic neoplasms and BD-IPMN [3,4].

In patients undergoing resection, either at the time of diagnosis or after observation, the chance of cure, the incidence of tumor recurrence, and disease-specific or overall survival depend on the cyst type and the presence of an invasive component, although long-term data are limited. This chapter describes long-term outcomes after observation of surgical resection of pancreatic cystic neoplasms.

### Serous Cystic Neoplasms

The almost invariably benign nature of serous cystic neoplasms, combined with the morbidity and potential mortality of pancreatic resections, led to a management strategy weighted towards surveillance. The safety of a periodic surveillance program and the generally slow growth rate of these lesions have been recently demonstrated by different institutions, including the authors' own [3,5]. The optimal interval between follow-up imaging tests in pancreatic serous cystic neoplasms is still unclear. Many institutions recommend imaging on a semi-annual or annual basis for all cystic neoplasms. According to the most recent data, cystic lesions presumed to be benign can be safely observed on a 2-year basis [6]. Clearly, surveillance can be tailored on the basis of cyst morphology (i.e., unclear discrimination between serous and mucinous lesions), patient's age, sex, and tumor location. As a matter of fact, most of the patients currently undergoing resections for a serous cystic neoplasm are misdiagnosed with another pancreatic neoplasm [5]. In patients managed operatively, complete surgical resection ensures cure, and serous cystic neoplasms do not recur. Therefore, a regular radiologic follow-up program is unnecessary, thereby saving cost. Follow-up outpatient visits should be better focused on quality of life. Malignant serous cystic neoplasms (serous cystoadenocarcinomas) are exceptionally rare, with less than 40 cases being published. Synchronous or metachronous liver metastases have been frequently noted (36%). Mean survival was 36 months among the few cases with follow-up; the prognosis seems to be favorable also in patients with metastatic disease [7].

## Mucinous Cystic Neoplasms

Mucinous cystic neoplasms generally require surgical resection, although small lesions without mural nodules, especially in elderly patients with comorbidities, may be observed. Such patients are, however, very uncommon. Because most patients with mucinous cystic neoplasms are middle-aged women with a long life expectancy, non-operative management of low-risk lesions based on periodic imaging would require years of radiologic follow-up at high cost [8].

Radical resection of noninvasive neoplasms ensures cure. These neoplasms do not recur and—as already pointed out for serous cystic neoplasms—outpatient follow-up should be focused on quality of life, because regular radiologic postresection surveillance is probably unnecessary.

Minimally invasive mucinous cystic neoplasms (invasion limited to the ovarian stroma), but without tissue invasion, have an excellent prognosis. On occasion, undocumented foci of invasive carcinoma may exist within a presumed noninvasive proliferative MCN; this emphasizes the importance of a careful histopathologic analysis of the entire lesion. In such cases, recurrence and metastases can be observed. In general, these patients should undergo a radiologic follow-up protocol, despite the fact that minimally invasive adenocarcinomas arising in mucinous cystic neoplasms can be virtually cured by surgery, particularly if the neoplasms are completely examined histologically [9].

Five-year survival of patients with invasive mucinous cystic neoplasms (true cystadenocarcinoma) appears to be quite poor, ranging from 15% to 35%, albeit somewhat better than the survival rate for patients with typical ductal adenocarcinoma of the pancreas. The extent of invasion is the most significant prognostic factor in malignant mucinous cystic neoplasms. Some authors have suggested that patients with resected mucinous cystadenocarcinoma should be carefully followed on a 6-month basis with cross-sectional imaging, matching the interval to follow-up of ductal adenocarcinoma [10]. However, proof that surveillance imaging improves the prognosis compared with a strategy based on symptom recurrence is lacking.

## Intraductal Papillary Mucinous Neoplasms

### Outcome of IPMN Managed Nonoperatively

The decision to follow an IPMN is based on multiple factors, namely the neoplasm type (main-duct/mixed *versus* branch duct), patient age, family history, symptoms, comorbidities, perceived pancreatic cancer risk, and patient preference [2,11]. Initial follow-up is generally proposed only to patients with BD-IPMN devoid of malignant features (Sendai-negative), in which the risk of invasive cancer appears to be low. The majority of papers confirm this policy to be relatively safe, although robust long-term data are lacking. In a cohort of 170 patients from MSKCC initially selected for surveillance, after a median follow-up period of 40 months, 97 underwent delayed resection because of endoscopic or radiologic changes, concern about premalignant conditions, or suspicious cytology. Of these, 79 had a noninvasive disease, 18 had an invasive IPMN. High-grade dysplasia or invasive IPMN were larger (median diameter of 3 cm), and were more likely to have main pancreatic duct involvement. Overall survival after delayed resection was 142 months for noninvasive disease and 126 months for invasive disease. Interestingly, 5 patients initially selected for surveillance developed a pancreatic ductal adenocarcinoma in a region remote from the lesion being monitored (median time from diagnosis to resection for invasive disease was 20 months). In spite of an active surveillance program, no patient had stage I disease [4]. Another multi-institutional series from Japan analyzing 349 follow-up BD-IPMN patients who had no mural nodules at initial diagnosis (median follow-up of 3.7 years) showed that 62 patients (17.8%) exhibited disease progression during follow-up. Twenty-two underwent surgery, leading to a pathologic diagnosis of invasive disease in 9 and adenoma in 13. A pancreatic ductal adenocarcinoma developed in 7 patients (2.0%). Of these, only 4 were resectable [12]. In two smaller series from France limited to low-risk BD-IPMN the follow-up period was longer. The former series included 49 patients. After a mean follow-up period of 77 months, 77.5% of patients remained symptom-free. Five patients were operated on because of recurrent pancreatitis and/or an increase in size of either cysts or the main duct (mean time delay after diagnosis was 20 months). Pathologically, none of these patients had malignancy [13]. In the latter series, analyzing 53 patients with follow-up ≥60 months (median 84 months), crossover to surgery was necessary in 3 patients, none of whom ultimately had an invasive disease. However, an invasive advanced carcinoma occurred in 2 patients, both after 84 months follow-up [14]. The same concept was reported by a Japanese series of 103 BD-IPMN patients conservatively followed up for ≥2 years (median 59 months). The 5-year actuarial rate of development of pancreatic cancer was 2.4% [15].

Interestingly, in a series of IPMN meeting criteria for resection (Sendai-positive) and not operated because of age and comorbidities, the outcome was relatively good (overall median disease-specific survival of 55 months),

especially in the BD-type. The authors proposed that a conservative approach in patients who are not surgically fit is also reasonable [16]. The most robust data in this setting come from a recent multi-institutional series of "Sendai-positive" IPMN that were managed conservatively. Of note, those presenting with "worrisome features" and not recommended for surgery mainly because of comorbidities had a 96% 5-year DSS. Conversely, the presence of "high-risk stigmata" was associated with a 40% risk of IPMN-related death [17]. In this regard, a conservative approach for individuals presenting with "worrisome features" seems appropriate, particularly in elderly patients. On the contrary, some authors claim that even Sendai-negative BD-IPMN and MD-IPMN with a main pancreatic duct of less than 1 cm have significant malignant potential (24.6–60 %), and propose a more liberal operative policy [18,19].

In general, there is little evidence in the literature to guide the frequency and type of surveillance for IPMN managed nonoperatively. Some authors propose that surveillance can be safely spaced at every 2 years or even discontinued after long-term stability in low-risk lesions. However, concern over the development of pancreatic ductal adenocarcinoma in the pancreas harboring IPMN prompts a continuation of active life-long surveillance at short intervals [2]. Undoubtedly, surveillance results in significant utilization of cross-sectional imaging, endoscopic ultrasound, and economic investment. Research is focusing on fluid cyst biomarkers able to distinguish invasive from noninvasive cysts.

## Outcome After Resection of IPMN

The outcome after resection of IPMN depends on different factors, including:

- Presence of an invasive component
- Epithelial histologic subtype
- Type of invasive component
- Duct involvement
- Resection margin
- Lymph node status (in invasive IPMN).

The prognosis of patients with noninvasive IPMN is excellent, and the 5-year survival rate is reported to be >70% in most series. Some series have even suggested a 5-year survival in excess of 90% after resection. Conversely, the 5-year survival rate for invasive IPMN (carcinoma arising in the background of IPMN) ranges from 34% to 62%. The outcome of invasive IPMN is therefore poor in comparison with noninvasive IPMN, but appears to be better than pancreatic ductal adenocarcinoma, which exhibits a 5-year survival ranging from 9% to 21%. Whether this is due to a stage-shift with earlier diagnosis of IPMN, or because of a truly less aggressive behavior of invasive IPMN remains controversial [20]. Disease recurrence may arise either in the pancreatic remnant or in peripancreatic or extrapancreatic sites.

Recent data indicate that invasive IPMN is a heterogeneous disease, because it can exhibit different histologic patterns, namely colloid (colloid carcinoma), tubular (tubular adenocarcinoma), or oncocytic (oncocytic carcinoma). According to reports by Furukawa et al. and by Mino-Kenudson et al., colloid carcinoma derives from intestinal-type IPMN, and is associated with a particularly indolent behavior [21]. Tubular adenocarcinoma correlates with gastric and pancreatobiliary epithelial subtypes, and is associated with a dismal prognosis, similar to that of pancreatic ductal adenocarcinoma. Oncocytic carcinoma derives from the uncommon oncocytic subtype, and has a significantly better outcome than ductal adenocarcinoma, even though it can present with very late tumor recurrence (up to 7 years after surgical resection) [20–22].

It is well established that the type of duct involvement, branch versus main duct, is associated with the risk of invasive cancer. Because the type of duct involvement correlates with epithelial subtypes of IPMN, it may also identify the likely histologic subtype of cancer. In particular, MD-type are mainly of intestinal and oncocytic type, whereas BD-type are often associated with gastric epithelial type. The association BD-IPMN/gastric subtype/tubular adenocarcinoma seems paradoxical, because gastric-type BD-IPMN most often harbor low-grade dysplasia and absence of invasion. In the series by Mino-Kenudson et al., 15.6% of surgically resected gastric-type IPMN gave rise to tubular adenocarcinoma [20]. According to these findings, the final pathologic report of resected invasive IPMN should indicate the histologic pattern of the invasive component and the background histologic subtype. This is of essential prognostic significance.

The clinical implications of surgical resection margin (frozen section of the pancreatic cut surface) are controversial, and the results in the literature are mixed on this topic [23]. In general, not all studies found a strong correlation between margin status and risk of recurrence. There have been reports of invasive carcinomas in association with only mild or moderate dysplasia (adenomas or borderline lesions) within the IPMN in the remnant pancreas. A recent meta-analysis showed that the recurrence rate in patients with noninvasive IPMN was 3.72% with negative margins, and 9.56% with positive margins. The same meta-analysis showed that recurrence after surgical resection of invasive IPMN occurred in 33.8% of patients with negative margins and in 53.6% of patients with positive margins [24]. This data is reinforced by a recent series from the MGH, stating that resection margin is indeed an independent predictor of tumor recurrence for invasive IPMN [25].

Because recurrence in the remnant stump may be due to the presence of multifocal disease or to the development of a metachronous IPMN rather than due to the progression of margin-positive disease, the margin should be used as a marker of residual disease throughout the remnant.

Lymph node status is another factor affecting long-term outcome in invasive IPMN. The 5-year survival of patients with positive lymph nodes ranged from 20% to 30%, while N0 patients lived much longer, in the range from 80% to 85%. Lymph node ratio >0.2 has been shown to be associated with worse prognosis [26]. Data from a meta-analysis demonstrated that nearly 77% of lymph node positive patients recurred, while disease recurrence occurred in only 30.8% of patients with negative lymph nodes [24].

## Solid Pseudopapillary Neoplasms

More than 95% of patients with solid pseudopapillary neoplasms limited to the pancreas are cured by complete surgical excision. Local invasion or resectable liver and lymph node metastases are not contraindications for resection, and some patients with advanced tumors can survive for more than 10 years after the operation [27]. During the follow-up period, recurrence of the disease in the liver or lymph nodes is uncommon, at 6.6%. Prognosis for solid pseudopapillary neoplasms with treated liver metastases usually surpasses 5 years. Conversely, from a recent internal review of the Verona case series, other factors such as presence of capsular invasion and pancreatic parenchyma invasion correlated with the likelihood of tumor recurrence after complete surgical excision. Overall, 2-year survival rate (with metastases or not) was 97%, and 5-year survival around 95%. In the few unresectable cases in which radiotherapy or chemotherapy were used, results were encouraging [28].

## Final Remarks

The natural history of pancreatic cystic neoplasms is largely unknown in the long term, and data beyond 5 years are virtually lacking. Because it seems that survival is clearly favorable in comparison with pancreatic ductal adenocarcinoma, it will be of great importance to understand how these neoplasms behave, with respect to the time to degeneration, the risk of developing a new IPMN or additional malignancy, and the risk of disease-specific mortality. Accurate surveillance, either pre- and post-operatively seems mandatory in the majority of cystic neoplasms, since most have the potential to become malignant or to recur. For those that become malignant, it may take perhaps as long as 10 years or more for that evolution. So early reports with limited length of follow-up are just the beginning, and are not long enough to really capture the natural history of these neoplasms.

## Incidence, Mortality Trends, Survival Prognosis

In 2012, worldwide, there were approximately 380,000 individuals diagnosed with pancreatic cancer and approximately 331,000 individuals died from their disease making pancreatic cancer the seventh most common cause of cancer death [1]. Pancreatic cancer is strongly associated with increased age, with the majority of cases occurring after age 60. In the United States, from 2009–2013 the incidence of pancreatic cancer in Whites increased from less than 5 per 100,000 before age 45, to 30.0 per 100,000 in individuals aged 60–64, and 93.7 per 100,000 in individuals aged 80–84 [2]. Incidence is approximately equal in men and women. The disease burden is strongest in developed countries compared to developing countries [1]. This difference is likely driven, in large part, by differences in the age structure as well as access to medical care necessary for the diagnosis of pancreatic cancer [3].

In developed countries the overall incidence of pancreatic cancer is expected to continue to increase with the general aging of the population, particularly in high-income countries [4,5]. Pancreatic cancer is projected to become the second leading cause of cancer death in the United States by 2030 [6]. However, other countries have seen a recent decrease in the incidence of pancreatic cancer that seems to reflect patterns in cigarette consumption. As discussed later, cigarette smoking is a major risk factor for pancreatic cancer and never smoking or smoking cessation is strongly associated with a decrease in risk. In contrast, increased body mass index (BMI) and diabetes mellitus are both associated with a greater risk of pancreatic cancer and the increasing prevalence of these risk factors is projected to lead to a rise in incidence of pancreatic cancer.

Pancreatic cancer is associated with an extremely poor prognosis with an estimated average 1-year relative survival rate of ~20%, and a 5-year rate of ~8% [4]. Survival rates have increased only slightly since the mid-1970s from 4–5% to around 8% in the United States [2]. The low survival rates are mainly due to advanced stage at diagnosis with only ~20% of patients presenting with local disease [2]. Among patients who undergo surgical resection, the 5-year survival rate is ~15–25% [7]. Outcomes after surgical resection of the pancreas are highly dependent on the experience of the surgeon and the hospital; mortality rates are 70% lower among high-volume surgeons compared with low-volume surgeons, and hospitals with a high patient volume compared with low-volume hospitals [8].

## Cigarette Smoking

Of modifiable risk factors, the relationship between active cigarette smoking and pancreatic cancer risk is well established. Approximately, 20% of all pancreatic cancers are attributable to cigarette smoking [9–11]. Numerous studies have explored the relationship between smoking and pancreatic cancer. A meta-analysis of 82 epidemiologic studies published between 1950 and 2007 [9] reported a 1.74-fold (95% CI: 1.61–1.87) increased risk of pancreatic cancer among current smokers and a 1.2-fold (95% CI: 1.11–1.29) increased risk of pancreatic cancer among former smokers when compared with never smokers. Pooled analysis of individual-level data from the nested case-control studies within the Cohort Consortium (PanScan) [11] as well as analysis of data from 12 case-control studies in the Pancreatic Cancer Case-Control Consortium (PanC4)

Companion website: www.wiley.com/go/beger/thepancreas

[10] showed that smokers have a 75–120% increased risk of pancreatic cancer compared with never smokers, and the risk persists for 10–20 years after smoking cessation [10,11]. Risk also increased according to the number of cigarettes consumed per day; smokers of more than 35 cigarettes per day have a threefold (95% CI: 2.2–4.1) increased risk of pancreatic cancer compared with never smokers [10]. Quitting smoking is associated with a reduced pancreatic cancer risk with a decreased odds ratio in former smokers when compared with active smokers. Studies suggest that the risk in former smokers returns to that of never smokers 15–20 years after smoking cessation [10,11].

## Diabetes

The relationship between diabetes and pancreatic cancer is quite complex; many newly diagnosed pancreatic cancer patients report a recent onset of diabetes, and those with long-standing diabetes report a recent worsening of diabetes. Thus, it is generally considered that while long-standing diabetes is a risk factor for pancreatic cancer, diabetes can also result as a consequence of pancreatic cancer.

There is considerable variability when estimating the prevalence of diabetes and/or glucose intolerance among newly diagnosed pancreatic cancer patients [12]. It has been estimated that up to 80% of newly diagnosed pancreatic cancer patients have glucose intolerance or diagnosed diabetes [13]. Studies that rely on patient or medical records of reported diabetes show lower prevalence estimates, including a large Mayo Clinic case-control study where 40% of patients reported diabetes [14]. Over 75% of pancreatic cancer patients who develop diabetes, do so within the 2 years preceding their pancreatic cancer diagnosis [15]. Thus, there is considerable interest in examining populations of newly diagnosed diabetics to determine whether this might enable earlier detection of pancreatic cancer. It has been shown that up to 1% of newly diagnosed diabetics develop pancreatic cancer within 3 years of their diabetes diagnosis [16].

While many pancreatic cancer patients develop diabetes as a consequence of their disease, there is considerable support from numerous population-based studies that long-standing diabetes (>3 yr) is associated with a modest increase in the risk of pancreatic cancer. Overall, the risk of pancreatic cancer in long-standing diabetes ranges from 1.5- to 2.4-fold [17–20]. However, as the duration of diabetes increases the association between diabetes and pancreatic cancer weakens, with some studies showing only modest or no increase in pancreatic cancer risk 15–20 years after diagnosis with diabetes [20,21]; however, some studies still support an association with diabetes of 20 years or more [19].

In patients with new-onset diabetes who undergo surgical resection, diabetes often resolves after removal of the pancreatic cancer. In contrast, diabetes does not resolve in patients with long-standing diabetes after surgical removal of their cancer [22].

## Body Mass Index

In addition to diabetes, increased weight or BMI has consistently been associated with increased risk of pancreatic cancer. The World Health Organization (WHO) defines overweight individuals as those with a BMI of 25.0–29.9 $kg/m^2$ and obese individuals as those with a BMI >30.0 $kg/m^2$.

Over the past 15 years many studies have demonstrated an increased risk of pancreatic cancer among obese individuals. In 2001, Michaud et al. reported a relative risk of pancreatic cancer of 1.72 (95% CI: 1.19–2.4) for individuals with a BMI >30 $kg/m^2$ compared with individuals with a BMI <23 $kg/m^2$ after controlling for the effect of age, smoking, and diabetes among participants of the Health Professionals Follow-Up Study and the Nurses' Health Study. Many subsequent studies have confirmed this finding; a pooled analysis of data from 13 prospective cohort studies reported an OR for pancreatic cancer of 1.33 (95% CI: 1.12–1.58) when comparing individuals in the lowest quartile of BMI with those in the highest quartile after controlling for the effects of age and smoking. Adjusting for the effect of diabetes, attenuates this association slightly (OR = 1.21, 95% CI: 1.01–1.44) [23].

## Alcohol

Numerous studies have examined the association between alcohol consumption and risk of pancreatic cancer. The results of these studies have been inconsistent, with some studies showing an association and others showing no relationship. One challenge to these studies is the strong relationship between smoking and heavy alcohol use, making it difficult to assess the independent association between alcohol use and pancreatic cancer risk. However, several recent large-scale studies that have pooled data across several studies, either using data from prospective cohort studies or retrospective case-control studies, have demonstrated that high levels of alcohol intake are associated with an increased risk of pancreatic cancer. These studies consistently report a ~20–45% increased risk of pancreatic cancer among heavy drinkers (defined as three drinks/day or ≥30 grams/day of alcohol), compared with non- or occasional

drinkers [24–26]. In addition, in a pooled analysis of data from the Pancreatic Cancer Case-Control Consortium [27], the risk increases up to 60% among extremely heavy alcohol drinkers (≥9 drinks /day). Heavy alcohol consumption is associated with pancreatitis, an established risk factor for pancreatic cancer. Furthermore, acetaldehyde is an established carcinogen. Thus the association between alcohol and pancreatic cancer risk could be either via alcohol-induced pancreatitis or as a direct effect of acetaldehyde.

## Pancreatitis

The relationship between pancreatitis and pancreatic cancer has been well established. Individuals with hereditary pancreatitis, a rare inherited condition, have a remarkably high lifetime risk of pancreatic cancer of 40% [28]. The risk is further increased by cigarette smoking [29]. Quantifying the association between pancreatitis and pancreatic cancer is challenging given the difficulties in diagnosis and differentiation between chronic and acute pancreatitis [30]. In addition, like diabetes, pancreatitis is both a risk factor and a manifestation of pancreatic cancer. The inflammation and damage of long-standing pancreatitis can lead to the development of pancreatic cancer. However, individuals with pancreatic cancer also experience pancreatitis as a consequence of their cancer. A recent large-scale study of 5,048 cases of ductal pancreatic adenocarcinoma and 10,947 controls from 10 case-control studies within the Pancreatic Cancer Case-Control Consortium examined the association between pancreatic cancer and pancreatitis. Overall, 6% of pancreatic cancer patients reported a history of pancreatitis compared to 1% of control individuals. The association between a recent diagnosis of pancreatitis (<1 yr) and pancreatic cancer was remarkably high (OR = 21.35, 95% CI: 12.03–37.86) [31]. In contrast, the association between a pancreatitis diagnosis of >2 years and pancreatic cancer was estimated to be (OR = 2.71, 95% CI: 1.96–3.74) [31]. The association between pancreatitis and pancreatic cancer persisted after controlling for other risk factors including smoking, alcohol consumption, BMI, and diabetes. Interestingly, there was evidence of effect modification by age, with a stronger association between pancreatitis and pancreatic cancer in patients diagnosed before the age of 65 [31].

## Dietary Factors

Given the generally late age of onset of pancreatic cancer and the complexity of lifetime dietary factors, identification of dietary factors that are consistently associated with pancreatic cancer risk has been remarkably challenging. Several studies have suggested a diet rich in fruit and vegetables may protect against pancreatic cancer with risk reduction in the order of 30–40%, when comparing the highest intake to the lowest intake of fruits and vegetables [32–34]. While a diet rich in fruit and vegetables may protect against pancreatic cancer, several studies have demonstrated an increased risk of pancreatic cancer among individuals who are frequent consumers of smoked or processed meats [35]. A meta-analysis including 6,643 pancreatic cancer cases from 11 prospective studies, reported that eating at least one serving of processed meat a day was associated with a 19% increased risk of pancreatic cancer [35].

## Gastrointestinal Microbiome

In recent years, the importance of the microbiome in human health and disease has gained recognition. Several studies have shown that periodontal disease and tooth loss is associated with pancreatic cancer risk [36]. In 2007, a study among males participating in the Health Professionals Follow-up Study reported that individuals with a history of periodontal disease had a HR of pancreatic cancer of 1.54 (95% CI: 1.16–2.04) compared with those without such a history [37]. A recent study examined the association between specific oral pathogens and pancreatic cancer risk using prospective samples collected within the PLCO trial. This study found that individuals circulating antibodies to *Porphyromonas gingivalis* and *Aggregatibacter actinomycetemcomitans* had higher odds of pancreatic cancer (OR = 1.60, 95% CI: 1.15–2.20, and OR = 2.20, 95% CI: 1.16–4.18, respectively), compared with noncarriers [38].

While some studies have shown an association between pancreatic cancer risk and *Helicobacter pylori* infection not all studies have shown a positive association. One possible explanation for these inconsistent results is that the relationship may vary between CagA-positive and CagA-negative infections; CagA-negative infection is positively associated with disease and CagA-positive infection potentially has a protective effect. A recent meta-analysis found an overall association of OR = 1.13, 95 % CI: 0.86–1.50 for *H. pylori* infection and pancreatic cancer risk. The association was OR = 0.78, 95% CI: 0.67–0.91, and OR = 1.30, 95 % CI: 1.02–1.65 for CagA-positive and CagA-negative strains, respectively [39].

## Allergy

Individuals with a history of allergies, including hay fever, allergic rhinitis, atopic dermatitis, and atopic asthma may have a lower risk of developing pancreatic

cancer. A meta-analysis published in 2005 reported an overall association between allergies and pancreatic cancer risk of RR = 0.82, 95% CI: 0.68–0.99). A stronger protective effect was reported in atopic allergies (RR = 0.71, 95% CI: 0.64–0.80) and no association was reported for asthma or food allergies [40]. A recent pooled analysis of data from the Pancreatic Cancer Case-Control Consortium reported a protective effect of hay fever and animal allergies (OR = 0.74, 95% CI: 0.56, 0.96, and OR = 0.62, 95% CI: 0.41, 0.94, respectively), and no association with asthma [41]. In contrast, a recent case-control study from Spain reported a protective effect of both allergy and asthma (OR = 0.66, 95% CI: 0.52–0.83, and OR = 0.64, 95% CI: 0.47–0.88, respectively) [42].

## Family History

One of the strongest risk factors for pancreatic cancer is having a family member with pancreatic cancer. The clustering of pancreatic cancer in families was first reported in the 1970s. Large-scale observational studies have consistently estimated an increased risk of pancreatic cancer among those with a family history of pancreatic cancer [43–51]. A recent pooled analysis of data from one case-control and six cohort studies estimated the odds of pancreatic cancer to be 1.76 higher (95% CI: 1.19–2.61) among individuals who had at least one first-degree relative with pancreatic cancer compared with those with a family history of pancreatic cancer [51]. Risk is even higher in familial pancreatic cancer kindreds (defined as a having at least one pair of first-degree relatives with pancreatic cancer) with a 6.79-fold increased risk of pancreatic cancer among first-degree relatives. Mutations in the following genes have been associated with a markedly increased risk of pancreatic cancer: *BRCA2*, *BRCA1*, *PALB2*, *ATM*, *CDKN2A*, *STK11*, *PRSS1*, *MSH2*, *MLH1*, *MHS6*, and *PMS2* [52–58].

## Conclusions

Pancreatic cancer is a leading cause of cancer mortality in developed countries. Unlike other cancers, the incidence of pancreatic cancer has increased in recent years. Major modifiable risk factors include cigarette smoking, diabetes, obesity, alcohol intake. Nonmodifiable risk factors include age and family history of pancreatic cancer.

## Introduction

Epidemiologic data clearly indicates that cigarette smoking is a risk factor for developing pancreatic cancer—in fact, cigarette smoking is the most important modifiable risk factor for these patients. While clear epidemiologic associations exist between inhaled cigarette smoke and pancreatic disease, our ability to delineate this association remains limited. Of note, no similar association has been demonstrated between smokeless tobacco and pipe or cigar smoking and pancreatic cancer.

## Experimental Data Regarding Smoking: A Risk Factor for Pancreatic Cancer

Due to the large number of chemicals in cigarette smoke, the effect of cigarette smoke on the pancreas is likely multifactorial and complex. Several of these chemicals display toxic, carcinogenic, or pharmacologically active properties, of which many have not yet been identified, contributing to our incomplete understanding of the effects of cigarette smoking on the pancreas. However, two mechanisms of action have been identified. First, chemicals such as polycyclic aromatic hydrocarbons have obvious carcinogenic properties that damage genomic DNA. Second, chemicals such as nicotine exert pharmacologic effects on cells, contributing to neoplasia.

During carcinogenesis of pancreatic cancer, genetic alterations in 12 signaling pathways are found in over 67% of patients [1]. Some of these pathways include integrin signaling, apoptosis, DNA damage control, and regulation of the G1/S phase, to name a few. Carcinogens derived from cigarette smoke are likely contributing to genetic alterations such as these. Following inhalation, carcinogens travel through the blood stream to the pancreas where they are taken up by acinar or ductal cells. Once carcinogens reach their target tissue, they then begin to exert their toxic properties. For example, 80 days of oral 2-aminoanthracene intake, a member of the anthracene family, was found to induce pancreatic acinar cell necrosis with formation of duct-like structures [2]. Other carcinogens have to be metabolized to more active compounds before they exert their toxic properties. Especially nitrosamines, nitroaromatic hydrocarbons, and aromatic and heterocyclic compounds, which are metabolized to reactive electrophiles. These reactive electrophiles are then able to interact with DNA to exert their genotoxic carcinogenic effects [3,4].

Several enzymatic systems are available for pancreatic carcinogen metabolism of which the cytochrome P450 system, glutathione S-transferases, and the UDP-glucuronosyltransferases are the most important ones. NNK (4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone), the most abundant and best studied carcinogen in cigarette smoke, undergoes CYP 450 dependent oxidation to form NNAL (4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol) whose S-enantiomer shows high adduct formation with pancreatic DNA [5]. This results in the creation of DNA adducts to either thymidine or guanine [6]. It can be postulated that these DNA adducts induce mutations and act as key steps in pancreatic cancer development if these mutations are randomly formed in critical gene loci such as *KRAS* or *P53*. In addition to DNA mutations in critical

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

loci, a disturbance of epigenetic regulation of gene expression can be induced by cigarette smoke through aberrant DNA methylation by benzo[a]pyrene, shown to be present in significantly high concentrations in cigarette smoke. This effect of aberrant DNA methylation has been previously demonstrated in the pancreas of mice treated with benzo[a]pyrene [7]. The carcinogen-induced DNA methylation can interfere with the expression of a variety of crucial genes in the pancreas.

Apart from their carcinogenic properties, compounds such as nicotine or NNK, NNN (N-nitrosonornicotine), and (N-nitrosdiethylamine) exert pharmacologic effects by functioning as ligands for cell surface receptors. These substances contained in cigarette smoke at high concentrations interact and activate nicotinergic acetylcholine receptors (nAChR). These receptors are expressed not only on normal acinar and ductal cells but also on pancreatic cancer cells [8]. Each substance can be found in different concentrations in cigarette smoke with nicotine demonstrating the highest concentration, followed by NNK and NNN. In addition to the varying quantities of these chemicals, substantial discrepancies in binding affinities also exist. NNK preferentially binds to α7nAChR while NNN has a higher affinity for α2-α6nAChR [9]. This activation of nAChR contributes to cigarette smoke-induced pancreatic carcinogenesis [8].

Independent of pancreatic carcinogenesis, nicotine is associated with the development of pancreatic inflammation. The inflammatory effects of nicotine on acinar cells are thought to occur in a calcium-dependent mechanism. In isolated acinar cells, nicotine activates nAChR, promoting the influx of calcium into the acinar cell and enhancing the secretion of digestive enzymes [10,11]. This appears to be a key event in the development of cigarette smoke-associated acute and chronic pancreatitis since pancreatic acinar cell damage can be observed experimentally following prolonged nicotine treatment [12]. While the mechanism is not well described, the influence of nicotine on calcium signaling also promotes tumor cell viability, even after the development of pancreatic cancer [13].

Apart from calcium signaling, nicotine also exerts its effects through other pathways. Of note, treatment of pancreatic ductal epithelial cells and pancreatic cancer cells with nicotine previously resulted in a dose-dependent secretion of adrenaline and noradrenaline, contributing to cellular proliferation. This nicotine-induced autocrine catecholamine loop was mediated by 3α, 5α, and 7α nAChR [14]. In addition, pancreatic ductal cells and pancreatic cancer cells secrete the neurotransmitter GABA following combined stimulation with nicotine and catecholamines. GABA can also act as a potent tumor suppressor, mitigating the damaging effects of chronic nicotine exposure in cells co-incubated with GABA [15]. Interestingly, nicotine is able to reduce GABA secretion in a time-dependent manner. This is thought to be mediated by a downregulation of the GABA synthesizing enzymes GAD65 and GAD67 in a 4α nAChR-dependent manner, abrogating the GABA-induced growth inhibition [15].

In addition to its effects on cellular proliferation, nicotine also influences the ability of tumor cells to migrate, invade surrounding tissues, and metastasize. In pancreatic cancer cell lines, cigarette smoke extracts and nicotine induce the expression of MUC4 in an α7 nAChR-dependent manner [16]. MUC4 is a mucin that promotes tumorigenesis and tumor progression [17]. Additionally, MUC4 is aberrantly expressed in pancreatic cancer and its expression is upregulated in progressively worsening PanIN lesions [18,19].

Nicotine has also been found to stimulate pancreatic cancer growth, invasion, and metastasis by inducing the expression of osteopontin, a secreted molecule expressed in many cancers. Following nicotine-dependent activation of nAChR, osteopontin confers tumorigenicity to cells, resulting in increased cell survival, cell motility, tumor growth, and metastasis [20,21]. This effect is mitigated in the presence of nAChR antagonists, preventing nicotine-induced osteopontin expression [22].

These pathways represent only a fraction of the pathways involved in cigarette smoke-associated pancreatic damage. The carcinogenic effects that are conveyed to many different types of cancer are not specific to the pancreas. Therefore, pancreas-specific effects of cigarette must be involved, rendering the pancreas susceptible to damage from cigarette smoke. These effects are also mediated by the activation of nAChR that regulate the secretory function of the pancreas. This is evident when CCK-stimulated acinar cells are treated with nicotine, resulting in a reduction of CCK-stimulated amylase secretion [23]. Additionally, it has been shown that chronic nicotine treatment not only reduces the secretion of amylase, but also increases the intracellular amylase content in pancreatic acinar cells [24]. Somewhat similar observations were made by cigarette smoke inhalation over a period of 12 weeks. Cigarette smoke inhalation induced a dose-dependent increase in trypsinogen expression while cigarette smoke inhalation did not influence the expression of genes associated with pancreatic ductal cells [25]. These secretory alterations were associated with focal inflammatory lesions detected throughout the pancreas [26]. When nicotine treatment was performed over a prolonged period in mice carrying a constitutively active *KRAS* gene, comparable effects were observed in the pancreas. Nicotine

treatment in conjunction with active *KRAS*-induced pancreatic acinar cell damage leading to higher grade PanIN lesions and increased acinar-to-ductal metaplasia [27]. This was associated with a loss of *GATA6* expression, which could be reversed by metformin. After full transition to pancreatic cancer cells, nicotine induced a cancer stem cell phenotype by interacting with α7-nAChR and further induced epithelia-mesenchymal transition, promoting cell migration. Similarly, these effects were also reversible with *GATA6* overexpression [27]. These pathways appear to be crucial steps in cigarette smoke-induced pancreatic damage. Another mechanism by which nicotine induces pancreatic cancer progression and metastasis is by inducing MUC4 expression in a dose-dependent manner [16]. Even though pancreatic inflammation and acinar-to-ductal metaplasia are very likely to be associated with pancreatic carcinogenesis, nicotine alone is not the sole factor in pancreatic tobacco-associated carcinogenesis but enhances it occurrence. Acinar cell stimulation plays an important role in these mechanisms since the stimulation of acinar cells by CCK also significantly increased the rate of pancreatic cancer formation indicating that nicotine may enhance the fatal action of carcinogens by altering the secretory function of acinar cells [28].

Other carcinogens are also able to induce acinar to ductal metaplasia. This has been demonstrated in rodent models of ductal adenocarcinoma in which 7,12-dimethylbenz(a)anthracene(DMBA) crystals are surgically implanted in the pancreatic tissue [29]. In this model, histologic alteration of the exocrine pancreas was observed and described as tubular complexes, representative of acinar-to-ductal metaplasia [30].

In summary, experimental evidence of cigarette smoke-induced pancreatic carcinogenesis can be placed into two categories (Fig. 89.1). The first is that carcinogens can induce genetic or epigenetic changes resulting in DNA damage. Second, carcinogens mediated their pharmacologic effects through nACh receptors. The latter can be further subcategorized. The first subset of nAChR-dependent mechanisms centers on the enhancement of pro carcinogenic events mediated by a variety of substances. The second subset of nAChR-dependent mechanisms involves alterations in acinar cell secretory function, contributing to the development of pancreatic inflammation [31,32].

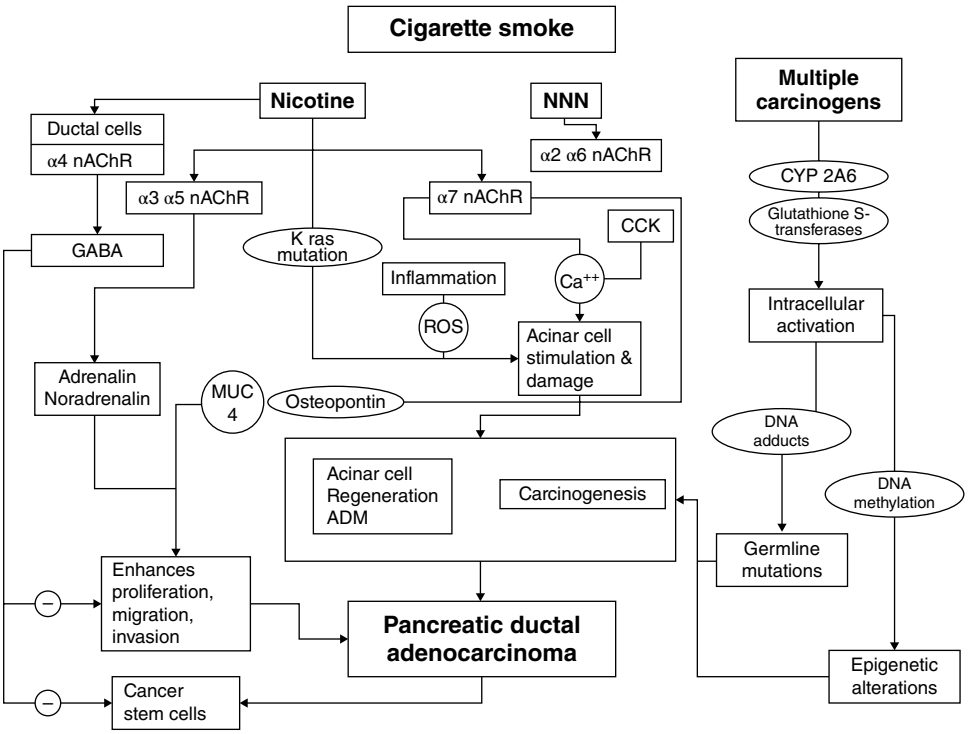

**Figure 89.1** Summary of experimental and clinical data on the effects of cigarette smoking on pancreatic carcinogenesis. The pharmacologic activity of cigarette smoke on the pancreas is mediated by nicotinergic acetylcholine receptors (nAChR) and induces pancreatic acinar cell damage and mediates a variety of adverse events. In addition to that, the carcinogenic action is induced after the intracellular activation of carcinogens by cytochrome P450 enzymes. Glutathione transferases seem to be involved in the intracellular detoxification.

## Clinical Data Supporting the Experimental Findings

Clinical data on cigarette smoke-induced pancreatic damage largely consists of the epidemiologic correlations between smoking, pancreatic inflammation, and cancer. Some of the key elements such as carcinogen accumulation and interference with the regulation of pancreatic enzyme secretion have been confirmed in clinical studies. Prior research has demonstrated that carcinogens do accumulate in pancreatic juice of smokers. In these studies, NNK was detectable in 83% of smokers [33]. Previous studies have also demonstrated that inhaled carcinogens are delivered to the pancreas and that enzymes metabolize these compounds into active electrophiles [34], at which point, they can exert their genotoxic properties within the pancreas [35,36]. As an example of the clinical relevance, the phenotypic variation of carcinogen metabolizing enzymes, such as CYP450 2A6, influenced the pathogenesis of pancreatic cancer. In an adjusted categorical analysis, subjects in the uppermost quartile of CYP2A6 activity carried an 80% greater risk of acquiring pancreatic cancer [37]. Similar observations have been made for glutathione S-transferases (GST), a family of phase II isoenzymes believed to protect cells from reactive chemical intermediates [38]. In this study, the adjusted odds ratios of pancreatic cancer for heavy smokers with the GSTT1-null genotype were 5.0 (95% CI: 1.8–14.5) for women and 3.2 (95% CI: 1.3–8.1) for men, indicating that the combination of heavy smoking and a deletion polymorphism in GSTT1 is associated with an increased risk of pancreatic cancer.

Tobacco-derived carcinogens are undoubtedly involved in the carcinogenesis of pancreatic cancer. $^{32}$P-postlabeling analysis indicates a specific adduct pattern in smokers, increased adducts in pancreatic DNA were observed in smokers but an association with BMI was also observed [39]. No clear association of DNA adducts in the pancreas with the individual smoking history utilizing chromatography has yet been established [40]. This could be due to the relatively limited amount of DNA adducts present or this quantity being below the limit of detection [41]. Independent of detection methods, non-smokers must be also exposed to many environmental carcinogens inducing the formations of DNA adducts similar to those observed in smokers [42].

Similar to experimental observations, cigarette smoke exerts widespread pharmacological effects on the human pancreas which are mediated by nicotine and other tobacco derived carcinogens displaying pharmacologic activities. In the 1970s, the relationship of cigarette smoking with the pancreatic secretion was discovered [43,44]. In a clinical experiment, smoking induced immediate and reproducible effects on the pancreatic secretion in volunteers. After smoking cigarettes, the fluid and bicarbonate secretion was immediately altered and returned to normal within 30–60 minutes. This effect directly correlated with the serum nicotine concentration. In accordance with this observation, cotinine, a derivate of nicotine with a longer half-life, was detected in the pancreatic juice of active smokers with an average concentration of 129 ηg/mL [33]. The concentration of these compounds has not been measured in pancreatic tissue, but the differential expression of nAChR receptors has been demonstrated on human pancreatic acinar and ductal cells [8,14].

The effects of cigarette smoke on pancreatic exocrine function is thought to be responsible for the induction of pancreatic acinar cell damage and has been shown to have a clear association with both acute and chronic pancreatitis [31,45,46]. While a small subset of patients experience inflammation of the entire gland, in most patients, the cigarette smoke induced pancreatic damage is only present in small focal areas of the pancreas where remodeling is occurring at the same time as sample acquisition. Similar to experimental data, an increase in small inflammatory foci with ongoing pancreatic regeneration was observed in humans as well. In this context, focal acinar cell dysplasia has been described at the time of autopsy and in surgical specimens. These acinar cell lesions were found to be acquired and correlated to history of smoking. Additionally, they were detectable in 83% of heavy smokers [47,48]. Acinar cell lesions are also associated with simple and atypical ductal hyperplasia, indicating that either the cigarette smoke induced damage leads to ductal lesions as well, or it can be speculated that these ductal lesions are the result of acinar to ductal metaplasia [49].

## Summary

Evidence today for cigarette smoke-induced pancreatic disease remains incomplete, but available experimental and clinical data proposes potential pathomechanisms of cigarette smoke-induced pancreatic carcinogens that remain to be further investigated in both experimental and clinical studies. The pancreas is susceptible to the effects of carcinogens found in cigarette smoke partly as a result of acetylcholine receptor mediated events, or by mutations, for example, of tumor suppressor genes [50]. These contribute to the induction proliferative signaling pathways and pancreatic inflammation. These events provide a fertile environment for pancreatic ductal adenocarcinoma to develop, at which point the smoking history appears to have no impact on the clinical course [51]. However, patients who continue to smoke following surgical resection of a ductal adenocarcinoma have decreased survival compared to individuals who refrain from smoking [52].

# Molecular Understanding of Development of Ductal Pancreatic Cancer

*Laura D. Wood and Ralph H. Hruban*

*Departments of Pathology and Oncology, The Sol Goldman Pancreatic Cancer Research Center, Johns Hopkins University School of Medicine, Baltimore, MD, USA*

## Introduction

Pancreatic cancer is predicted to be the second leading cause of cancer death by the year 2030 [1]. A fundamental understanding of the molecular underpinnings of pancreatic cancer will not only provide insight into the pathophysiology driving this neoplasm, but will also provide new tools that can be used to detect early curable pancreatic neoplasms and to treat advanced cancers.

The groundwork for our understanding of the genetic drivers of ductal adenocarcinoma was laid decades ago, but this knowledge has exploded in recent years. The first gene identified as targeted in ductal adenocarcinoma was the *KRAS* oncogene in the mid-1980s [2–4]. It took almost another decade before the *TP53* tumor suppressor gene was shown to be inactivated in most of these cancers [5,6]. In the 1990s a team led by Scott Kern extensively characterized the allelic losses in a series of ductal adenocarcinomas and in so doing identified a number of recurrent genetic alterations, including homozygous deletions on chromosomes 9p, 13q, and 18q, in these cancers—these loci correspond to three additional tumor suppressor gene loci that drive ductal adenocarcinoma [7–9]. The homozygous deletion identified on chromosome 9p proved to target the *p16*/*CDKN2A* tumor suppressor gene, the deletion on 13q led to the discovery of the *BRCA2* gene, and the homozygous deletion on 18q led to the discovery of *SMAD4* (*DPC4*) [10,11]. Thus, by the mid-1990s the four genes most frequently targeted in ductal adenocarcinomas had been discovered (*KRAS*, *TP53*, *SMAD4*, *p16*/*CDKN2A*), as had one of the major familial pancreatic cancer genes (*BRCA2*). Over the ensuing decade, a number of additional genes were found to be targeted in ductal adenocarcinomas, often using candidate gene approaches [12–14]. Most of these proved to be low prevalence genes (altered only in a small fractions of the cancers), such as *BRAF* and *FBXW7* [14].

The completion of the draft map of the human genome was completed in 2001, providing a foundation for dramatically changing the pace of gene discovery in ductal adenocarcinomas [15]. Jones and colleagues used the draft map of the human genome to Sanger sequence the complete exomes of a series of 24 well-characterized ductal adenocarcinomas, providing a first complete catalogue of protein-coding mutations in this cancer type [16]. This work had several important results: the oncogene *KRAS* and the tumor suppressor genes *TP53*, *SMAD4*, and *p16*/*CDKN2A* were confirmed to be the most commonly targeted "mountains" in ductal adenocarcinoma (Table 90.1), and a number of "hills" with less prevalent mutations were also identified (Table 90.2). In addition, the Jones study led to the discovery of a familial pancreatic cancer gene (*PALB2*) [16–18]. For the first time, a comprehensive understanding of the genetic drivers of pancreatic tumorigenesis was possible. A number of large-scale studies followed, and in recent years several groups, including the International Cancer Genome Consortium (ICGC), The Cancer Genome Atlas (TCGA), and a team at Baylor University, have extended Jones' whole exome sequencing study by sequencing the exomes and even genomes of additional ductal adenocarcinomas [19–22]. The time is now ripe to translate this understanding into patient care.

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

**Table 90.1** "Mountains" of pancreatic tumorigenesis

| Gene | Chromosome | Gene type | Function | Mechanism of alteration |
|---|---|---|---|---|
| *KRAS* | 12 | Oncogene | MAPK signaling | Point mutation (hotspots) |
| *P16/CDKN2A* | 9 | Tumor suppressor | Cell cycle regulation | Point mutation/LOH, homozygous deletion, methylation |
| *TP53* | 17 | Tumor suppressor | DNA damage response | Point mutation/LOH |
| *SMAD4* | 18 | Tumor suppressor | TGFβ signaling | Point mutation/LOH, homozygous deletion |

LOH, loss of heterozygosity; MAPK, mitogen-activated protein kinase; TGFβ, transforming growth factor β.

**Table 90.2** Well-defined "hills" of pancreatic tumorigenesis

| Gene | Chromosome | Function |
|---|---|---|
| *AKT2* | 19 | PI3K signaling |
| *ARID1A* | 1 | Chromatin remodeling |
| *ATM* | 11 | DNA repair |
| *BRAF* | 7 | MAPK signaling |
| *BRCA2* | 17 | DNA repair |
| *CDK6* | 7 | Cell cycle regulation |
| *FBXW7* | 4 | Cell cycle regulation |
| *GATA6* | 18 | Transcription factor |
| *KDM6A* | X | Chromatin remodeling |
| *MAP2K4* | 17 | MAPK signaling |
| *MET* | 7 | Growth factor signaling |
| *MLL3* | 7 | Chromatin remodeling |
| *MTAP** | 9 | Polyamine metabolism |
| *MYC* | 8 | Cell cycle regulation |
| *ROBO2* | 3 | Axon guidance |
| *SLIT2* | 4 | Axon guidance |
| *SMARCA4* | 19 | Chromatin remodeling |
| *TGFBR1* | 9 | TGFβ signaling |
| *TGFBR2* | 3 | TGFβ signaling |

* Gene often included in p16/CDKN2A homozygous deletions; PI3K, phosphoinositide 3-kinase; MAPK, mitogen-activated protein kinase; TGFβ, transforming growth factor β.

## Genetic Alterations: The Four Mountains

### *KRAS*

The *KRAS* oncogene is activated in >90% of ductal adenocarcinomas, usually by a point mutation at codon 12, 13, or 61 [23]. *KRAS* gene mutations activate a complex cascade of downstream signaling pathways including the mitogen-activated protein kinase and phosphoinositide 3′-kinase pathways [24–27]. *KRAS* gene mutations also contribute to the "Warburg effect" and increase autophagy in the neoplastic cells [24–26]. The resultant changes caused by *KRAS* gene mutations combine to promote tumorigenesis.

*KRAS* wild-type ductal adenocarcinomas can have other distinctive genetic alterations [14,28]. Some *KRAS* wild-type tumors harbor *BRAF* mutations, and others, as will be discussed in greater detail later, are microsatellite unstable [14,19,28].

### *p16/CDKN2A*

The *p16/CDKN2A* tumor suppressor gene on chromosome 9p is inactivated in 90% of ductal adenocarcinomas [7,29]. In ~40% of the cancers the gene is inactivated by an intragenic mutation in one allele coupled with loss of the second allele (loss of heterozygosity, LOH). In another 40% the *p16/CDKN2A* gene is inactivated by homozygous deletion, and in 10–15% of the cancers it is inactivated by hypermethylation of the *p16/CDKN2A* gene promoter [29,30]. Loss of p16 protein function leads to the loss of a major regulator of the cell cycle. The *MTAP* gene on chromosome 9p is often included in the homozygous deletions that target *p16/CDKN2A* [31]. As will be discussed later, the deletion of *MTAP* has potential therapeutic implications.

### *TP53*

The *TP53* tumor suppressor gene on chromosome 17p is inactivated, usually by an intragenic mutation in one allele coupled with LOH in the remaining allele, in ~75% of ductal adenocarcinomas [16,32]. Loss of p53 function disrupts a number of critical tumor suppressive pathways including response to DNA damage, apoptosis, cell cycle arrest and senescence [33]. Aberrant protein expression patterns, as seen on immunohistochemical assays, are correlated with gene mutation—these include strong diffuse nuclear expression (Fig. 90.1) as well as complete absence of expression.

### *SMAD4*

The *SMAD4* tumor suppressor gene on chromosome 18q is inactivated in ~55% of ductal adenocarcinomas [11]. As noted earlier, *SMAD4* was discovered by Scott

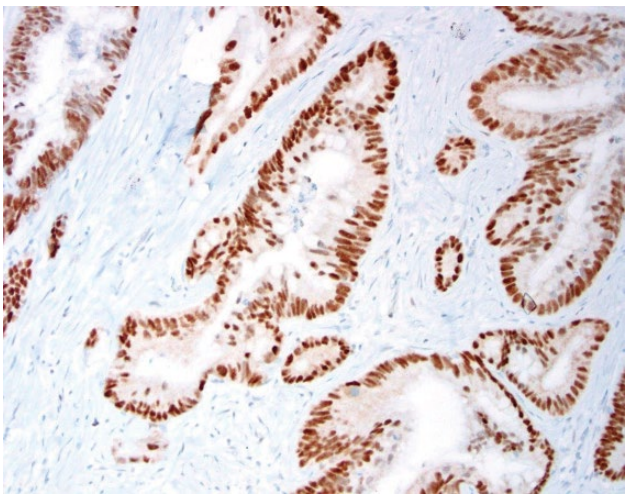

**Figure 90.1** Aberrant p53 protein expression in *TP53* mutant ductal adenocarcinoma. Immunohistochemistry for p53 shows strong diffuse nuclear labeling, which is strikingly different from the occasional weak nuclear labeling seen in the nonneoplastic stromal cells.

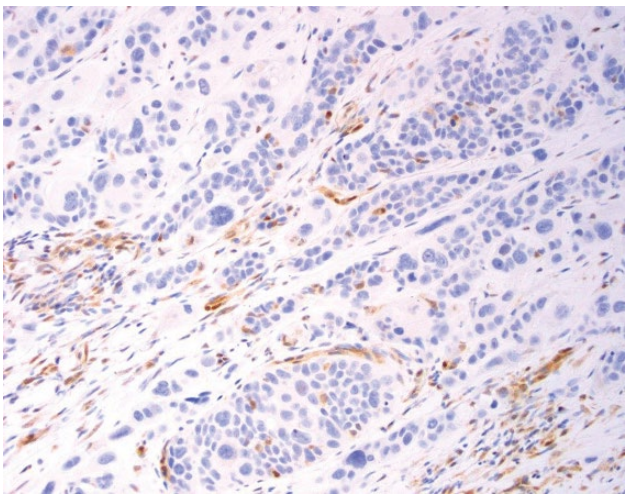

**Figure 90.2** Loss of SMAD4 protein expression in *SMAD4* mutant ductal adenocarcinoma. Immunohistochemistry for SMAD4 shows loss of protein expression in malignant cells, while retained expression in nonneoplastic stromal cells serves as an internal control.

Kern and colleagues as a recurrent homozygous deletion identified using a panel of microsatellite markers [11]. Subsequently, *SMAD4* has been shown to encode a protein that functions in the transforming growth factor-beta (TGF-β) pathway. Immunolabeling for the Smad4 protein is a good surrogate marker for *SMAD4* gene inactivation, as inactivating mutations in *SMAD4* are associated with loss of Smad4 protein expression (Fig. 90.2) [34].

## Genetic Alterations: The Hills

In addition to the four mountains, the four genes targeted in >50% of pancreatic cancers, a growing number of genes have been found that are altered in only a small fraction (usually <10%) of ductal adenocarcinomas (Table 90.2) [16,19–21]. For example, Biankin and colleagues sequenced the exomes of close to 100 ductal adenocarcinomas and reported that genes coding for embryonic regulators of axon guidance, including *ROBO* and *SLIT*, are targeted in a minority of these cancers [20]. Sausen and colleagues report uncommon mutations in chromatin regulating genes (such as *MLL3* and *ARID1A*) that are associated with improved survival [35]. Others have reported focal gene amplifications in ductal adenocarcinomas, including amplification of *MYC*, *GATA6*, *BRAF*, *CDK6*, and *MET* [21,36–38].

## Chromosome Instability

In addition to the specific genes noted earlier that are targeted by focal chromosomal alterations, ductal adenocarcinomas of the pancreas are also characterized by larger chromosome abnormalities [21,39,40]. These larger chromosome abnormalities were first noted in karyotyping studies of pancreatic cancer [39]. Subsequently, the exact loci involved could be defined better in whole genome sequencing studies [21]. These latter studies also showed that chromosome instability is associated with the inactivation of DNA maintenance genes (*BRCA1*, *BRCA2*, or *PALB2*) and a DNA damage repair deficiency mutational signature [21].

## Microsatellite Instability

A small fraction (2–3%) of pancreatic cancers have microsatellite instability, with defective DNA repair pathways leading to a large number of point mutations [28,41,42]. Some pancreatic cancers with microsatellite instability (also known as MSI-high cancers) arise in association with intraductal papillary mucinous neoplasms (IPMN) and others have a characteristic medullary histology that includes poor differentiation, a syncytial growth pattern, and pushing tumor borders (Fig. 90.3) [41]. These carcinomas are important to recognize because, despite their poor differentiation, they are associated with a good prognosis [41,42]. In addition, as will be discussed later, MSI-high pancreatic cancers may be particularly sensitive to immunotherapies [43].

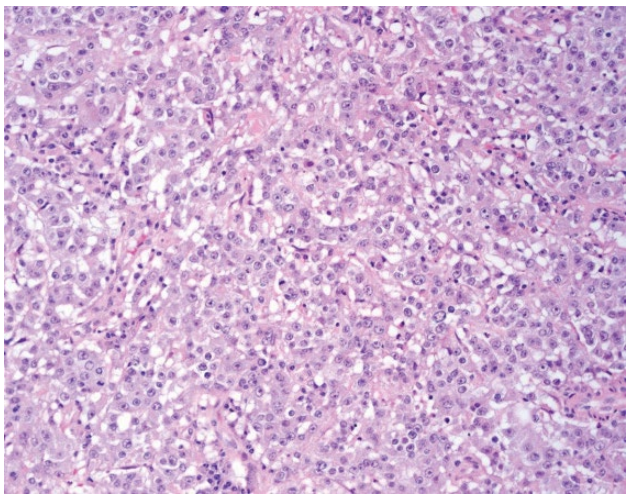

**Figure 90.3** Medullary carcinoma. The characteristic morphology of medullary carcinoma (poor differentiation, syncytial growth, pushing borders) is frequently seen in tumors with microsatellite instability.

## Mitochondrial Gene Mutations

Although we tend to focus on the nuclear genome, eukaryotic cells also have a mitochondrial genome. Jones and colleagues sequenced the mitochondrial genome (mtDNA) of a series of pancreatic cancers and homoplasmic mtDNA somatic mutations were identified in nearly all of the cancers [44]. While it could not be determined whether any of these mtDNA mutations were driving the neoplastic process, Jones and colleagues were able to show that mtDNA is greatly (six- to eightfold) increased in ductal adenocarcinoma cells relative to normal cells. This finding suggests that mtDNA mutations may be easier to detect than nuclear mutations, and that mtDNA mutations may be useful in screening tests [44,45].

## Expression Changes

A number of genes are overexpressed in ductal adenocarcinomas relative to normal nonneoplastic pancreatic ductal cells [46–52]. Many of these overexpressed genes were identified at the mRNA level using techniques such as serial analysis of gene expression (SAGE) and expression microarrays, and then protein overexpression was confirmed using Western blotting or immunohistochemical labeling [46–52]. Other overexpressed proteins were discovered using mass spectrometry and other proteomic approaches [53]. The list of genes and proteins overexpressed in ductal adenocarcinomas is long, and includes mesothelin, claudins, annexins, S-100-related proteins, and others [48,54–59]. Pandey and colleagues have reviewed the literature and established a centralized resource for the collection and sharing of these overexpressed genes [60,61]. As discussed later, differentially expressed genes may be useful targets for developing early detection tests and for novel therapies. The technologies to distinguish quantitatively among peptides are now so refined that normal proteins can be distinguished from mutant proteins created by some of the DNA mutations discussed earlier [62].

In addition to the overexpressed genes, a number of genes are downregulated in ductal adenocarcinomas. Promoter hypermethylation often accounts for this downregulation [63]. Genome-wide analyses of DNA methylation in ductal adenocarcinomas have identified over 1,000 genes that are differentially methylated in pancreatic cancer relative to normal pancreatic ductal cells, and many of these differentially methylated genes are differentially expressed at the protein level [63,64].

MicroRNA are small noncoding RNA that have emerged as important regulators of a number of cell functions, and the expression of a number of microRNA is dysregulated in ductal adenocarcinomas of the pancreas [65]. These microRNA include miR-21, miR-101, miR-155, miR-192, miR-193, miR-194, miR-196, miR-210, and miR-335 [65,66]. Some of these microRNA have been proposed as prognosticators and others as potential therapeutic targets in ductal adenocarcinomas [67].

## Precursor Lesions

Most invasive ductal adenocarcinomas of the pancreas are widely metastatic and incurable at the time of diagnosis [68]. We believe that early detection is one of the best hopes to impact the dismal prognosis associated with these cancers. An understanding of the biology of the precursor lesions that give rise to invasive carcinoma is therefore essential.

Three precursor lesions are currently recognized: pancreatic intraepithelial neoplasia (PanIN), intraductal papillary mucinous neoplasms (IPMN), and mucinous cystic neoplasms (MCN) (Table 90.3). A number of studies have examined the genetic alterations and gene expression changes in these precursors, and increasing degrees of dysplasia are associated with the accumulation of genetic alterations and changes in gene expression [66,69–71]. Lesions with high-grade dysplasia have many of the same changes that are found in invasive ductal adenocarcinomas [66,69–71]. For example, most of the microRNA overexpressed in invasive ductal adenocarcinoma are also overexpressed in precursor lesions with high-grade dysplasia. These findings suggest that gene mutations and changes in expression may be useful markers for the early detection of pancreatic neoplasms [66].

**Table 90.3** Precursors to ductal adenocarcinoma

| Precursor | Abbreviation | Location | Size | Key genetic alterations |
|---|---|---|---|---|
| Pancreatic intraepithelial neoplasia | PanIN | Head = Tail | <0.5 cm | Early: *KRAS*, *CDKN2A* Late: *TP53*, *SMAD4* |
| Intraductal papillary mucinous neoplasm | IPMN | Head > Tail | ≥1 cm | Early: *KRAS*, *GNAS*, *RNF43*, *CDKN2A* Late: *TP53*, *SMAD4* |
| Mucinous cystic neoplasm | MCN | Tail > Head | Broad range | Early: *KRAS*, *RNF43*, *CDKN2A* Late: *TP53*, *SMAD4* |

## Neoplasms with Acinar Differentiation

Although the vast majority of "pancreatic cancers" are ductal adenocarcinomas, malignancies with acinar differentiation do occur, and these cancers are clinically and molecularly unique [72]. Acinar cell carcinomas form solid masses in older adults and have a poor prognosis. Recent whole exome sequencing studies have revealed that acinar cell carcinomas exhibit striking genomic stability, commonly having either microsatellite instability or chromosomal instability [72]. There is striking heterogeneity in the genes altered in individual tumors, with no single gene mutated in >30% of cancers [72]. Uncommon mutations occurred in well-characterized drivers of ductal adenocarcinoma (*SMAD4*) and pancreatic cystic neoplasms (*GNAS*), as well as genes commonly altered in other tumor types (*APC*, *BRAF*). Pancreatoblastoma, the most common pancreatic tumor in childhood, can contain a variety of cell types but at a minimum contains an acinar component and squamoid nests. These neoplasms contain far fewer somatic mutations than acinar cell carcinomas, and alterations in the Wnt pathway (*APC*, *CTNNB1*) as well as loss of a highly imprinted region on chromosome 11p are the most common genetic alterations [72,73].

## Clinical Applications

These are exciting times. We are on the cusp of translating our growing understanding of the underlying biology of pancreatic cancer into patient care. We anticipate that in the near future, new molecular approaches will be developed to enhance the early detection, diagnosis, treatment, and monitoring of pancreatic cancer. Let us give examples of each of these.

Early detection is one of the most promising areas for the translation of molecular genetics into patient care. For example, mutant *GNAS* shed from noninvasive IPMN can be detected in secretin-stimulated pancreatic secretions (pancreatic juice) collected at the time of endoscopic ultrasound (EUS) [74]. Similarly, mutant *KRAS* shed from early stage (operable) ductal adenocarcinomas of the pancreas is detectable in the blood [75]. Panels of new biomarkers such as tumor-specific genetic mutations, applied to the right biosamples, will provide exciting new opportunities for the early detection of curable pancreatic neoplasms.

Molecular genetics can also be used to supplement tissue diagnoses. For example, in patients with a known pancreatic cancer it can be difficult to determine if an adenocarcinoma in a distant site, such as the lung, represents a metastasis or a new primary. In these instances, the loss of Smad4 expression, as determined by immunohistochemical labeling, supports the diagnosis of a metastasis from a pancreatic primary over a second lung primary (Fig. 90.2) [34].

Notable advances have also been made in the application of molecular genetics to personalized therapy of ductal adenocarcinomas. Five examples include: (i) Approximately 2–3% of pancreatic cancers are microsatellite unstable (MSI-high), and these cancers appear to be remarkably sensitive to immunotherapy, particularly with PD-1 blocking agents [43]. (ii) Most pancreatic cancers overexpress mesothelin and a number of anti-mesothelin specific vaccines have been developed [76,77]. (iii) Pancreatic cancers with a mutation signature indicative of DNA damage repair deficiency (including those with *BRCA2* mutations) are likely to respond to specific chemotherapeutic regimens, including platinum agents and poly(ADP ribose) polymerase (PARP) inhibitors [78,79]. (iv) *KRAS* wild-type ductal adenocarcinomas often harbor *BRAF* mutations, and these *BRAF* mutant cancers are highly sensitive to targeted BRAF inhibition [19]. (v) As mentioned earlier, the *MTAP* gene on chromosome 9p is homozygously deleted with *P16/CDKN2A* in 30–40% of pancreatic cancers. This gene codes for the enzyme methylthioadenosine phosphorylase (MTAP), and MTAP-deficient cells may be differentially sensitive to methylthioadenosine (MTA, the substrate for the MTAP enzyme) and to small molecular inhibition of protein arginine methyltransferase 5 (PRMT5, an enzyme upstream from MTAP) [80,81].

Finally, a molecular genetics approach can be used to monitor patients for response to therapy. Neoplasms release mutant DNA into the circulation (circulating

tumor DNA, ctDNA) and this ctDNA can be quantified [35,75]. Velculescu and colleagues have shown that monitoring ctDNA can be used to quantify the response of a neoplasm to therapy.

## Summary and Conclusions

These are the best of times. Hundreds of ductal adenocarcinomas of the pancreas have been sequenced, and the fundamental drivers of tumorigenesis in the pancreas are now defined. These drivers give us new tools for the early detection of pancreatic neoplasms, and it is hoped that these early detection efforts will save lives, especially when applied to high-risk populations such as individuals with a deleterious germline mutation in a familial pancreatic cancer gene. Despite our best efforts at early detection, we recognize that most patients will still be diagnosed with an invasive carcinoma, and new approaches to personalized therapies are needed. These may include immunotherapy for MSI-high cancers and PARP inhibitors for *BRCA2* mutant cancers. In the near future we will also be able to follow the effectiveness of new therapies using novel approaches such as monitoring circulating tumor DNA (ctDNA). The future is bright!

# Familial Pancreatic Cancer

*Alison P. Klein*

*Departments of Oncology and Epidemiology, Sidney Kimmel Comprehensive Cancer Center, Johns Hopkins School of Medicine, Baltimore, MD, USA*

## Introduction

Pancreatic cancer, like all cancers, is fundamentally a genetic disease driven by both acquired and inherited genetic changes. Having a family history of pancreatic cancer is one of the strongest risk factors for the development of pancreatic cancer [1,2].

## Familial Pancreatic Cancer

Familial pancreatic cancer is defined as a kindred in which a pair of first-degree relatives have been diagnosed with pancreatic cancer (i.e., a parent and child or a pair of siblings). Observational studies suggest that having at least one single family member with pancreatic cancer increases the risk of pancreatic cancer 1.5- to 13-fold [1,3–11]. Prospective studies within the National Familial Pancreatic Tumor Registry have shown that first-degree relatives of familial pancreatic cancer patients (individuals with at least two family members with pancreatic cancer) have a 6.79-fold, 95% CI: 4.54–9.75 increased risk of pancreatic cancer [1].

Unlike other inherited cancer syndromes where there is a profound difference in the mean age of onset between the familial and sporadic forms of the disease, the age of onset of pancreatic cancer in patients with a family history of pancreatic cancer is at most 6 years younger than those with sporadic disease [12,13], with other studies showing no age difference [9,14].

In addition to higher pancreatic cancer risk, relatives of familial pancreatic cancer patients have a higher risk of other cancers. Relatives of familial pancreatic cancer patients have a significantly increased risk of dying from breast (wSMR 1.66, 95% CI: 1.15–2.34), ovarian (wSMR 2.05, 95% CI: 1.10–3.49), and bile duct cancers (wSMR 2.89, 95% CI: 1.04–6.39). Relatives of sporadic pancreatic cancer patients are at higher risk of bile duct cancer (wSMR 3.01, 95% CI: 1.09–6.67) [15]. Other studies also showed pancreatic cancer patients are more likely to report a family member with prostate cancer (OR 1.45, 95% CI: 1.12–1.89) [11] or liver carcinoma (SIR 2.70, 95% CI: 1.51–4.46) [16].

## Pathology of Familial Pancreatic Cancer

The pathologic phenotype of cancers that develop in individuals with a hereditary cancer syndrome can differ from the phenotype of cancers that develop in patients with apparently sporadic disease, such as mismatch repair deficient cancers among Lynch syndrome patients [17,18], or an excess of triple-negative breast cancers among *BRCA1* mutation carriers [19]. In contrast, familial and apparently sporadic pancreatic cancer appear remarkably similar. A review, blinded to family history, of 519 familial and 651 sporadic pancreatic cancers [20] reported no statistically significant differences in histologic subtypes between familial and apparently sporadic invasive pancreatic cancers. Additionally, among resected tumors there were no significant differences in mean tumor size, location, perineural invasion, angiolymphatic invasion, lymph node metastasis, or pathologic stage. The somatic genetic profile of familial pancreatic cancer does not differ from that of apparently sporadic cancer [12]. In combination, these data further support the finding that the etiology of familial and sporadic pancreatic cancer is very similar.

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

In contrast, there is evidence supporting an increased prevalence of pancreatic intraepithelial neoplasia (PanIN) and intraductal papillary mucinous neoplasia in the pancreata of individuals with familial pancreatic cancer compared to those with sporadic disease. Familial pancreatic cancer patients had a significantly higher rate of PanIN per square centimeter 2.75 (95% CI: 2.05–3.70; adjusted for age) than patients with sporadic pancreatic cancer. The precursor lesions observed in familial patients were more advanced than those observed in patients with sporadic disease, relative rate of PanIN-3 lesions 4.20 (95% CI: 2.22–7.93) and the observation of high-grade IPMN was limited to familial cases [21].

## Predisposition Genes

The ability to understand the inherited genetic variation that increases risk of pancreatic cancer is hindered by its underlying genetic heterogeneity [22]. Advances in both genotyping and sequencing technology has led to the identification of several new high-penetrance mutations associated with pancreatic cancer risk [22–24] and common genetic variation associated with an increase in pancreatic cancer risk [25–28]. However, mutations in the high-penetrance genes that are firmly associated with pancreatic cancer explain only about 20% of the familial clustering of pancreatic cancer and the causative mutations have yet to be identified in ~80% of familial pancreatic cancer kindreds. This 80% is likely due to a combination of high-penetrance mutations, polygenic effects, and environmental effects. For the 20% of familial pancreatic cancer kindreds where a causative mutation has been identified, knowledge of the precise genetic mutation can help guide therapeutic decisions for those who develop pancreatic cancer and early detection screening choices for at-risk relatives. Examples include: early detection screening clinical trials using imaging techniques for patients who have a strong family history of pancreatic cancer and/or carry germline mutations in established familial pancreatic cancer genes [29–33], increased sensitivity of *BRCA2* or *PALB2* deficient cancers to Parp inhibitors (PARP) or Mitomycin C [34–37], and improved survival of pancreatic cancer patients with a family history of breast, ovarian, or pancreatic cancer when treated with platinum-containing agents [38].

### *BRCA2*

Of the individuals who undergo germline genetic testing of pancreatic cancer, mutations in *BRCA2* account for the largest proportion of individuals with identifiable mutations [39]. Mutations in the *BRCA2* gene are best known for predisposing to breast and ovarian cancers yet carriers are also at increased risk of prostate and pancreatic cancer. The first report of an increased frequency of *BRCA2* mutations in pancreatic cancer was by Goggins et al., who reported deleterious *BRCA2* mutations in 7% of pancreatic cancer patients, unselected for family history [40]. *BRCA2* mutation prevalence has been shown to vary somewhat by family history with prevalence estimates as high at 16% for pancreatic cancer patients reporting three or more family members with pancreatic cancer [41], 12% in German pancreatic cancer patients from families with a least two pancreatic cancers [42], and 6% among US and Canadian pancreatic cancer patients with a first- or second-degree relative with pancreatic cancer [43]. Like the initial report by Goggins et al., more recent studies have also demonstrated that a substantial fraction, up to 3.6%, of pancreatic cancer patients, unselected for family history, carry deleterious mutations in *BRCA2* [44]. While some families found to have deleterious *BRCA2* mutations report a family history of breast and/or ovarian cancer, many do not [40,41]. Deleterious *BRCA2* mutations have also been reported in 4.6% of resected Ashkenazi Jewish pancreatic cancer patients, irrespective of family history of cancer [45]. Studies of the lifetime risk of pancreatic cancer among *BRCA2* carriers are limited to families ascertained based on a history of breast/ovarian cancer, and suggest a 3.51- to 5.79-fold increased risk of pancreatic cancer [46,47].

### *BRCA1*

Individuals who carry deleterious mutations in *BRCA1* have also been shown to be at increased risk of pancreatic cancer. However, risk of pancreatic cancer in *BRCA1* carriers is thought to be less than that of *BRCA2* carriers. Studies of the lifetime risk of pancreatic cancer in *BRCA1* carriers are limited to families ascertained based upon a history of breast and/or ovarian cancer. Risk estimates range from 2.26- to 4.11-fold [47,48]. While not all studies report an excess of *BRCA1* mutations among patient with pancreatic cancer [45,49], other studies have reported a prevalence of 1.2% in patients with familial pancreatic cancer [39]. As with *BRCA2*, the lack of a reported family history of breast and/or ovarian cancer does not rule out the presence of a deleterious *BRCA1* mutation.

### *PALB2*

Mutations in the *PALB2* gene, a binding partner of *BRCA2*, have also been associated with pancreatic cancer risk. While the initial reports suggested that up to 3% of FPC patients carry deleterious *PALB2* mutation [23], subsequent studies suggest the prevalence may be closer to 1% [39,50,51].

### *ATM*

Recently, mutations in the DNA repair gene *ATM* have also been associated with familial pancreatic cancer. Approximately 2.6–3.4% [22,24] of patients with familial pancreatic cancer harbor deleterious mutations in *ATM*. Mutations in *ATM* have also been reported in apparently sporadic pancreatic cancer patients [52].

### *CDKN2A*

Germline *p16/CDKN2A* mutations have been reported in 2.5% of patients with familial pancreatic cancer [39] and are associated with a 38-fold increased risk of pancreatic cancer [53]. Mutation carriers have a lifetime risk of pancreatic cancer of 17% [54,55].

### Lynch Syndrome

Individuals with Lynch syndrome have been shown to have a 3.68% (95% CI: 1.45–5.88) risk of pancreatic cancer by age 70 [56].

### Peutz–Jeghers

Individuals with Peutz–Jeghers syndrome have a remarkably high risk of 11–32% [57] of developing pancreatic cancer [58,59].

### Hereditary Pancreatitis

The risk of developing pancreatic cancer is extremely high among individuals with hereditary pancreatitis, risk by age 70 is 30–40% [60,61]. Individuals with hereditary pancreatitis who smoke develop the disease 20 years prior to non-smokers [61]. A portion of patients with hereditary pancreatitis have inherited mutation in the *PRSS1* genes [62–64].

## Common Genetic Variants

In addition to mutations in high-penetrance genes, several recent genome-wide association studies have identified common variants in the following regions as also significantly associated with pancreatic cancer risk: 9q34(*ABO*), 13q21, 1q31(NR5A2), 5p15.33 (*CLPTM1L* and *TERT*)), 7q32.3, 16q23.1 (*BCAR1/CTRB1/CTRB2*), 13q12.12 (*PDX1*), 22q12.1 (*ZNRF3*), 2p13.3 (near *ETAA1*), 3q29 (*TP63*), 7p13 (*SUGCT*), 17q25.1 (*LINC00673*) [25–28,65]. Individually, these variants have only a small effect on pancreatic cancer increase with per-allele odds ratios ranging from 1.1 to 1.3. Many of these same variants have also been shown to have a similar association with familial pancreatic cancer [66].

## Summary

Inherited genetic variants play an important role in pancreatic cancer risk. Individuals with a family history of pancreatic cancer have been shown to be at increased risk of developing pancreatic cancer as well as other cancers. The genetic underpinnings of the familial clustering of pancreatic cancer is highly heterogeneous. However, an understanding of the causative genetic mutations can help inform early detection screening in at-risk individuals and treatment decisions for those who do develop pancreatic cancer.

## Introduction

The bulk of the normal pancreas is composed of acinar cells, yet the majority of neoplasms of the pancreas have ductal differentiation. The classification of exocrine neoplasms of the pancreas is based on more than a century of integrating gross and microscopic findings with patient outcome. The recent introduction of molecular genetics and gene expression technologies has supported this gross and histologic classification: most pathologically defined neoplasms of the pancreas have distinct genetic and gene expression profiles [1,2].

The purpose of this chapter is to describe the pathologic features of exocrine neoplasms of the pancreas, with emphasis on clinical correlates.

## Ductal Adenocarcinoma

Pancreatic ductal adenocarcinoma (PDAC), commonly known as "pancreatic cancer," is defined as a malignant gland-forming epithelial neoplasm of the pancreas [3]. Despite many years of study, the 5-year survival rate remains at a dismal 8% [4,5]. This high mortality rate is in large part due to widespread local and metastatic disease at the time of diagnosis, combined with the poor response of most PDACs to existing therapies [6].

Endoscopic ultrasonography (EUS) can be used to define the local extent of disease and to biopsy lesions by fine-needle aspiration (FNA), a technique that has a high sensitivity for diagnosis of PDACs when performed by experienced endoscopists [7]. Because only 15–20% of PDACs are resectable at diagnosis, FNA is often the only way for most patients to receive a definitive diagnosis prior to treatment [6].

### Gross

PDACs are grossly white or gray sclerotic lesions that form firm, ill-defined masses that subtly infiltrate the normal soft, lobulated yellow pancreatic parenchyma (Fig. 92.1). These carcinomas may invade or obliterate the common bile duct, the main pancreatic duct, or both, which results in upstream dilatation of the affected duct and fibrous atrophy of the pancreatic parenchyma. The majority of PDACs occur in the pancreatic head, followed by the body and tail; there are even rare case reports of PDAC arising in heterotopic pancreas [3,8].

Careful gross examination of pancreaticoduodenectomy (Whipple) specimens is critical for margin assessment and for accurate grading and staging of the tumor. Margins to investigate include the common bile duct (usually taken parallel to the margin as a "shave" section), the pancreatic neck/distal pancreatic margin (shave), the proximal and distal bowel margins, and the uncinate/retroperitoneal/superior mesenteric artery margin (radial). The pancreatic neck and retroperitoneal margins are important in distal pancreatectomies. Patients with no residual tumor (R0) have a better prognosis than those with microscopically positive margins (R1) [9,10]. Adequate sampling of the primary tumor is important for grading of the carcinoma because overall grade depends on the highest grade component of the tumor. Finally, assessment of at least 12 pancreatic lymph nodes is important for staging, although in general, the more lymph nodes that can be examined, the more accurate the prognosis given to the patient [11,12].

### Histology

PDACs are characterized by haphazardly arranged glands and duct-like structures embedded in dense desmoplastic stroma (Fig. 92.2a). The cells lining the glands may be

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

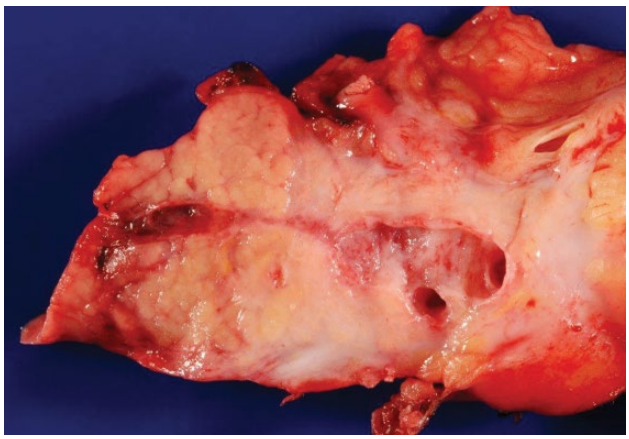

**Figure 92.1** Pancreatic adenocarcinoma. This photograph of a pancreatic specimen demonstrates the obstruction caused by pancreatic adenocarcinoma. The pancreatic duct is patent at its most proximal end (left) and is surrounded by normal tan-yellow, lobulated pancreatic parenchyma. Moving distally (right), the duct narrows and is surrounded by pale tan-white tissue, a mixture of adenocarcinoma and desmoplastic stroma. The obstruction has caused significant dilation of distal ducts, which are completely surrounded by the white fibrotic tissue of chronic pancreatitis.

cuboidal or columnar and often have intracytoplasmic mucin. Two histologic features stand out in PDAC. First, the neoplastic cells are extremely infiltrative. Perineural and intravascular invasion are present in practically all cases (Fig. 92.2b). The perineural invasion may explain some of the pain experienced by patients with PDAC, and nerves also serve as pathways for neoplastic spread beyond the pancreas [13]. Vascular invasion often leads to widespread dissemination of the neoplastic cells to other organs, particularly the liver. PDAC can grow into the lumina of vessels in a very distinctive way. Instead of forming a tumor thrombus, the neoplastic cells of PDAC can flatten out and grow along the endothelial surface of a vessel, mimicking the appearance of a duct (Fig. 92.2c) [14]. PDAC can also grow into pre-existing pancreatic ducts in a similar fashion. This extension of the malignancy along ducts is referred to as "cancerization" of a duct. An abrupt transition from benign to malignant cytology favors cancerization (Fig. 92.2d) [15]. A second striking feature of PDAC is the dense, desmoplastic stroma. This stroma explains the firm consistency of PDAC, and it has been suggested that the stroma may impede the delivery of chemotherapy to the neoplastic cells [16–18].

Histologic grading of PDAC takes into account both cytologic and architectural features of the malignancy. PDACs that resemble normal pancreatic ducts are designated "well differentiated," while those that do not form glands, or which form poorly-formed glands, are designated as "poorly differentiated." When more than one grade is present in a tumor, the highest/worst grade should be given; this grade drives prognosis [19,20]. Well-differentiated PDAC can be quite bland by histology with well-formed ductular structures and relatively uniform nuclei. Well-differentiated PDAC can be histologically distinguished from the reactive glands of chronic pancreatitis using "architectural" features: loss of normal lobular architecture, incomplete ductules, and the presence of ducts next to muscular arteries. Other helpful features include necrosis within glandular lumina, perineural invasion, and vascular space invasion [16]. A particularly tricky histologic variant of well-differentiated PDAC is the "large duct" variant, which can mimic cystic neoplasms grossly and histologically. The glands of the large duct variant form irregular dilated structures lined with a mucinous epithelium. Again, the clues to the diagnosis of an invasive PDAC are primarily architectural: loss of lobular organization and large ducts that dissect through a desmoplastic stroma [21].

Moderately differentiated PDAC has greater variation in cytologic appearance and increased numbers of mitotic figures. Poorly differentiated PDAC is defined by the presence of solid sheets and/or individual neoplastic cells that range in morphology from small cells with scant cytoplasm to larger bizarre cells with abundant eosinophilic cytoplasm. Histologic grading is important because the prognosis of a poorly differentiated PDAC is significantly worse than that of a well or moderately differentiated one [3,20].

Gene expression in PDAC is important for multiple reasons. First, the protein products can be interrogated for diagnostic purposes. These include keratins 7 and 19, carcinoembryonic antigen (CEA), mesothelin, and mucin 1 (MUC1). Second, several genes are known to be mutated as part of pancreatic carcinogenesis. These provide potential pathways for therapeutic targets and include *KRAS, SMAD4/DPC4*, and *p16/CDKN2A*. Finally, genetic information from PDAC has allowed for advances in the understanding of and screening for familial PDACs.

## Histologic Variants of Ductal Adenocarcinoma

Several morphologic variants of PDAC with distinct clinical features have been described.

### Adenosquamous Carcinoma

Adenosquamous carcinoma is, as the name suggests, an adenocarcinoma with a significant component with squamous differentiation (at least 30%). If no adenocarcinoma component can be found on extensive sampling, a metastasis from a primary squamous cell carcinoma from another organ must be considered. Patients with adenosquamous carcinoma of the pancreas have a worse prognosis when compared to patients with PDAC, but recent studies have reported that some adenosquamous carcinomas respond to platinum-containing chemotherapies [22,23].

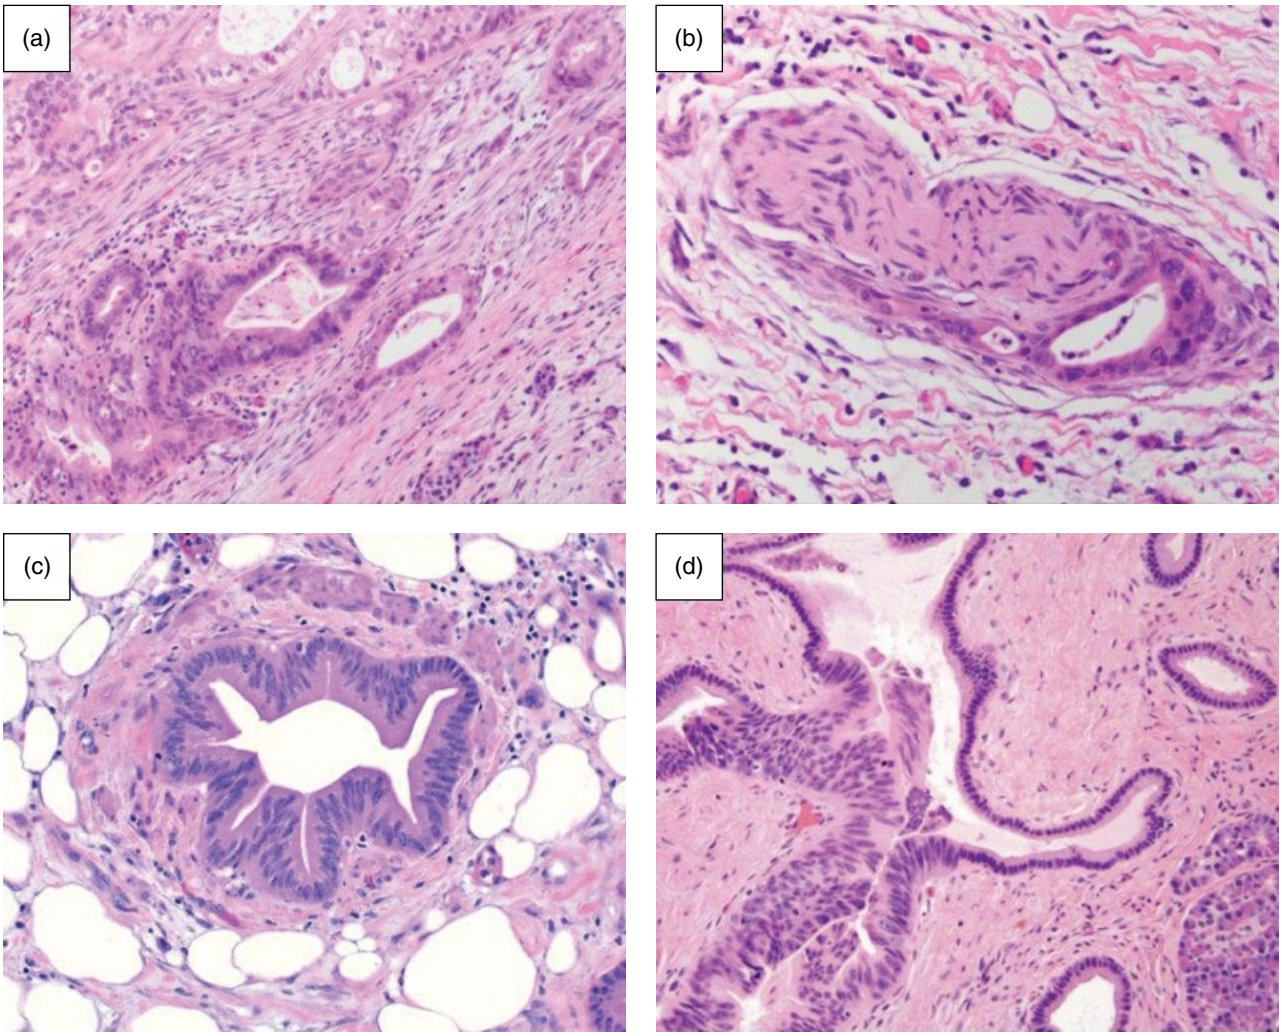

**Figure 92.2** Pancreatic adenocarcinoma (a) demonstrates tubular or glandular formation on histology. The nuclei are enlarged (compare to residual endocrine cells in bottom right corner of the photomicrograph) and hyperchromatic. The cytoplasm of PDAC is often eosinophilic but may also have a cleared appearance. The presence of desmoplastic stroma may be helpful to diagnose invasion in small biopsies. Perineural invasion (b) is a commonly seen feature of PDAC and may explain the pain experienced by patients. Vascular invasion (c). Cancerization of ducts is another interesting growth pattern of PDAC in which the adenocarcinoma tracks along and replaces existing ductal epithelium (d).

#### Colloid Carcinoma

Colloid, or mucinous noncystic, carcinoma is a variant of PDAC associated with intestinal-type intraductal papillary mucinous neoplasms (IPMNs, discussed later). In this subtype pools of mucin dissect through stroma, and associated neoplastic epithelium either lines the mucin pools or floats within the mucin. Care must be taken not to overcall a ruptured cyst with mucin extruded into the stroma with a truly invasive colloid carcinoma. Malignant epithelium must be seen with the mucin for a diagnosis of invasion [24].

#### Medullary Carcinoma

Like its counterpart in other organs, this variant is characterized by the syncytial growth of poorly differentiated epithelioid neoplastic cells with large nuclei. Medullary carcinomas also have "pushing" rather than infiltrating borders, and there is often a brisk inflammatory infiltrate of predominately lymphocytes surrounding and infiltrating into the tumor, but fibrous stroma is scant [25]. Medullary carcinomas are important to recognize for three reasons. First, despite their poor differentiation, they are associated with a good prognosis [26]. Second, patients with a medullary carcinoma are more likely to have a family history of cancer [25]. Third, medullary carcinomas are more likely than ductal adenocarcinomas to have the genetic change of microsatellite instability (mismatch repair defect) [27]. Not only may these mismatch repair deficient PDAC be the first presentation of Lynch syndrome [28,29], but new treatment options such as PD-1 inhibitors may be effective in mismatch repair deficient malignancies [30].

#### Undifferentiated Carcinoma

Undifferentiated carcinomas are composed of predominantly spindled cells or bizarre large cells without a clear direction of differentiation. A lower grade component of conventional PDAC can often be found in these neoplasms, but the histologic grade and prognosis are defined by the undifferentiated "grade 4" component [3,31]. Undifferentiated carcinomas are less cohesive than typical PDAC, a feature that can be demonstrated by loss of e-cadherin expression and which may contribute to the extremely poor prognosis of this variant: the mean survival is less than 1 year [32].

#### Undifferentiated Carcinoma with Osteoclast-Like Giant Cells

Undifferentiated carcinoma with osteoclast-like giant cells is a distinctive neoplasm characterized by the presence of numerous intratumoral multinucleated nonneoplastic giant cells. Admixed with these giant cells are undifferentiated spindled or bizarre malignant cells that often, but not always, label with antibodies to keratins by immunohistochemistry. The giant cells express histiocytic markers, such as CD68. Genetic analyses of single cells microdissected from these carcinomas have shown that the multinucleated giant cells are not neoplastic, but that the undifferentiated cells in between the giant cells are [33]. As is true for undifferentiated carcinomas, the prognosis of patients with an undifferentiated carcinoma with osteoclast-like giant cells is poor, with mean survival of less than 1 year [34,35].

#### Uncommon Variants

The hepatoid and signet ring cell variants of PDAC are unique in that they can resemble metastases from other organs to the pancreas. As the name suggests, the hepatoid variant consists of polygonal eosinophilic cells that mimic a hepatocellular carcinoma and that may even label with hepatocyte antigens, such as Hep-Par and α-fetoprotein [36,37]. Metastasis to the pancreas from the liver must be ruled out before a diagnosis of primary hepatoid PDAC is rendered [3].

The signet ring variant of PDAC is characterized by cells that contain intracytoplasmic mucin with indented and displaced nuclei. The neoplastic cells grow as single, infiltrating cells rather than in well-formed glands or sheets [38]. This carcinoma most closely mimics lobular breast carcinoma or diffuse gastric carcinoma, both of which should be considered in the differential for a malignancy of this morphology.

#### Ductal Malignancies with Mixed Differentiation

Carcinomas of the pancreas can rarely have multiple different directions of differentiation. These include mixed ductal-neuroendocrine carcinoma and mixed ductal-neuroendocrine-acinar carcinoma. Diagnosis of a "mixed" carcinoma requires that at least one third of the malignancy be composed of each neoplastic component. The prognosis for patients with a mixed carcinoma is generally driven by the worst component, in these cases, the PDAC [39,40].

#### Staging

The staging of PDAC and its variants by the WHO and the American Joint Committee on Cancer, 7th edition, takes into account the size of the malignancy, the extent of local direct spread, regional lymph node involvement, and distant metastases (the TNM system) [3,41]. Questions often arise when attempting to differentiate a T2 (tumor limited to the pancreas), from a T3 (tumor in peripancreatic tissue). Because there is no clear histologic demarcation of the edge of the pancreas, and because bouts of malignancy-induced pancreatitis distort the relationship between the pancreas and surrounding adipose tissue, the 8th edition AJCC T staging places greater emphasis on size of the neoplasm.

## Cystic Neoplasms

### Intraductal Papillary Mucinous Neoplasm

The intraductal papillary mucinous neoplasm (IPMN) is a mucin producing, duct-based, usually papillary neoplasm that, by definition, is greater than 1.0 cm [15,42]. IPMN may arise in the main pancreatic duct or within a branch duct. Main-duct IPMNs are more likely to be symptomatic and to progress to invasive carcinoma [43]. IPMNs are often multifocal, and patients are at risk for synchronous and metachronous disease. Genetic analyses have suggested that this multifocality can be caused by intraductal spread of neoplastic cells or by genetically distinct and physically separate neoplasms. Because of this multifocality, patients who undergo partial pancreatectomy for IPMN remain at risk for additional neoplastic cysts and even PDAC in their remnant pancreas [44]. EUS-guided biopsy with sampling of cystic fluid for cytology and molecular studies can be important for preoperative diagnosis and planning [45,46].

#### Gross

Main-duct IPMNs diffusely dilate the main pancreatic duct. Long finger-like papillae can often be seen projecting into the duct, and the duct typically contains thick, tenacious mucin. Branch-duct IPMNs, by contrast, more often appear as a small group of cysts, often compared to a cluster of grapes, adjacent to but not involving the main duct. Many IPMNs are mixed and involve both main and

branch ducts [42]. Foci of dense sclerosis adjacent to an IPMN suggest the possibility of an associated invasive adenocarcinoma. For this reason, and because invasion can be focal, the general rule for pathologic examination of IPMNs is very extensive, if not complete, submission for histology [47].

**Histology**

Histologically, the dilated ducts of IPMNs are lined by columnar mucin-producing neoplastic epithelial cells that may have intestinal, gastric, biliary, or oncocytic type differentiation (Fig. 92.3a–d). A single IPMN may have mixed differentiation, making the correlation between subtype and prognosis all the more complicated [42].

Intestinal-type IPMNs have interspersed goblet cells, typical of intestinal epithelium, and immunolabel with antibodies to MUC2, MUC5AC, and CDX-2 [42]. Of interest, many intestinal-type IPMNs have been found to harbor *GNAS* gene mutations [48]. Early somatic *GNAS* mutations are the underlying genetic defect in McCune-Albright syndrome, and IPMNs are known to be associated with this disorder [49].

Gastric-type IPMNs have small nuclei with an apical, eosinophilic mucin cap similar to foveolar cells of the stomach, and these IPMNs label with antibodies to

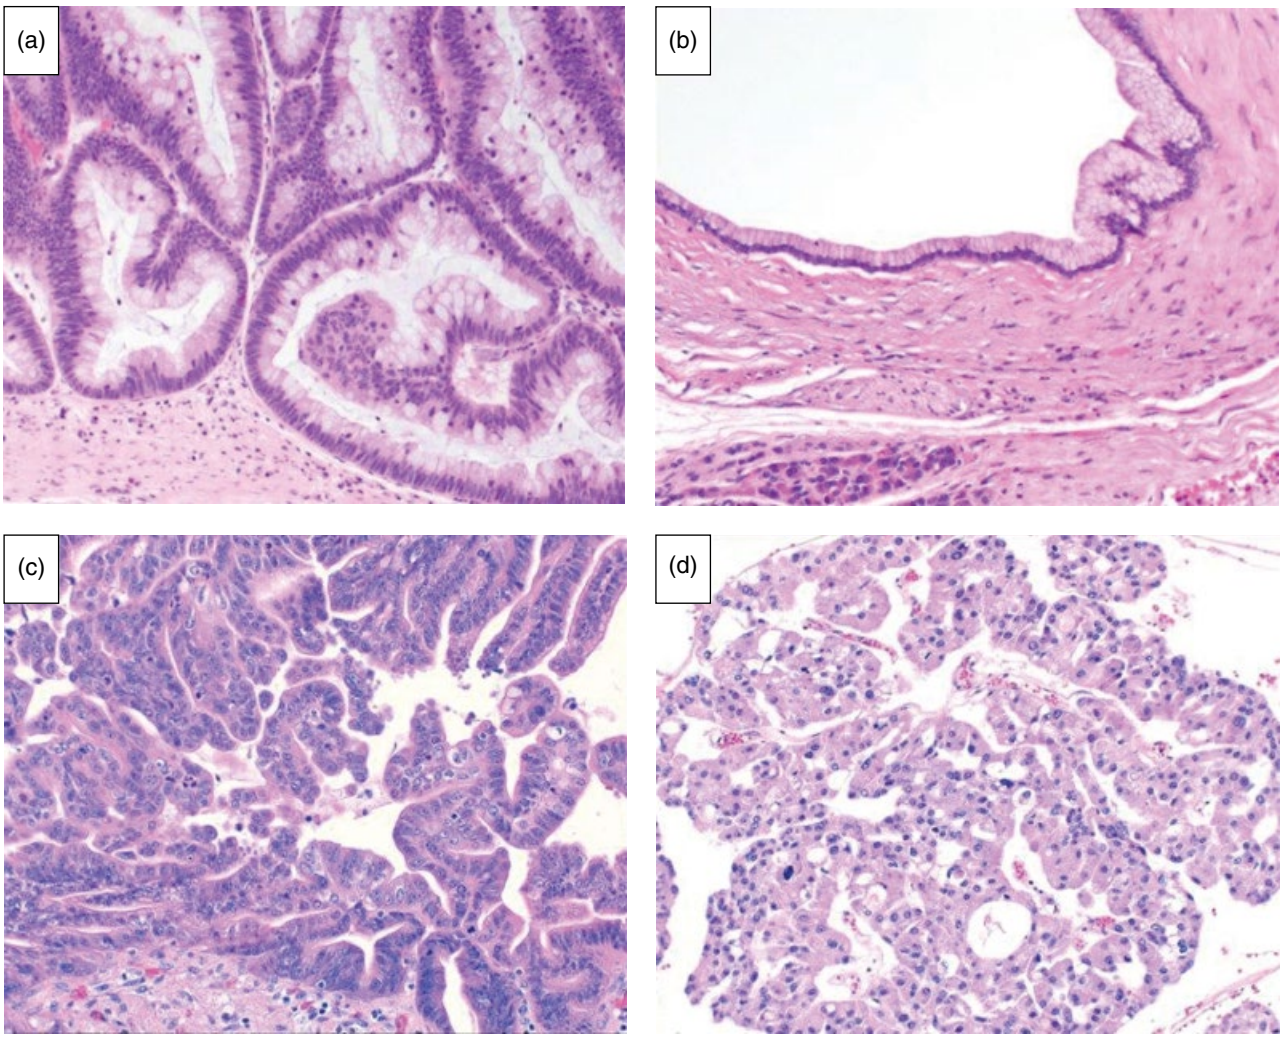

**Figure 92.3** IPMN subtypes. The intestinal subtype (a) occurs most often in the main duct and consists of columnar cells with cigar-shaped nuclei and goblet cells. The gastric subtype (b) is usually a low-grade neoplasm that occurs in branch ducts. The lining is again columnar, but the nuclei are small and basally oriented with a mucin cap reminiscent of the foveolar mucin in the stomach. The pancreatobiliary subtype (c) is typically a high-grade lesion that can involve both main and branch ducts. The lining cells are cuboidal with enlarged, hyperchromatic, round nuclei that are pseudostratified. The cytoplasm is amphophilic rather than mucinous, and the architecture is complex and branching. The oncocytic subtype (d) appears as a high-grade lesion with complex branching architecture and pseudostratified, hyperchromatic nuclei in columnar cells with abundant eosinophilic cytoplasm.

MUC5AC. Pancreatobiliary-type IPMN are composed of cuboidal cells with increased nuclear : cytoplasmic ratio and minimal intracytoplasmic mucin, and they immunolabel with antibodies to MUC1 and MUC5AC. The oncocytic variant of IPMN, known as the IOPN, is composed of an eosinophilic, multilayered epithelium with large nuclei and prominent nucleoli; this variant immunolabels with antibodies to MUC6. Despite the marked atypia in oncocytic IPMN, invasive carcinoma is not common in this subtype [47].

IPMNs are graded as having low-, intermediate-, or high-grade dysplasia based on the degree of architectural and cytologic atypia. Low-grade dysplasia is defined as a single layer of cells with small, uniform nuclei growing along cyst walls with well-formed papillae. Intermediate-grade dysplasia has the beginning of nuclear stratification, pleomorphism, and micropapillae formation. High-grade dysplasia is characterized by loss of nuclear polarity with nuclear hyperchromiasia and pleomorphism along with architectural irregularities including irregular papillae and cribriform growth. Most gastric IPMNs are low- to intermediate grade, while pancreatobiliary and oncocytic IPMNs are usually high grade. Intestinal-type IPMNs may have low-, intermediate-, or high-grade dysplasia [3,42,43]. IPMNs with low-grade and IPMNs with intermediate-grade dysplasia can be combined under the umbrella designation "low-grade IPMN."

Approximately one third of surgically resected IPMNs have an associated invasive PDAC. The risk is greater with main-duct IPMNs, if a mural nodule is present, and with increasing grades of dysplasia. High-grade intestinal-type and pancreatobiliary-type IPMNs are the most likely to have an associated invasive adenocarcinoma of colloid (mucinous noncystic) and tubular type, respectively [47]. Genetic analyses have shown that the carcinomas that arise in direct anatomic association with IPMN usually arose from the IPMN [50].

## Mucinous Cystic Neoplasm

Mucinous cystic neoplasms (MCNs) are mucin-producing epithelial neoplasms of the pancreas that typically do not involve the duct system, and which, by definition, have a characteristic ovarian-type stroma (Fig. 92.4a). MCNs, like IPMNs, also can progress to invasive adenocarcinoma. MCNs are most often located in the tail of the pancreas, and the vast majority arise in women.

### Gross

Gross examination of MCNs shows a well-demarcated multilocular cystic lesion. The cysts can be filled with mucin, or in some instances blood-tinged fluid. The cysts can have a smooth lining or papillary projections may protrude into the lumina. The latter finding often corresponds to high-grade dysplasia and increased risk for invasive carcinoma.

### Histology

Histologically, MCN is lined by columnar mucin-producing epithelium that may have intestinal or gastric differentiation with varying degrees of dysplasia that is graded similarly to IPMN as low-, intermediate-, or high grade. The key diagnostic feature for MCN is the specialized "ovarian-type" spindle-cell stroma seen underlying the epithelium. Immunohistochemical stains for smooth muscle actin and progesterone receptor can be used to highlight the ovarian stroma [3,51].

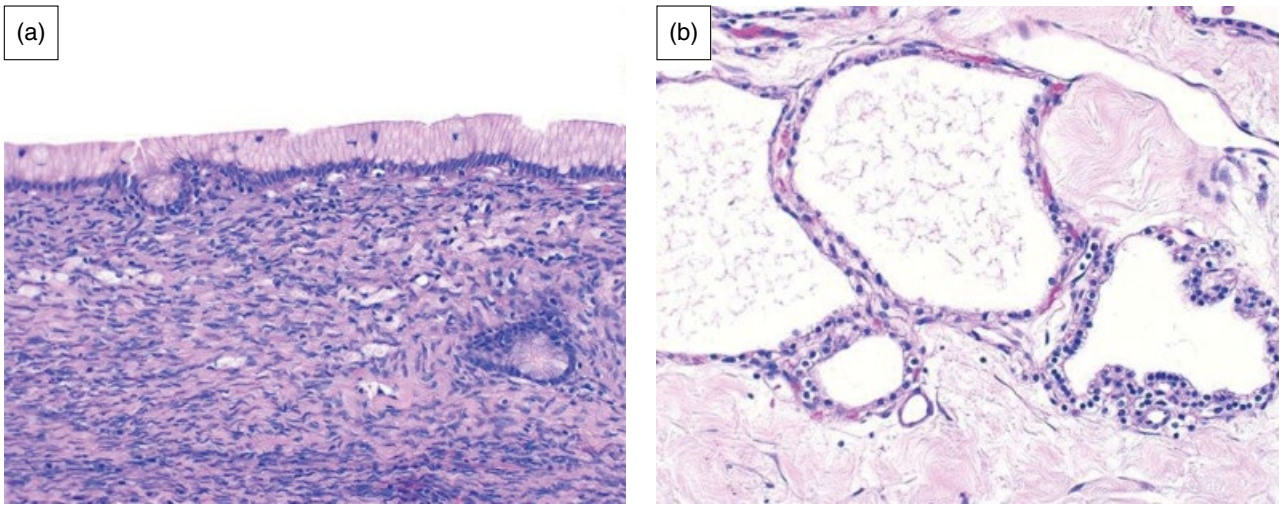

**Figure 92.4** Other cystic neoplasms. A mucinous cystic neoplasm is defined by its ovarian-type stroma made up of spindled cells. Even when these cysts have attenuated mucinous lining (a), the presence of progesterone receptor positive stroma is diagnostic for this neoplasm. A serous cystadenoma generally has very little stroma, and instead demonstrates back to back tubules lined by epithelial cells with clear cytoplasm and small, dark nuclei (b).

Because MCNs are unifocal lesions, surgical resection of an MCN without invasive carcinoma is considered curative; however, up to 30% of MCNs have an associated invasive adenocarcinoma. The invasive component is usually a typical PDAC rather than a colloid carcinoma [3,51]. The depth and extent of invasion of the carcinoma have proven to be important prognosticators [52].

### Serous Cystadenoma

Serous cystadenomas (SCAs) are cystic neoplasms of the pancreas composed of multiple cysts lined by glycogen-rich cells (Fig. 92.4b). The cyst fluid is watery or serous rather than mucinous.

#### Gross

The most common form of SCA is the microcystic SCA. Microcystic SCAs have innumerable small (millimeter) cysts, often surrounding a central scar. The macrocystic variant of SCA consists of one or at most a few large cysts. This latter variant can mimic an IPMN or MCN on imaging. Multiple SCAs throughout the pancreas suggest the von Hippel-Lindau (VHL) syndrome, as do mixed serous-neuroendocrine tumors [53]. The solid serous adenoma is a variant of SCA that, as the name suggests, grossly appears to be solid. Because solid serous adenoma remains well circumscribed, the differential diagnosis on both imaging and gross examination includes a neuroendocrine tumor [54].

#### Histology

All SCA variants are lined by a serous epithelium made up of cuboidal cells with clear to eosinophilic cytoplasm and small, centrally placed uniform nuclei. Transformation to a malignant serous cystadenocarcinoma (as defined by the presence of metastatic disease) is rare; therefore, asymptomatic patients do not require surgery, and in symptomatic cases surgical resection of an SCA is considered definitive therapy [3,55,56].

### Solid-Pseudopapillary Neoplasm

The solid-pseudopapillary neoplasm (SPN) is a neoplasm of uncertain histogenesis and low malignant potential [57,58]. SPNs occur with equal frequency in the pancreatic head, body, and tail.

#### Gross

On imaging and gross examination, SPNs are often large and heterogeneous but well demarcated. On cross-section, the tumor may be predominantly solid or cystic, and is often filled with hemorrhagic and necrotic material (Fig. 92.5a).

#### Histology

By light microscopy SPNs are composed of loosely cohesive monomorphic epithelial cells with clear cytoplasm and round to oval grooved nuclei growing in pseudopapillae (Fig. 92.5b). Hyaline globules are often seen within the epithelial cytoplasm (Fig. 92.5c), and foreign-body giant cells may be present. Touch preparations at the time of intraoperative consultation can beautifully demonstrate the branching vascular architecture, cellular uniformity, and poor cohesion of the neoplastic cell population (Fig. 92.5d). SPNs label with beta-catenin (nuclear), which reflects the underlying β-catenin gene mutation in this neoplasm, and with CD10 [57,59].

All SPNs are classified as malignant. Although the majority of SPNs are indolent and cured by resection, cases of widespread metastatic disease are reported [3,60,61].

## Acinar Cell Lesions

### Acinar Cell Cystadenoma

This lesion is the subject of case series due to its rarity, and the reactive versus neoplastic nature is disputed because these lesions have not been found to harbor clonal mutations commonly associated with pancreatic neoplasia [62,63]. On gross examination, the cysts are well circumscribed and filled with clear, nonmucinous fluid. Histologic examination reveals an epithelial lining composed of cells with acinar differentiation and granular two-toned cytoplasm. There have been no reports of malignant transformation of this lesion [3,62].

### Acinar Cell Carcinoma

Acinar cell carcinoma (ACC) of the pancreas is also quite rare, making up less than 2% of resected pancreatic neoplasms. ACCs have been reported in children as well as adults [64,65], and this malignancy usually harbors a high number of mutations [66].

#### Gross

ACCs are well circumscribed but bulky, fleshy, and often hemorrhagic neoplasms that may resemble the more common pancreatic neuroendocrine tumor (PanNET).

#### Histology

Histologic review shows a predominantly cellular neoplasm that is composed of a monomorphic population of cells with granular cytoplasm, large nuclei, and single prominent nucleoli (Fig. 92.6a). Several architectural patterns can be seen, from the formation of well-defined acini to solid sheets of cells. Desmoplastic stroma is not a prominent feature of ACC [65].

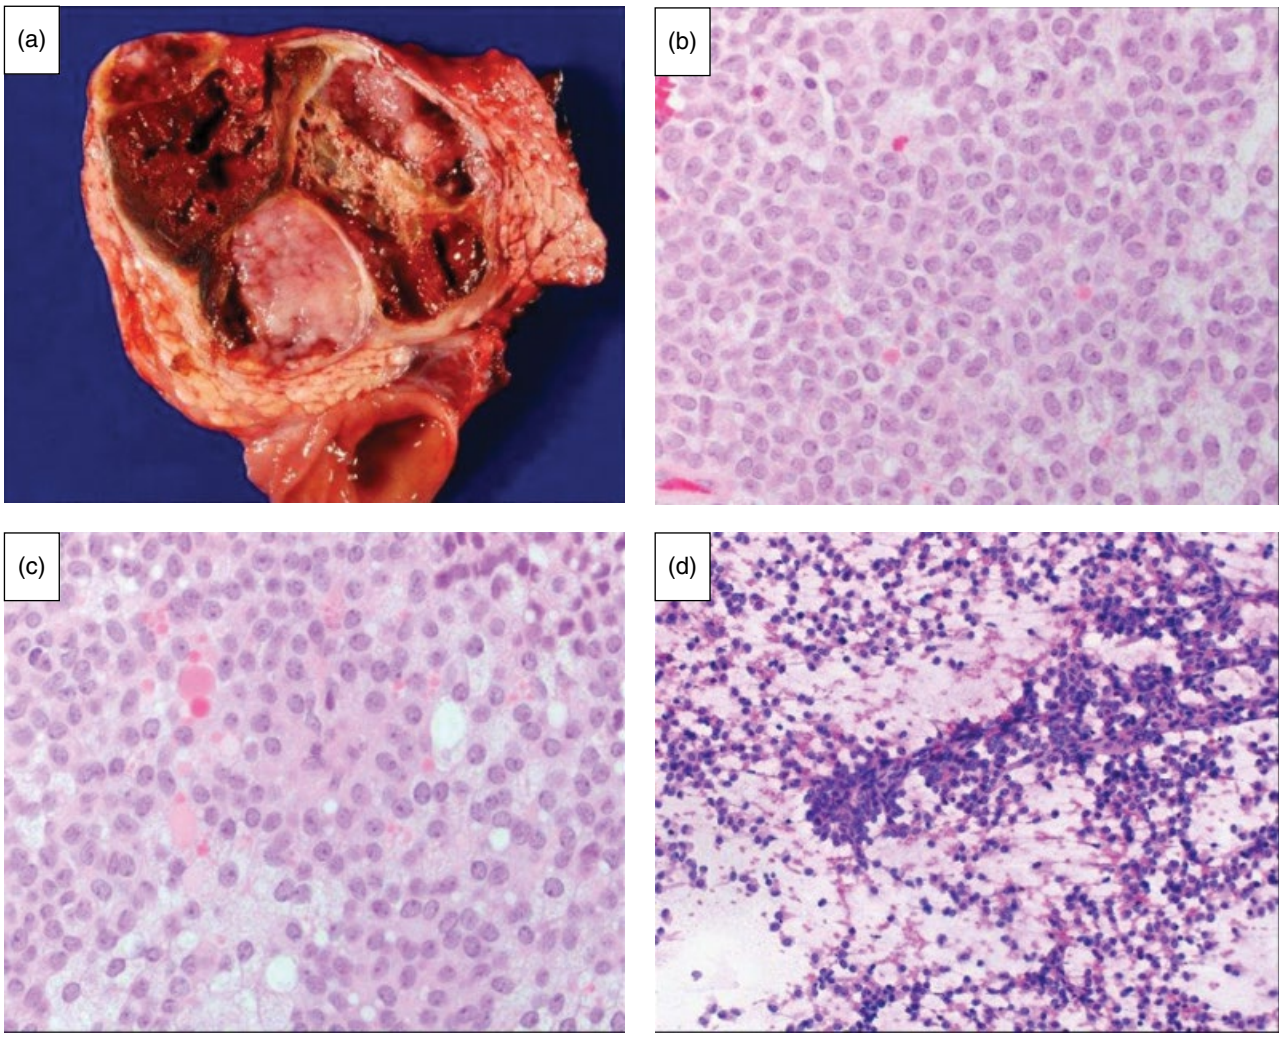

**Figure 92.5** Solid-pseudopapillary neoplasm. On gross examination, a solid-pseudopapillary neoplasm is heterogenous with solid areas as well as evidence of hemorrhage and cystic degeneration (a). The nuclei are relatively monomorphic and may have grooves (b) and cytoplasmic hyaline globules (c). A touch preparation made during the intraoperative consultation demonstrates the delicate branching architecture (d).

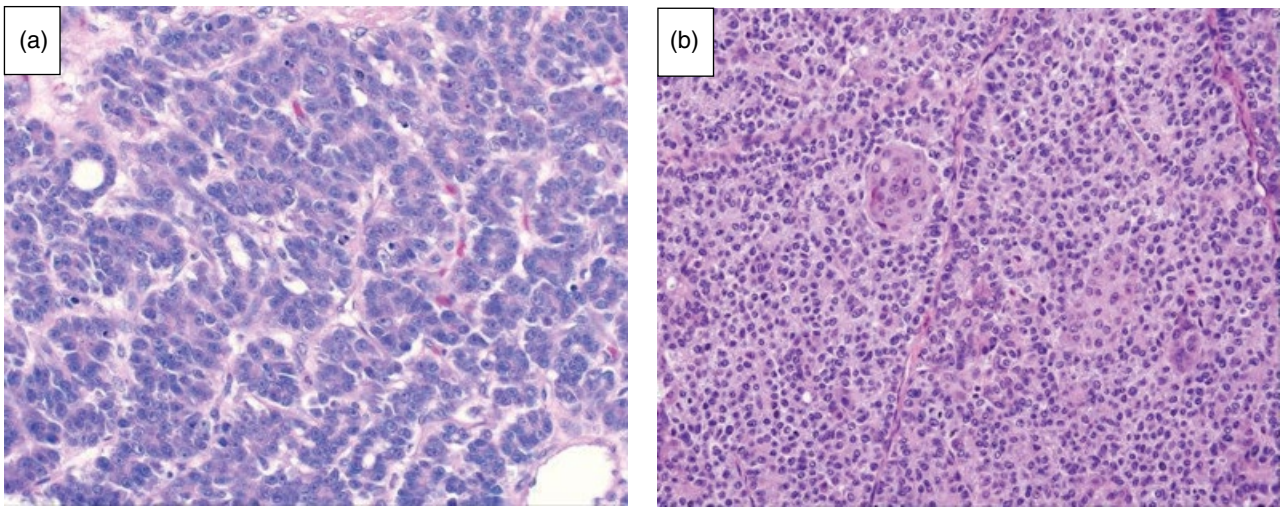

**Figure 92.6** Acinar lesions. Acinar cell carcinomas are typically very cellular with scant stroma (a). The classic cytologic features of this carcinoma are round nuclei with prominent nucleoli and granular eosinophilic cytoplasm. Various architectural patterns, including acinar and solid, may be observed. Pancreatoblastoma has the acinar features of an acinar cell carcinoma, however, the presence of squamoid nests are diagnostic of this neoplasm (b). Endocrine and heterologous mesenchymal elements may also be seen in pancreatoblastoma.

Ancillary stains are usually necessary to definitively diagnose an acinar cell carcinoma. Immunolabeling with antibodies to the pancreatic enzymes trypsin and chymotrypsin will highlight the cells, although a simple periodic acid–Schiff with diastase (PAS-D) can also highlight the enzymatic granules [65]. Another helpful immunostain is BCL-10, which labels the nuclei in 85% of acinar cell carcinomas [67]. Up to one third of acinar cell carcinomas will show patchy labeling with neuroendocrine markers, specifically chromogranin A [65]. To diagnose a true mixed acinar cell/neuroendocrine carcinoma, however, at least 25–30% of the neoplastic cells need to have definitive neuroendocrine differentiation in addition to the cells with definitive acinar differentiation [68]. Mixed acinar/ductal adenocarcinomas have also been described [40]. The prognosis in mixed tumors is driven by the most aggressive component [40,68]. In pure acinar cell carcinoma, the prognosis is better than that of stage-matched PDAC, with a 25–50% 5-year survival rate. Staging of acinar cell carcinoma follows the rules of PDAC [3].

### Pancreatoblastoma

Pancreatoblastomas are more common in childhood [69,70]. Although most are nonsyndromic, pancreatoblastomas have been reported in infants with Beckwith-Wiedemann syndrome and in older children/young adults with familial adenomatous polyposis [71,72]. Cases in adult patients can occur, but with even less frequency than in children [73].

#### Gross

On gross examination fleshy lobules of tumor, fibrosis, necrosis, and calcifications all may all be present in a single neoplasm [74].

#### Histology

On histologic review, pancreatoblastomas are composed of neoplastic cells with acinar cell differentiation admixed with squamoid nests (Fig. 92.6b). Squamoid nests are aggregates of cells with spindled to epithelioid morphology. Squamoid nests differentiate pancreatoblastoma from pure acinar cell carcinoma. Cells with neuroendocrine differentiation are also usually present, and rarely heterologous elements or small cell features may be seen within a pancreatoblastoma [64].

Like an acinar cell carcinoma, pancreatoblastoma is reactive for PAS-D, trypsin, chymotrypsin, and BCL-10; and scattered neuroendocrine markers may be expressed across the tumor. Abnormal, often patchy, nuclear labeling with antibodies to beta-catenin is seen in a subset of pancreatoblastoma.

Surgical resection is considered first line of treatment, and patients with nonresectable disease have a dismal prognosis. Even with resection, the 5-year survival rate for pancreatoblastoma is only 65% [70,75].

## Conclusions

Exocrine malignancies of the pancreas include benign lesions as well as some of the deadliest malignancies known. The importance of accurate pathologic diagnosis and staging for patient prognosis and treatment cannot be overstated, especially when dealing with the complicated area of cystic neoplasia. A new understanding of the molecular drivers of pancreatic neoplasia supports the current gross and histologic classification presented here. We hope that this chapter has provided the tools for confident gross examination histologic diagnosis of exocrine pancreatic lesions.

# Pancreatic Cancer: Precancerous Lesions

*Michaël Noë, Lodewijk A.A. Brosens, and Johan Offerhaus*

*Department of Pathology, University Medical Center Utrecht, Utrecht, The Netherlands*

## Introduction

Different precursor lesions can give rise to pancreatic ductal adenocarcinoma (PDAC). The initial basis for the current classification of these lesions was established in an international consensus meeting in 1999 [1]. Since then, three additional consensus meetings have been held [2–4]. At present, four precursor lesions are recognized: pancreatic intraepithelial neoplasia (PanIN), intraductal papillary mucinous neoplasm (IPMN), intraductal tubulopapillary neoplasm (ITPN), and mucinous cystic neoplasm (MCN) [4]. These precursors exhibit a unique multistep morphologic and genetic progression to invasive carcinoma [5].

## Pancreatic Intraepithelial Neoplasia

### Clinical Features

Pancreatic intraepithelial neoplasia (PanIN) is the most common precursor lesion of PDAC and it is believed that most PDAC arise from PanIN [6,7]. Hulst (Boerhaave Laboratory, Leiden, The Netherlands) was the first to describe this microscopic lesion a century ago as a lesion in between (*Zwischenform*) normal tissue and invasive carcinoma [8]. These lesions were shown to be more common in pancreata with an invasive carcinoma than in pancreata without cancer. PanIN can be found in 82% of pancreata with invasive carcinoma, in 60% of pancreata with chronic pancreatitis, and in 16% of normal pancreata [9].

Both sexes are equally affected and their incidence tends to increase with age [9–12]. In patients with a family history of pancreatic adenocarcinoma, PanIN typically occur multifocally [13–15].

Because of their small size (by definition <0.5 cm), it is impossible to detect PanIN on noninvasive imaging. Only nonspecific findings such as lobular atrophy and fibrosis can suggest their presence [13]. PanIN are not associated with specific clinical signs or symptoms and are typically found incidentally in resections or biopsy specimens [10,16,17]. Most studies show that PanIN are more common in the head of the gland than in the tail [9,10,18].

### Pathologic Features

PanIN are noninvasive, microscopic, epithelial neoplasms and by definition involve pancreatic ducts less than 0.5 cm in diameter [1,4,7]. Initially, it was thought PanIN arose only from ductules or small ducts [1,19,20]. However, several case reports have suggested that some PanIN can arise from larger ducts, including the main duct [16,19,21]. Some PanIN may cause obstruction and retrograde dilatation. This can make the differential diagnosis with an intraductal papillary mucinous neoplasm (IPMN) difficult. PanIN are characterized by cuboid-to-columnar cells with varying amounts of apical cytoplasmic mucin and varying degrees of cytologic atypia. PanIN almost always show gastric-foveolar differentiation and have a micropapillary or flat architecture [4].

Since the first classification of the precursor lesions in 1999, three grades are discriminated in the progression of PanIN, based on the increasing degree of epithelial atypia and architectural complexity: PanIN-1, PanIN-2, and PanIN-3 (see Fig. 93.1) [1]. PanIN-1 lesions are characterized by minimal nuclear atypia, inconspicuous nucleoli, and absent mitotic figures, and can be further subdivided into flat (PanIN-1A) and micropapillary types with slight nuclear stratification

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

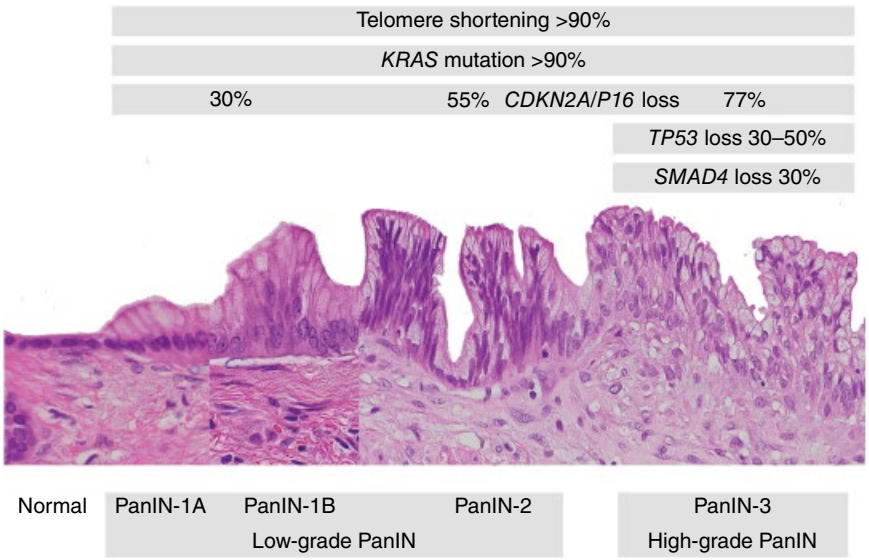

**Figure 93.1** The progression of PanIN is associated with an increase in cellular and architectural atypia and accumulation of genetic mutations. PanIN-1 shows minimal nuclear atypia. PanIN-1A has a flat growth pattern, while PanIN-1B shows formation of micropapillae. PanIN-2 shows moderate nuclear atypia and pseudostratification. PanIN-1 and PanIN-2 are both grouped as low-grade PanIN. PanIN-3 or high-grade PanIN has the most severe nuclear and architectural atypia.

(PanIN-1B). Because of the absence of nuclear atypia and presence of mucin, which is not normally observed in pancreatic ductal cells without histochemical staining, these lesions were previously designated as "mucinous metaplasia" or "mucous cell hypertrophy" [22,23]. Moderate nuclear atypia, pseudostratification, loss of polarity, hyperchromasia, and rare mitotic figures are features of PanIN-2. PanIN-3 lesions have marked atypia, contain (atypical) mitotic figures, show loss of polarity and have a papillary, micropapillary, or occasional flat architecture. Cribriform structures, necrosis, and tufting of epithelial cells in the lumen may be present. PanIN-3 is almost exclusively found in association with invasive PDAC [9,10]. This feature is so striking that, in pancreata without a PDAC, a PanIN-3 lesion may serve as a surrogate marker for invasion elsewhere [9,24]. When PDAC is present, PanIN-3 is very hard to differentiate from the infiltrating carcinoma, growing into preexisting pancreatic ducts (i.e., ductal cancerization). Indications for this phenomenon of so-called ductal cancerization are a close proximity of an invasive carcinoma to a ductal lesion, an abrupt transition from highly atypical epithelium to normal ductal epithelium, luminal obstruction, and ductal destruction [1,7,25].

Of note, the presence of PanIN lesions of any grade at the surgical margin of pancreata resected for invasive PDAC, does not influence patient prognosis and additional surgery is not required [26].

Recently, an expert panel advised to use a two-tiered grading system with low-grade PanIN (former PanIN-1(A/B) and PanIN-2) and high-grade PanIN (former PanIN-3). The reason for this advice was the poor interobserver agreement between PanIN-1 and PanIN-2 [27]. Moreover both PanIN-1 and PanIN-2 show very limited progression to PDAC [9,28].

There are some descriptions of rare morphologic variants of PanIN, without any further biologic or clinical significance [26]. These variants are: *foam gland type*, which is associated with the foam gland subtype of pancreatic carcinoma and is characterized by foamy cells; *oncocytic type* with granular, eosinophilic cytoplasm and round nuclei with evident nucleoli; and *intestinal type* with goblet cells and pseudostratified nuclei [26,29]. However, intestinal type and oncocytic type PanIN could be early manifestations of IPMN.

PanIN show an increased expression of MUC1/EMA and the gastric foveolar mucin, MUC5AC in higher grades of dysplasia [30–33]. The opposite is seen for the pyloric gland mucin MUC6, showing reduced expression in higher grades of dysplasia [31,34].

## Molecular Features

The lowest grade PanIN lesions with minimal cytologic atypia were not originally regarded as neoplastic, but instead were interpreted as hyperplasia or metaplasia [18,35]. After finding activating *KRAS* mutations, these lesions were considered neoplastic and the term "pancreatic intraepithelial neoplasia" was proposed [1,22–24,35,36]. Another early event, frequently found in PanIN, is telomere shortening [37]. In 10% of the lesions that meet the criteria for PanIN, *GNAS* mutations were found, frequently as early events [38]. Since *GNAS* mutations are found in 60% of intraductal papillary mucinous neoplasms (IPMN), these lesions could also represent early IPMN [39,40]. Further in the progression of PanIN, genetic and epigenetic inactivation of *CDKN2A/P16* is seen [41–43]. Mutations in *TP53* and *SMAD4* are considered transitional events in the progression of PanIN to invasive ductal carcinoma, changing TGFβ and BMP signaling from tumor suppressive to tumor promoting (see Fig. 93.1) [5,33,44–47a].

## Intraductal Papillary Mucinous Neoplasm

### Clinical Features

The first description of what is now known as an intraductal papillary mucinous neoplasms (IPMN) of the pancreas, probably dates back to 1936 [48,49]. Haban et al. described a pancreatic lesion with "aneurysma-like" cyst formation, papillary growth of the epithelium, and mucin production. Until 1994, these tumors had various names, each emphasizing a different morphologic feature of the tumor. In 1994, all these entities were grouped together under the term "intraductal papillary mucinous neoplasm" [50,51].

Initially, IPMN was considered a disease of older, cigarette-smoking men. However, a meta-analysis showed that there are geographic differences in the gender of patients with an IPMN. In Asia, main-duct (MD-IPMN) and branch-duct (BD-IPMN) type IPMN affect more men than women. In the United States and in Europe, MD-IPMN affect more men, while BD-IPMN affect more women [52]. Worldwide, the mean age of patients at the time of an IPMN diagnosis is 60–66 years [53–57]. Only a minority develop a PDAC from an IPMN. The mean age of diagnosis of patients with an IPMN with PDAC is 3–6 years older than the mean age of patients at the time of an IPMN diagnosis [53–57]. IPMN are seen more frequently in patients with a family history of pancreatic cancer, Peutz–Jeghers syndrome, familial adenomatous polyposis (FAP), Lynch syndrome, Carney complex, and McCune-Albright syndrome [14,58–64].

Due to the widespread implementation of cross-sectional abdominal imaging techniques, macroscopic, pancreatic cysts like IPMN are relatively common findings. Epidemiologic studies show great variety in the prevalence of pancreatic cysts due to the use of different imaging techniques and different study populations [65–74]. If only cysts larger than 0.5 cm in patients imaged for other indications than pancreatic pathology and without a history of pancreatic pathology are considered, the prevalence is 10–21% [66,67]. A younger and partially healthy population scanned at a center for preventive medicine, had a much lower prevalence of 2.4% [75]. Of course, not all pancreatic cysts are IPMN. About one third of resected asymptomatic pancreatic cysts appear to be an IPMN [76,77].

Most people diagnosed with IPMN are asymptomatic. Only few patients experience nonspecific symptoms [78]. Main duct involvement is more often associated with acute pancreatitis than an IPMN involving only the smaller pancreatic ducts [53,56,77,79,80]. On endoscopy, a classic patulous papilla extruding mucus can be seen in 25% of patients with IPMN. This is also called a "fish-eye" or "fish-mouth" and is virtually diagnostic for the presence of an IPMN [81,82].

IPMN are most frequently located in the proximal pancreas (the pancreatic head and the processus uncinatus). Based on the involvement of the different pancreatic ducts on radiologic and pathologic examination, IPMN are classified as MD-IPMN, BD-IPMN, or mixed-type IPMN [83]. However, there is considerable discrepancy between the radiologic and the histopathologic assessment of the involved ducts. Studies have shown that the main duct often shows some degree of involvement, even in IPMN that were classical BD-IPMN by radiologic imaging [84,85]. These BD-IPMN with minimal involvement of the main duct were very similar to pure BD-IPMN with regard to clinicopathologic features as well as clinical outcome [84].]

Data from multiple studies showed that invasive carcinoma was present in 43.6% of MD-IPMN, in 45.3% of mixed-type IPMN, and in 16.6% of BD-IPMN [86].

### Pathologic Features

IPMN have been defined in a consensus meeting as: "*grossly visible, predominantly papillary or rarely flat, noninvasive mucin-producing epithelial neoplasm arising in the main pancreatic duct or branch ducts.*" By definition, an IPMN is at least 1.0 cm in diameter [1,4,7]. An intraductal neoplastic precursor lesion, larger than a PanIN ($\geq$ 0.5 cm), but smaller than a true IPMN (<1.0 cm) can be either a large PanIN or a small IPMN. Features that occur predominantly in the setting of an IPMN, like the differentiation towards intestinal-, pancreatobiliary- or oncocytic-type epithelium or a mutation specific for IPMN (such as a *GNAS* mutation), are clues for a small IPMN [4,40,87]. If one of these features is present, the lesion can be called "incipient IPMN" [40]. Gastric-type differentiation can be seen in both PanIN and IPMN, making it a nondistinctive feature. Gastric-type lesions of at least 0.5 cm but smaller than 1.0 cm should be documented descriptively [4]. In the past, other features have been used to make the distinction between both lesions: MUC2, although insensitive, is a specific marker for IPMN, IPMN has taller and more complex papillae and IPMN produces more luminal mucin [7].

Similarly to PanIN, a consensus meeting recommended to replace the current three-tiered grading system with a two-tiered grading system, for better reproducibility and risk assessment. The former "IPMN with low-grade dysplasia" and "IPMN with intermediate-grade dysplasia" become "IPMN, low-grade." The former "IPMN with high-grade dysplasia" become "IPMN, high-grade" [4].

IPMN are subtyped by their direction of differentiation as gastric, intestinal, pancreatobiliary, or oncocytic [87].

Gastric-type IPMN is characterized by cells that resemble the foveolar epithelium of the stomach. The epithelium consists of a monolayer of columnar cells

with basally oriented nuclei and abundant mucinous cytoplasm (see Fig. 93.2a). The growth pattern can be flat, papillary, or tubular. The tubular growth pattern can sometimes predominate. The tubular-predominant, gastric-type IPMN was previously considered as an intraductal tubulopapillary neoplasm (ITPN) with low-grade cytonuclear features. In the past, this entity was called "intraductal tubular adenoma, pyloric gland type" or "pyloric gland adenoma" [88–96]. Later, the high-grade cytonuclear features of true ITPN were acknowledged and they were called "intraductal tubular carcinomas" (ITC), to differentiate them from "intraductal tubular adenomas" (ITA) (see Table 93.1). Eventually, immunohistochemical and molecular studies showed that ITA have more features in common with gastric-type IPMN than with ITPN [97]. Gastric-type IPMN typically involve the branch ducts [98].

The pancreatobiliary-type IPMN is lined by mucin-depleted cells with nuclei with marked variation in size and shape and these nuclei have irregular contours and prominent nucleoli (see Fig. 93.2b). The histologic features of pancreaticobiliary-type IPMN and what some people consider high-grade, gastric-type IPMN, are very similar [2]. For this reason, some people consider these as the same entity but with different grades of dysplasia, with gastric-type IPMN being the low-grade dysplastic variant and pancreatobiliary-type the high-grade dysplastic variant [99,100]. Gastric-type IPMN is rarely

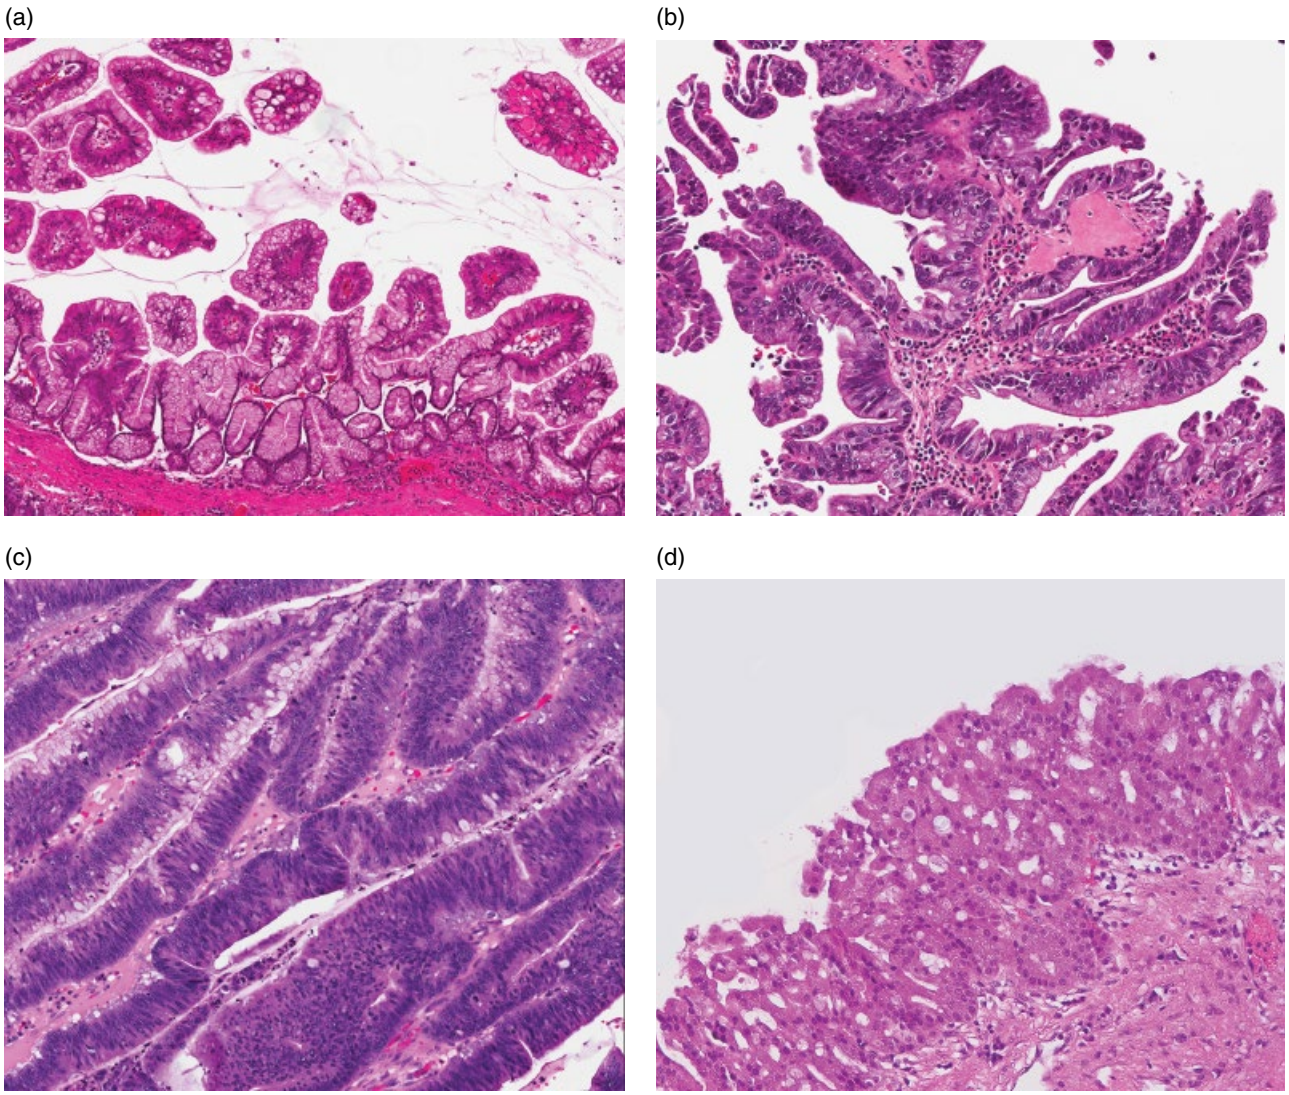

**Figure 93.2** The different subtypes of IPMN. (a) Gastric-type IPMN with a flat architecture and a single layer of gastric foveolar-type epithelium. (b) Pancreatobiliary-type IPMN lined by cells with marked atypia and prominent nucleoli. (c) Intestinal-type IPMN with scattered goblet cells. (d) Oncocytic-type IPMN, composed of cells with abundant eosinophilic cytoplasm, reflecting the accumulation of mitochondria.

**Table 93.1** Nomenclature of the entities, now known as tubular-predominant, gastric-type IPMN and ITPN and previously considered as (different grades of) the same entity

| Current name | Former names |
|---|---|
| Gastric-type IPMN with extensive tubular growth | Intraductal tubular adenoma, pyloric gland type; pyloric gland adenoma; intraductal tubular adenoma (ITA) |
| Intraductal tubulopapillary neoplasm (ITPN) | Intraductal tubular adenoma, pyloric gland type; pyloric gland adenoma; intraductal tubular carcinoma (ITC) |

associated with high-grade dysplasia and has the lowest risk of invasive carcinoma, while pancreatobiliary-type IPMN has the most aggressive behavior [98,101].

The intestinal-type IPMN is morphologically similar to a colonic villous adenoma. The nuclei of the cells are hyperchromatic, elongated, show some degree of pseudostratification and contain variable amounts of intracellular mucin. Dispersed goblet cells can be observed. The papillae are typically long and occasionally branching (see Fig. 93.2c). This subtype most frequently involves the main duct [98].

Oncocytic-type IPMN is a rare entity, characterized by cells with abundant eosinophilic cytoplasm, due to the accumulation of mitochondria. The nuclei of these oncocytic cells contain a single, prominent, eccentric nucleolus. The growth pattern of these oncocytic-type IPMN is distinctive, consisting of arborizing papillae, lined by one to five layers of cuboidal cells. A specific feature is the punched-out spaces in the epithelium (see Fig. 93.2d).

The 2010 World Health Organization classification of tumors of the digestive system provided an immunohistochemical aid for subtyping these IPMN based on mucin glycoprotein-stains. All IPMN stain positive for MUC5AC, while intestinal-type IPMN also show positivity for MUC2 and CDX2, and pancreatobiliary-type for MUC1/EMA. Oncocytic-type IPMN show more positivity for MUC6 than for MUC5AC [2,87,100,102,103]. However, several studies have shown that some IPMN are unclassifiable due to their uncharacteristic morphology and immunophenotype [104–108]. Mixed epithelial differentiation makes subtyping impossible in 25% of cases. Because of these reasons and the moderate interobserver agreement for morphologic subtyping of pancreatic IPMN, subtyping of IPMN has a poor reproducibility [109]. The fact that studies have reported differences in prognosis between the various subtypes of IPMN, despite the poor reproducibility, suggests that associations between histologic type and prognosis may be even stronger than reported [98,101,105,109–112].

### Molecular Features

Whole exome sequencing of IPMN revealed an average of 26 mutations per IPMN [39]. *KRAS* and *GNAS* are the most frequently mutated genes in 50–80% and 40–60% of IPMN, respectively [39,113]. Moreover, *RNF43*, an E3 ubiquitin-protein ligase acting as a negative regulator of the Wnt-signaling pathway is also frequently mutated in IPMN [39]. In addition, *TP53* and *SMAD4* mutations can be found in high-grade dysplasia.

Several studies suggest the existence of two distinct molecular progression pathways in IPMN [32,114]. These two distinct pathways are a reflection of the observation that IPMN can progress into a tubular carcinoma or a colloid carcinoma. Tubular carcinomas are more associated with a pancreatobiliary-type IPMN with a mutation profile resembling conventional PDAC with frequent *KRAS* mutations [114–116]. In contrast, colloid carcinomas are associated with intestinal-type IPMN and harbor frequent *GNAS* mutations [117].

These different pathways are also reflected in a different immunophenotype with colloid carcinomas being MUC1 negative (0%) and MUC2 positive (100%), while tubular carcinomas are typically MUC1 positive (63%) and MUC2 negative (1%) [32]. Colloid carcinomas have a less aggressive behavior and a better prognosis than tubular carcinomas [105,106]. In gastric-type IPMN, *KRAS* and *GNAS* mutations are identified equally. This suggests that gastric-type IPMN are a heterogenic group of early lesions [114].

Oncocytic-type IPMN is genetically distinct from other IPMN subtypes and does not contain *KRAS* or *GNAS* mutations [117a].

## Intraductal Tubulopapillary Neoplasm

### Clinical Features

Intraductal tubulopapillary neoplasms (ITPN) are rare intraductal neoplasms of the pancreas. Together with IPMN, they are grouped as “intraductal neoplasms” [118]. They occur equally in men and women. The presenting symptoms are nonspecific. About 50% of these neoplasms involve the head of the pancreas, 15% are localized in the tail of the pancreas and 30% of the cases involve the pancreas diffusely [118,119]. As much as 40% of cases harbor an associated invasive carcinoma. With a 5-year survival of more than 30%, prognosis of an ITPN-associated invasive tumor is significantly better than the prognosis of conventional PDAC. Recurrence or metastasis to lymph nodes or to the liver is seen in about one third of cases. Even these patients sometimes experience a protracted clinical course over >2 years, which is unusual for conventional PDAC [119].

### Pathologic Features

ITPN is characterized by densely packed tubules that frequently lie back to back, forming large sheets. Tubulopapillary growth is sometimes seen. The cells are cuboidal with modest amounts of eosinophilic cytoplasm and do not contain apparent mucin. There is moderate nuclear atypia and increased mitotic activity. Extracellular mucin production is not prominent and cyst formation is less evident than in IPMN. Comedo-like necrosis is sometimes present [120].

In contrast to IPMN, immunohistochemistry for MUC5AC is typically negative in ITPN [44,120]. MUC1 and MUC6 are positive in 100% and 60% of cases, respectively [120]. Because of similar morphology and shared positivity for MUC6 with gastric and duodenal pyloric gland adenomas, ITPN has previously been described as "intraductal tubular adenomas, pyloric gland type," "pyloric gland adenoma", or "intraductal tubular carcinomas" (ITC) (see Table 93.1) [88,96].

### Molecular Features

ITPN differ from IPMN on a molecular level: *KRAS* mutations are found in only 7% of ITPN. *GNAS* mutations have never been observed in ITPN [121–123]. *PIK3CA* mutations are the single, most frequently observed mutations in ITPN (21–27%) [121,124].

## Mucinous Cystic Neoplasms

### Clinical Features

The vast majority of mucinous cystic neoplasms (MCN) occur in perimenopausal women [76,118,125–129]. The mean age of presentation of patients with a noninvasive MCN is 44 years. The mean age of presentation of patients with an MCN with associated adenocarcinoma is 55 years [12]. Only a few, rare cases have been described in men [130]. MCN are commonly found in the pancreatic body and tail. Because of the close proximity of the female gonad to the pancreatic tail during embryologic life and the fact that similar lesions occur in the other side of the body, it has been hypothesized that the pancreatic MCN develops from a remnant of endodermal immature gonadal stroma, stimulated by female hormones [125,131]. This is reflected in the ovarian-type stroma surrounding the cyst [132]. Similar lesions are found in neighboring organs: mucinous cystadenomas of the hepatobiliary tree, mesentery and retroperitoneum, and the mixed epithelial and stromal tumor (MEST) of the kidney [133–136].

The prognosis after surgical resection is excellent if the neoplasm is noninvasive or if invasive carcinoma is confined to the ovarian-type stroma of the septa [128,129,137,138]. The prognosis of patients with an MCN with an associated invasive carcinoma after resection is better than that of patients with conventional invasive ductal adenocarcinoma not arising in an MCN; the 5-year survival rate of the MCN patients with an associated invasive carcinoma is up to 50% [125,128].

### Pathologic Features

MCN usually do not communicate with the pancreatic duct system and show a "cyst-in-cyst" growth pattern, by the formation of septae. Microscopically, MCN are defined as having two components: the cyst is lined by neoplastic, mucinous, columnar epithelial cells, surrounded by a nonneoplastic, ovarian-type stroma (see Fig. 93.3). The epithelium can harbor varying degrees of architectural and cytologic atypia [118]. The atypia is graded in a two-tiered system, as recommended by the latest consensus meeting. This two-tiered system replaces the three-tiered system: "MCN with low-grade dysplasia" and "MCN with intermediate-grade dysplasia" are now both classified as "MCN, low-grade" [4].

Ovarian-type stroma may be only focally present or not obvious due to fibrosis or hypocellularity [125,139]. Sometimes, nests of epithelioid cells are seen in the stroma suggesting luteinization. Rarely, a corpus luteum can be seen in the stroma. The cells of the ovarian-type stroma frequently express progesterone and estrogen receptor, inhibin, caldesmon, alpha-SMA, and desmin [133,140].

When an MCN evolves into an invasive carcinoma, this is typically a tubular adenocarcinoma. MCN rarely evolve into a colloid carcinoma, although 51% of MCN

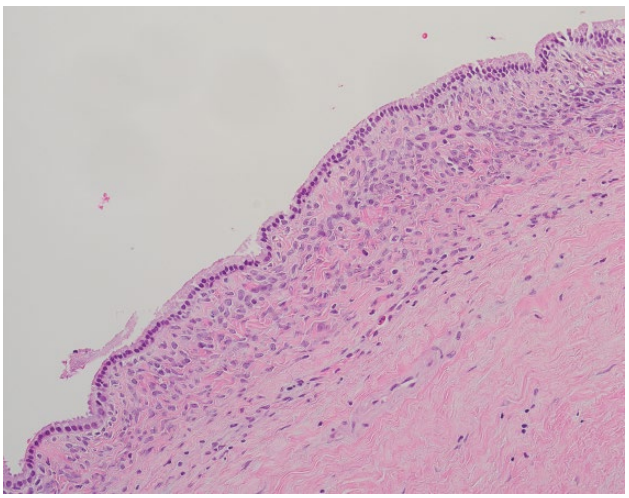

**Figure 93.3** MCN with mucinous epithelium with low-grade dysplasia and characteristic ovarian-type stroma.

show intestinal differentiation by immunostaining for CDX2 [141,142]. MCN with malignant, sarcomatous stroma have been reported but are more likely spindle cell carcinomas rather than true mesenchymal neoplasms, since the ovarian-type stroma of the MCN is nonneoplastic [143–146].

### Molecular Features

Whole-exome sequencing of the MCN showed on average 16.0 ± 7.6 nonsynonymous somatic mutations and relatively few "loss of heterozygosity" events, compared with IPMN [39]. This could explain the lower frequency of progression towards an invasive carcinoma in MCN, since there is a correlation between aneuploidy and a poor prognosis [147]. Only one region on chromosome 17q, containing the gene *RNF43*, was lost in more than one tumor. In three MCN, intragenic mutations were found in the *RNF43* gene. Further analysis showed mutations in the four main pancreatic cancer genes *KRAS*, *CDKN2A*, *TP53*, and *SMAD4* [39].

# Clinical History and Risk Factors of Pancreatic Cancer

*Norbert Hüser, Volker Aßfalg, and Helmut Friess*

*Technical University of Munich, School of Medicine, Klinikum rechts der Isar, Department of Surgery, Munich, Germany*

## Introduction

It does not matter which way you look at it or by what means you endeavor to access the extensive field of pancreatic carcinoma—whether as a nonspecialist but interested reader, or as an oncology expert, or even as an afflicted patient—and no matter the angle of view or the basic discipline you use to acquaint yourself with pancreatic carcinoma—whether by pathology, internal medicine, or surgery—the catchy introductory phrase is almost always followed by the stereotypical statement: "The diagnosis of pancreatic carcinoma most frequently implies an unfavorable prognosis." This monotonous introduction to pancreatic carcinoma is clear evidence of the lack of effective therapeutic options, especially in the case of an unresectable tumor. There are multiple reasons, but undoubtedly the relatively long period of freedom from symptoms greatly contributes to the fact that only around one fifth of patients are diagnosed early enough to consider a curative approach. Moreover, numerous widespread, but rarely specific, factors exist that often cannot be influenced but may increase the likelihood of developing pancreatic carcinoma. Although it should be noted that phenomena such as pancreatitis or diabetes tend to be part of the clinical appearance of the tumor disease rather than risk factors. This chapter aims to make a connection between current knowledge in terms of relevant risk factors and the clinical appearance and symptoms of pancreatic carcinoma. Finally, by raising the reader's awareness, it is hoped to improve early detection and intervention as a basis for a more effective therapeutic approach and thus a better prognosis for the patient.

## Clinical History of Pancreatic Cancer

Probably the greatest hindrance to the prompt diagnosis of pancreatic carcinoma is the lack of early disease-specific symptoms. On the one hand, it is difficult to distinguish these from other nonspecific symptoms, and on the other hand, afflictions that possibly indicate malignant disease can often be explained otherwise and may be misinterpreted. This problem was demonstrated in a groundbreaking study during the 1970s: in 57% of the patients with respective symptomatic complaints, the authors found concurrent reasons, including malignant diseases in 13% and nonpancreatic, nonmalignant diseases in 44%, respectively [1]. Moreover, symptoms may vary significantly depending on the tumor's location in the pancreas.

### Functional Impairment of the Pancreas

Increasing loss of exocrine function is one potential tumor-related symptom. The absence of important digestive enzymes in the functionally complex interaction of intestinal digestion causes an inadequate fragmentation of carbohydrates, proteins, and fats. Therefore resorption across the intestinal wall into the portal system is insufficient, the major portion of the undigested fat remains in the gut, which causes so-called *fatty stools* (*steatorrhea*). This may lead to considerable *diarrhea*, *flatulence*, and *abdominal cramps*.

Furthermore, the tumor may noticeably compromise the endogeneous function of the pancreas by destroying insulin-producing cells. Several studies have proved that *diabetes* frequently predates a diagnosis of pancreatic carcinoma. This particularly applies when diabetes is first

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

diagnosed during or beyond a patient's sixth decade and without familial disposition [2]. A retrospective analysis of 736 patients with pancreatic carcinoma revealed diabetes prior to the malignant disease in approximately 40% of cases, whereas only 19% were identified in a control group. In the majority of these cases, diabetes was noticed between several months and up to 2 years prior to the diagnosis of pancreatic cancer. However, the authors add that in most cases this was type 2 diabetes but not a pancreatic carcinoma-associated diabetes [3]. It is therefore likely that the mechanism of diabetes development in pancreatic carcinoma is probably not only due to B-cell destruction because even pancreatic carcinomas that involve only small parts of the organ are already associated with diabetes. In molecular analyses of sera from patients with pancreatic carcinomas, for example, peptides were identified that are able to induce diabetic effects [4].

## Invasion into Intra- and Extrapancreatic Nerve Plexus

Rapid *loss of weight* and reduced general state of health in afflicted patients are frequently triggered by *pain symptoms* in the upper abdomen and the back. Pain in the upper abdomen can be found in approximately 70% of patients with pancreatic carcinoma. Symptoms usually start intermittently and after a distinct period of time develop into continuous pain. Inside the pancreas specific changes in neural structures occur as tumor cells are able to perform intra- and extrapancreatic perineural invasion. This phenomenon is known as *neuropathic pain*, which, in contrast to *nociceptive pain*, develops in the absence of any stimulus. The continuous spread of the tumor cell and the consecutive degree of severity of neural invasion increase both the risk of neural metastatic spread into the adjacent extrapancreatic nerve plexus and the spread of pain. The morphologically detectable changes in intrapancreatic nerve integrity culminate in the destruction of the whole nerve plexus. Noticeably, patients with severe abdominal pain show a higher degree of neural invasion and increased nerve hypertrophy compared with patients who are pain free [5, 6].

The development of neuropathic pain is not only effected by neurons but also by immune cells, Schwann cells, and glial cells of the central nervous system [7]. Current research is investigating the genesis of neuropathic pain with the aim of developing adequate pain management.

## Tumor Cell Ingrowth into Adjacent Organs and Nearby Vessels

Whereas a tumor located in the head of the pancreas characteristically causes both pain-free *jaundice* and intra- and extrahepatic cholestasis, lesions in the panceatic corpus and caudate rarely give rise to these symptoms [8]. Jaundice of sclerae and skin and the accompanying troublesome *pruritus* is caused by intrapancreatic biliary obstruction with consecutive storage of bile acids and bilirubin in the tissue. The tumor causes constriction of the common bile duct that passes through the pancreatic head and then leads to the major duodenal papilla and the duodenum together with the pancreatic duct. In case of constriction of the pancreatic duct, *acute pancreatitis* may develop. Patients usually also report *discoloration of feces and urine*. As a consequence of the impaired biliary excretion via the bowel, feces become light and clay-colored. The accumulated bilirubin in the serum is then compensatorily excreted by the kidneys, turning the urine brown.

Furthermore, local tumor growth and infiltration of adjacent organs may cause gastric emptying disorders or duodenal obstructions, resulting in *nausea*, *loss of appetite*, *a sensation of pressure in the upper abdomen*, and *increasing emesis*. Because of the close anatomic proximity of the pancreas to adjacent vessels (portal vein, celiac trunk, and superior mesenteric artery) even relatively small tumors may invade vessels. However, the so-called *paraneoplastic syndromes*—especially thromboses of the major femoral and lower leg veins with respective clinical appearance—are independent of local tumor growth.

## Clinical Symptoms of Neuroendocrine Tumors of the Pancreas

Apart from the afore-mentioned nonspecific and sometimes nondirective symptoms of pancreatic carcinomas, neuroendocrine tumors (NET) of the pancreas often secrete hormones into the bloodstream. Various types of NET produce different hormones, which in turn cause varying clinical symptoms. However, not all NET of the pancreas are hormonally active.

***Gastrinomas*** are functionally active NET that produce the hormone gastrin, which causes increased secretion of gastric acid. Typically, gastric and intestinal ulcers resistant to medication develop in up to 95% of afflicted patients over time or rapidly reoccur after end of treatment. Subsequently, *intense abdominal pain* and/or *intestinal bleeding* may appear. A smaller number of patients (~60%) develop pathologic *gastroesophageal reflux* with *pyrosis* or *dysphagia*. Over 30% of patients suffer from *diarrhea* and/or *steatorrhea*.

***Insulinomas*** are the most frequent type of functionally active NET of the pancreas. These tumors typically release insulin, which depresses blood glucose levels and provokes symptoms of *hypoglycemia* such as *trembling*, *ravenous appetite*, and *confusion*.

***Glucagonomas*** may cause nonspecific *loss of capability* or *body weight*. Hyperglycemia caused by release of glucagon and *necrotizing dermatitis* are characteristic symptoms of glucagonomas.

***Somatostatomas***, ***VIPomas***, and ***PPomas*** are rare hormone-producing NET. A list of specific and nonspecific symptoms are shown in Table 94.1, together with symptoms of the afore-mentioned tumors.

## Risk Factors for Pancreatic Cancer

The triggers for development of a pancreatic carcinoma can be difficult to identify retrospectively. Comprehensive observational studies have detected predisposing factors but they may not be found in all patients; conversely, not all individuals who have one or more risk factors will inevitably develop a pancreatic carcinoma.

### Smoking

The etiology of numerous diseases can be attributed to inhalation of tobacco. This mainly applies to respiratory organs, the cardiovascular system, and malignant tumors. Smoking is an unambiguous risk factor for development of pancreatic cancer. A meta-analysis of 82 cohorts and case-control studies reports on a relative risk of 1.7 (95% CI: 1.6–1.9) for smokers and 1.2 (95% CI: 1.1–1.3) for ex-smokers independent of gender and region. The investigation of cigar smokers and pipe smokers ascertains a pooled risk of 1.5 (95% CI: 1.02–2.3) and 1.4 (95% CI: 0.94–2.0), respectively [9]. Another pooled analysis studied the impact of cigar and pipe tobacco and smokeless tobacco on pancreatic cancer risk. The results principally confirm an association between cigarette smoking (odds ratio [OR] = 1.5, 95% CI: 1.4–1.6) and cigar smoking (OR = 1.6, 95% CI: 1.2–2.3) and pancreatic carcinoma. However, any impact of pipe smoking on later occurence of pancreatic carcinoma could not be demonstrated [10]. Data on smokeless tobacco use (mainly snus) is rare. Here the authors show results consistent with a respective meta-analysis, which does not show any excessive risk of pancreatic carcinoma in several case studies [11]. Conversely, another meta-analysis refers to

**Table 94.1** Clinical symptoms of pancreatic carcinoma.

**By functional impairment of the pancreatic gland**

Digestive difficulties (diarrhea, abdominal pain, flatulence)

Changes in stools

Development of diabetes

Loss of weight

**By intra- and extrapancreatic nerval invasion**

Pain in the upper abdomen and the back

**By infiltrative tumor growth into adjacent organs and vessels**

Jaundice

Nausea and vomiting

Inappetence

Sensation of pressure in the upper abdomen

Acute pancreatitis

Thromboses (including paraneoplastic syndromes)

**By specific hormones of neuroendocrine pancreatic tumors**

| Type of tumor | Hormone | Symptoms |
|---|---|---|
| Gastrinoma | gastrin | Acid reflux, burning abdominal pain, excess fat in stool, weight loss |
| Glucagonoma | glucagon | High blood glucose, anemia, weight loss, swelling/irritation of skin |
| Insulinoma | insulin | Low blood glucose, perspiration, confusion, shakiness, accelerated heartbeat |
| Somatostatinoma | somatostatin | Nonspecific symptoms like diabetes, gallstones, diarrhea, weight loss |
| VIPoma | vasoactive intestinal peptide | Watery diarrhea, fatigue, nausea |
| PPoma | pancreatic polypeptide | Belly pain, enlarged liver, watery diarrhea |

VIPoma, vasoactive intestinal peptide-releasing tumor; PPoma, pancreatic polypeptide-producing tumor.

an association between smokeless tobacco and pancreatic carcinoma [12]. However, the consumption of smokeless tobacco in particular has not been proven to be a distinct risk factor because of the marked heterogeneity of ingredients.

The risk seems to increase according to both quantity of tobacco use and length of exposure to cigarette smoke. However, the elevated risk of pancreatic cancer diminishes after complete cessation of smoking. Due to the high prevalence of smoking worldwide experts assume that as many as 25% of pancreatic carcinomas can be attributed to cigarette consumption [13].

## Diabetes Mellitus

As stated in the introduction to this chapter, risk factors and early symptoms of pancreatic cancer can be difficult to distinguish. A comprehensive study revealed a threefold increased risk of pancreatic cancer in patients with type 2 diabetes (OR = 3.22, 95% CI: 3.03–3.42) [14]. These results can be supported by results from an earlier meta-analysis that also identified diabetes type 2 as a risk factor for pancreatic carcinoma (OR = 1.82, 95% CI: 1.66–1.89) [15]. Individuals who were diagnosed with diabetes <4 years previously showed a 50% higher risk of tumor disease compared with patients with a diagnosis of diabetes >5 years previously (OR = 2.1 vs. 1.5). These findings again support the theory that the onset of diabetes may be an early symptom of pancreatic cancer (as outlined in the earlier section "Functional impairment of the pancreas"), because otherwise an increasing risk could be expected over the ongoing length of time of diabetes disease. However, the authors hint at the fact that in most of the included studies there was no distinction between type 1 and type 2 diabetes. Nevertheless, it could be assumed that most individuals had type 2 diabetes, which is the most frequent type of diabetes in the elderly [15]. In a meta-analysis of three cohorts and six case-control studies the investigators took this factor into account and analyzed 39 patients with type 1 diabetes and young-onset diabetes (interpreted as type 1). Type 1 diabetes could be identified as a risk factor for pancreatic carcinoma with a relative risk of 2.00 (95% CI: 1.37–3.01) but the authors urgently call for confirmation by further studies because of the low number of patients [16]. A prospective cohort study was initiated to determine the independent association between postload plasma glucose concentration and the risk of pancreatic cancer development among patients without self-reported diabetes. After an observation period of 25 years and after adjusting for age, race, cigarette smoking, and body mass index (BMI), the relative risk of pancreatic cancer mortality was 1.65 (95% CI: 1.05–2.60, for postload plasma glucose levels between 6.7 and 8.8 mmol/L). The authors concluded that factors associated with abnormal glucose metabolism have a significant impact on the development of pancreatic cancer [17]. Furthermore, another study reported a positive association between pancreatic cancer and elevated baseline fasting serum concentrations of glucose and insulin, and insulin resistance, respectively [18].

## Overweight and Obesity

The World Health Organization (WHO) defines overweight and obesity by use of the BMI calculated as weight in kilograms divided by height in meters squared. Thereby, underweight (BMI < 18.5 $kg/m^2$), normal weight (1.5–24.9 $kg/m^2$), and overweight (>25 $kg/m^2$) can be differentiated. In several cohort studies and case-control studies an up to threefold increased risk for development of pancreatic carcinoma was found for overweight individuals. Next, it was shown that overweight (OR = 1.67, 95% CI: 1.20–2.34) and obese individuals (OR = 2.58, 95% CI: 1.70–3.90) had an elevated risk for pancreatic carcinoma independent of concomittant diabetic disorders [19]. An interesting aspect of this study was the finding that overweight and obesity during early adulthood increased the risk of developing pancreatic cancer and that it usually develops 2–6 years earlier than average (between 20 and 49 years). This was the first report of an association between excess body weight across an individual's life span and the risk of pancreatic cancer, which emphasizes the importance of these findings with regard to public health [19]. These results were confirmed in a recently published pooled analysis of 20 prospective cohort studies. This analysis determined an association between increased pancreatic cancer mortality and BMI during early adulthood in individuals who are overweight or obese [20]. Along with other studies, it was concluded that there is an increased risk of obesity-associated pancreatic cancer in males [19]. These findings raise the question whether those (rather few) individuals who manage to reduce their body weight significantly and approach normal weight during their life can thereby reduce the risk of pancreatic cancer development. Therefore, an important prevention measure is body weight control at younger ages.

## Chronic Pancreatitis and Consumption of Alcohol

The positive correlation between chronic pancreatitis and development of pancreatic carcinoma was proven in a precedent-setting cohort study [21]. Including 2,000 patients with chronic pancreatitis, the authors demonstrated an increased lifetime risk of approximately 4% in this population group in terms of development

of pancreatic carcinoma. Population-based prospective surveys assume a standardized incidence ratio of 4.8, which approximates to a risk of 0.6% after 20 years. Amongst approximately 1,500 patients who were observed for a period of at least 2 years, the percentage distribution of pancreatitis was alcohol-induced in 77%, idiopathic in 17%, hereditary in 1.9%, and of different origin in 4.1%, respectively. Even though the relation may have turned slightly towards a higher rate of hereditary pancreatitis during the last two decades, this study identified chronic pancreatitis to be a risk factor, which is independent of age, region, and underlying origin. Numerous other reports suggest that chronic pancreatitis is a risk factor for pancreatic carcinoma; however, the relative risk varies considerably in the literature (range: 2.3 [22] and 18.5 [23]). Most likely these variations can be attributed to methodologic concerns and the retrospective design of many studies. In a prospective analysis of 373 patients with proven chronic pancreatitis and a follow-up of at least 2 years, a significantly increased risk for pancreatic cancer was validated compared with the general population [24].

The true impact of alcohol as a direct risk factor for pancreatic cancer is under debate and different mechanisms are postulated. Inducing different cascades of inflammation, alcohol might indirectly induce carcinogenesis via both chronic pancreatitis and diabetes, respectively [25]. However, one point of criticism of the partially inconsistent studies is the fact that analyses were performed without considering the relationship of doses and pattern of alcohol exposure. Heavy alcohol consumption was associated with an increased risk for development of pancreatic cancer in males in a population-based study. According to dose, duration, and pattern of alcohol abuse the OR was increased 1.5-fold to sixfold [26].

### Environmental Factors

A range of environmental factors has hitherto been identified to have a possible association with pancreatic carcinoma development. Table 94.2 shows an excerpt of these ubiquitously present and numerous triggers. Aromatic amines seem to be the substrate of the carcinogenic effect of both smoking and consumption of cooked meat and fish. The same applies to occupations with comparatively high exposure to these amines.

### Hereditary Factors

A positive family history of pancreatic carcinoma has repeatedly been shown to be a risk factor for its cumulative appearance. These aspects and the respective tumor predisposition syndromes are the subject of Chapter 91.

**Table 94.2** Risk factors for pancreatic adenocarcinoma.

## Conclusion

The identification of early symptoms of pancreatic cancer and the subsequent timely start of diagnostics in daily clinical practice remain highly demanding. In contrast, several specific and nonspecific risk factors of pancreatic carcinoma have been identified with more or less certainty so far, which can be proved by respective studies. If possible, abstinence and avoidance should be practiced to the greatest extent to prevent development of pancreatic cancer. With regard to numerous predisposing factors and especially a positive family history this cannot be performed satisfactorily. An early diagnosis is the only possibility to improve a patient's survival. Therefore, every worrisome finding should be investigated and resected in case of doubt.

Finally, particular attention must be drawn to the group of cystic pancreatic tumors with their numerous and different entities and distinct clinical and morphologic characteristics. These neoplastic and nonneoplastic, mucinous, and serous cystic lesions can be detected even earlier and at a smaller stage because of continuing improvements in imaging methods. Nowadays, these tumors can be

investigated by a highly precise risk stratification, which results in distinct therapeutic recommendations. Based on several clearly defined criteria, the pancreatic cystic tumors should be either observed or resected. This strategy allows for early resection of precancerous lesions or even pancreatic cancer with the chance of cure.

## Embryology of the Pancreas

The pancreas is a two-headed organ in two respects: origin and function. It develops from two separate primordia at the foregut–midgut junction. The following sections provide an overview of its organogenesis.

The development of the pancreas begins approximately 5 weeks after gestation in common with the development of other endoderm-derived organs in the region of the foregut (for development of the pancreas, see Chapter 1). It originates from two pouches of the endodermal lining of the duodenum, which will form the ventral and dorsal pancreas. These pouches initially grow and differentiate independently, but later fuse to form a single organ. They occur on the ventral and dorsal surfaces of the primitive digestive tube forming the ventral and dorsal pancreatic bud. The dorsal bud will develop into the tail of the pancreas, the body, the isthmus, and the accessory pancreatic duct as well as a part of the head. The much smaller ventral bud gives rise to the other part of the pancreatic head, the uncinate process forming the lower portion of the pancreatic head and the main pancreatic duct. The ventral pancreatic primordium forms in the interspace between the liver and the gall bladder primordia (also endoderm-derived) and the primitive gut.

In contrast to the ventral bud, the dorsal bud grows more rapidly. An asymmetric growth of the duodenum causes its rotation together with the ventral pancreas, annexed to the primordium of the common bile duct, towards the dorsal pancreas. This moves the originally ventral part to a dorsal location. Finally, the ventral and dorsal parts merge and the ductal systems fuse, forming a single organ and the main pancreatic duct so that secretions of the dorsal part enter the shared ductal system of the ventral part and the common bile duct (Fig. 95.1). The region of the primary duct of the ventral pancreas proximal to the duodenum fuses with the primary duct of the dorsal pancreas and becomes the primary drainage into the duodenum, entering the duodenum immediately adjacent to the common bile duct.

## Radiologic Characteristics

Over the past few years, there have been significant technical developments in the area of cross-sectional imaging. This draws imaging into focus with regard to the diagnosis of pancreatic cancer. In case of suspicion, multidetector computed tomography (MDCT) and/or magnetic resonance imaging (MRI) are deployed. MDCT and MRI are of equal value with respect to the diagnosis of pancreatic cancer. When it comes to the diagnosis of liver metastases, there is a slight advantage in using MRI in combination with a hepatobiliary contrast agent. Despite the higher accuracy of endoscopic ultrasound examination, in daily practice, it is used in cases of unclear results or when there is an urgent clinical suspicion and in combination with imaging.

Cross-sectional imaging plays a central role in the diagnosis and staging of pancreatic tumors. The methods are useful to assess the response of a therapy and for early detection of recurrence. The increasing use of high-resolution cross-sectional imaging will facilitate more frequent discovery of prior unknown tumors of the pancreas [1–4]. This concerns primarily cystic lesions, which are usually benign, but also solid tumors that are malignant in most cases. For general screening of pancreatic cancer, these methods are not yet appropriate and early detection measures are confined to high-risk groups [2].

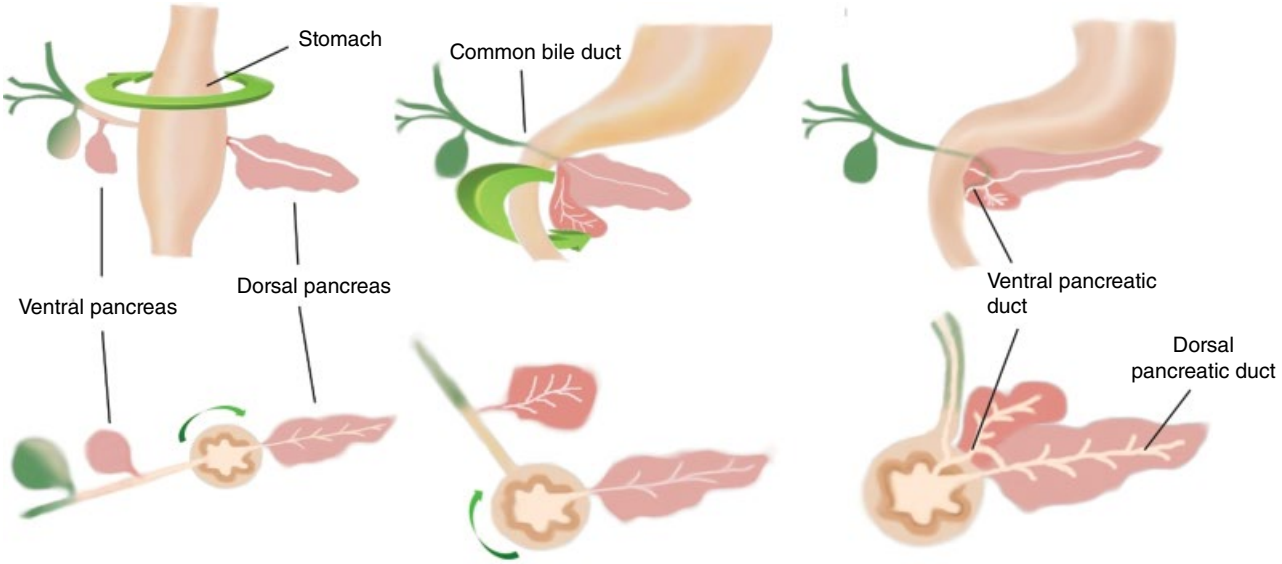

**Figure 95.1** Fusion process of the ventral and dorsal pancreatic bud.

Following the recent recommendation by the American Joint Committee on Cancer, the staging of pancreatic cancer is based on the assessment of resectability by a spiral CT.

Tumor imaging of the pancreas has three objectives:

- Detection and characterization of tumors
- Differentiation of ductal carcinomas and other forms of tumors or chronic pancreatitis (which is often not possible with absolute certainty)
- Staging and evaluation of resectability.

## Clinical Characteristics of the Uncinate Process Pancreatic Cancer (UPDAC)

Because of the embryologic and anatomical uniqueness of the uncinate process, the clinical presentation of patients with UPDAC varies. In contrast to the literature concerning ductal adenocarcinoma of the pancreas, there is a lack of data regarding UPDAC. Only a handful of published series of UPDAC exist. It is therefore difficult to quantify the incidence of UPDAC (the literature data vary from 2.5% to 11%) [5,6].

By tradition, UPDAC are considered to have a lower resection rate and a poorer prognosis than comparable cancers of the pancreatic head. The reason is the immediate positional relation of the mesenteric vessels and the retroperitoneum. The overall resectability (31.7% for UPDAC vs. 46.2% for non-uncinate process pancreatic head cancer; $P = 0.003$), the rate of curative resection (24.8% vs. 41.8%; $P < 0.001$), and R0 resection rate (22.3% vs. 35.6%; $P = 0.003$) are significantly lower for UPDAC. UPDAC is more often unresectable (68.3% vs. 53.8%; $P = 0.003$) [7]. The percentage of vascular (SMV/PV and/or SMA) invasion at the time of diagnosis is significantly higher in the case of UPDAC than in patients with non-UPDAC (58.2% vs. 38.1%; $P = 0.019$) [8]. The rate of isolated PV or SMV encasement is also significantly higher (45.5% vs. 20.0%; $P = 0.001$ and 54.5% vs. 36.2%; $P = 0.026$, respectively). The rates of PV-resection and consecutive reconstruction do not differ significantly (11.8% vs. 11.1%; $P = 0.885$) [7].

In the uncinate process, because one part of the head extends posteriorly and medially to lie dorsally of the portal vein, the superior mesenteric artery (SMA), and the superior mesenteric vein (SMV), it is closer to the SMA and set back from the courses of the common bile duct or pancreatic duct compared with the remaining part of the head. This peculiarity [6,7,9–12] may result in distinct clinical features and the key anatomical position of the uncinate process makes its separation from the SMA, SMV, and the retroperitoneum or even partial vessel resection (SMV and/or PV), of surgical importance in achieving R0 resection in case of uncinate cancer.

Clinical symptoms of UPDAC often appear late in the course of the disease. In contrast to cancer arising in the head of the pancreas, there is a lack of jaundice as a presenting symptom (Tables 95.1 and 95.2). The literature provides only scanty data on UPDAC [5]. Described clinical symptoms are abdominal pain (74%), weight loss (69%), jaundice (28%), and duodenal obstruction (9%). The cumulative resectability lies between 16.7% and 31%.

**Table 95.1** Clinicopathologic findings of patients with UPDAC: an overview of the reported series.

* mostly associated with lumbar pain.

**Table 95.2** Comparison of clinicopathologic findings of uncinate process (UPDAC) and non-uncinate process cancer (non-UPDAC) [8].

| | UPDAC (161) | Non-UPDAC (292) | *P* |
|---|---|---|---|
| Age | 62.0 ± 10.6 | 61.1 ± 10.9 | 0.710 |
| Sex (m:f) | 1.88:1 | 1.89:1 | |
| Symptoms | | | |
| Abdominal pain | 62.3% | (51.7%) | 0.032 |
| Weight loss | 46.8% | 35.8% | 0.022 |
| Jaundice | 45.3% | 56.2% | 0.027 |
| Duodenal obstruction | 8.7% | 4.8% | 0.099 |
| Symptom duration (months) | 1.9 ± 2.1 | 1.7 ± 1.8 | 0.189 |
| Operation | 42.2% | 58.6% | 0.001 |
| Resection | 31.7% | 46.2% | 0.003 |
| curative intended | 24.8% | 41.8% | <0.001 |
| R0 resection | 22.3% | 35.6% | 0.003 |
| Recurrence after R0 resection | 66.7% | 65.4% | 0.889 |
| Median survival after R0 resection (months) | 21 | 26 | 0.018 |

Despite advances in the treatment of many surgical malignant entities the outcome of surgery for uncinate process pancreatic cancer remains poor. The 1- and 3-year survival rates are 71% and 5.9%, respectively (Fig. 95.2). The median overall survival after R0 resection is lower for UPDAC than for non-UPDAC (15 months vs. 19 months; $P = 0.036$) [6].

The invariably final part of removing the resectate during a pancreatoduodenectomy is the division of the uncinate process and the retroperitoneal separation. This approach is made more difficult when the cancer emerges in the uncinate process. In this case, vascular and nodal as well as margin involvement and thus reduced survival are more likely. However, there is still a lack of evidence of increased venous and nodal involvement and a higher rate of either macroscopic or microscopic positive resection margins in UPDAC. Despite improvements in chemotherapy and surgical techniques for treating UPDAC (Tables 95.1 and 95.2) in recent decades, the short-term prognosis remains poor and further investigations of this entity are highly desirable.

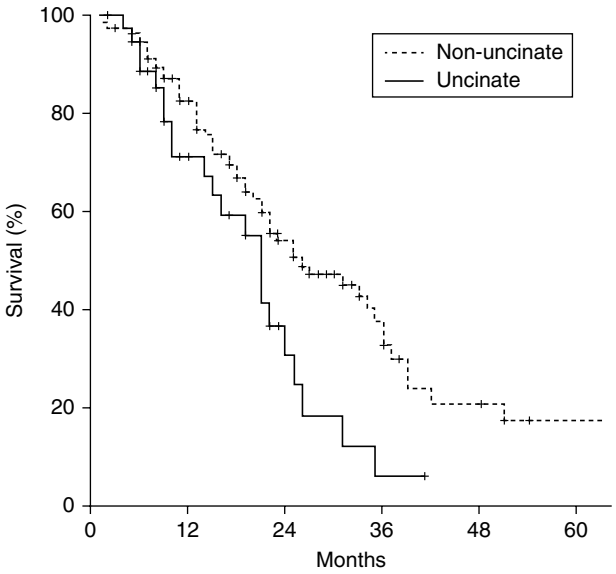

**Figure 95.2** Kaplan-Meier curve for overall survival in patients after R0 resection according to the tumor location.

# The Role of EUS in the Diagnosis and Differential Diagnosis of Neoplastic Lesions

*Susumu Hijioka, Kazuo Hara, Nobumasa Mizuno, Nozomi Okuno, and Kenji Yamao*

*Department of Gastroenterology, Aichi Cancer Center Hospital, Nagoya, Aichi, Japan*

## Introduction

Imaging modalities such as ultrasonography (US), computed tomography (CT), magnetic resonance imaging (MRI), and endoscopic ultrasonography (EUS), have remarkably improved the visualization of small lesions. Although these modalities can detect pancreatic lesions <2 cm, differentiating benign from malignant lesions based on morphologic appearance alone remains challenging. Therefore, a safe, accurate, and straightforward method of tissue sampling is required. Minimally invasive EUS was developed during the 1980s to visualize and collect tissues from embedded organs such as the pancreas.

Among various methods of sampling pancreatic lesions, EUS-FNA has become indispensable [1]. This section describes EUS and EUS-guided FNA (EUS-FNA) for evaluating and differentially diagnosing pancreatic disorders.

## Characteristics of Endoscopic Ultrasound

Endoscopic ultrasound (EUS) is the most popular endoscopic technique used to diagnose and evaluate pancreatic masses [2]. High-resolution images of the pancreas can be generated by placing a high-frequency probe in close proximity to the pancreas [3].

The EUS equipment includes probes for various imaging procedures (Fig. 96.1): radial probes allow 360° imaging perpendicular to the long axis, and convex probes allow imaging along a plane parallel to the long axis of the instrument (Table 96.1). The former allows only diagnostic imaging, whereas the latter was developed for fine-needle aspiration (FNA) [4,5]. Pancreatic masses can be detected by EUS with 93–100% sensitivity and a negative predictive value approaching 100%, particularly when combined with FNA [6]. Small masses (<2 cm) that can be detected by EUS, may be identified as occult according to other imaging modalities and for patients with previous indeterminate findings.

The National Comprehensive Cancer Network (NCCN) guidelines for pancreatic adenocarcinoma state that patients without a pancreatic mass evident on cross-sectional images should undergo further evaluation with EUS and/or endoscopic retrograde cholangiopancreatography (ERCP) as clinically indicated [7]. Another advantage of EUS is that pancreatic masses can be detected and characterized without intravenous contrast, which is of particular importance when patients have renal dysfunction or other contraindications.

## New Screening Modality Comprising Contrast EUS and Elastography

Conventional EUS sometimes cannot detect pancreatic tumors in patients with chronic pancreatitis, diffusely infiltrating carcinoma, or a recent episode of acute pancreatitis [8]. Contrast enhanced (CH)-EUS and EUS elastography may help to improve the diagnostic accuracy of EUS.

Parenchymal perfusion and the pancreatic microvasculature can be visualized without artifacts by CH-EUS [9], and it is useful in the differential diagnosis of pancreatic cancer, especially when tumors are small [10,11]. Fusaroli et al. [12] reported that pancreatic tumor visualization is more precise by CH-EUS than by conventional EUS. A recent meta-analysis of 1,139 patients found that the sensitivity and specificity of CE-EUS for a differential diagnosis of pancreatic cancer were 94% and 89%, respectively [10].

Radial scope

Convex scope

**Figure 96.1** Radial and convex EUS. Radial EUS image is 360° perpendicular to the long axis. Convex EUS image is along a plane parallel to the long axis of the instrument.

**Table 96.1** Advantages and disadvantages of EUS imaging modalities.

| | Radial scope | Convex scope |
|---|---|---|
| Advantages | • Scanning range is 360°<br>• Pancreas is easily seen as a longitudinal and continuous image | • Histologic diagnosis is possible<br>• Junction between the pancreatic head and body can be seen from the stomach |
| Disadvantages | • Histologic diagnosis is impossible<br>• Operator-dependent | • Scanning range is 180°<br>• Images of the body and tail of the pancreas become cross-sectional images |

The higher sensitivity of CH-EUS allows it to identify targets of EUS-FNA [12–14] and might also help to avoid puncturing necrotic and inflammatory areas of malignant masses or hard and scirrhous areas of inflammatory masses, thus reducing the need for repeated FNA assessments.

Another emerging technology is EUS elastography, which can visualize tissue stiffness in real time. It is based on the premise that compression causes less strain on hard, than on soft tissues [15]. The results of recent investigations using EUS elastography for diagnosing pancreatic focal lesions are promising [16–18]. As malignant lesions are generally harder than normal adjacent tissue, measuring strain might help to classify pancreatic masses. Two meta-analyses recently found high pooled sensitivity (95–97%) and low pooled specificity (67–76%), for a differential diagnosis of solid pancreatic masses [19,20]. However, CH-EUS and EUS elastography are not widely available and have yet to be widely tested as screening tools for pancreatic cancer [21,22].

## EUS-FNA for Solid Pancreatic Lesions (Figs 96.2 and 96.3)

### Indications

A fundamental principle of EUS-FNA is that the information obtained should have the potential to affect patient management [23,24]. In addition, the indications for EUS-FNA should be guided by its diagnostic accuracy, cost-effectiveness, and patient comfort and safety [23–26]. EUS-FNA is indicated for cytopathologic diagnoses of lesions of the gastrointestinal tract (and adjacent tissue) and of lymph nodes in their vicinity when less invasive or other sampling methods have failed.

### Contraindications

When the risks associated with the procedure outweigh the expected benefits of the diagnostic information obtained, EUS-FNA is contraindicated. Contraindications would include all conditions where the FNA findings would not affect patient management, when the lesion cannot be clearly visualized or a tumor mass or vessel is interposed between the needle-to-target path, when a patient is susceptible to bleeding or has a risk of tumor seeding [23–26].

## Diagnostic Yield and Safety of EUS-FNA for Solid Pancreatic Lesions

The reported sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and accuracy of EUS-FNA for detecting pancreatic cancers are 79–98%, 71–100%, 96–100%, 33–85%, and 82–98%, respectively [26–31]. False negative and false positive

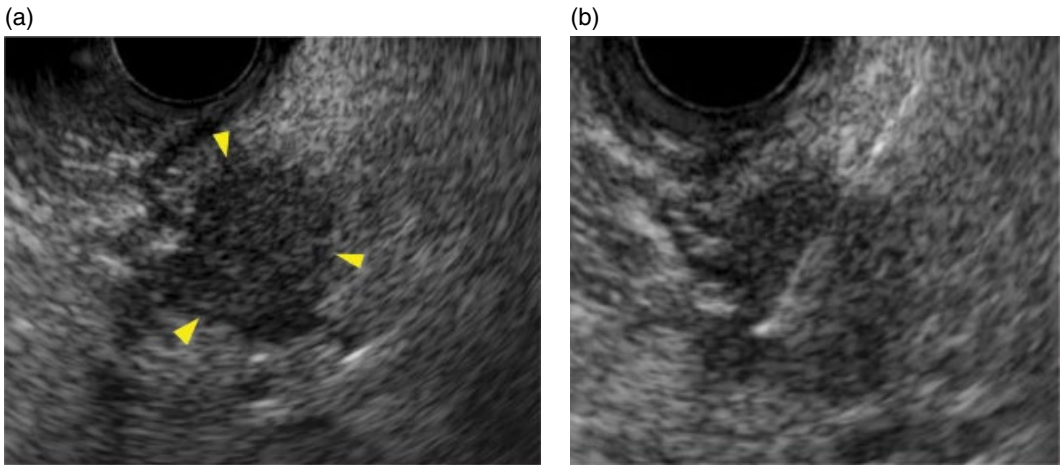

**Figure 96.2** Representative EUS findings of an adenocarcinoma. (a) Convex EUS shows a 12 mm low echoic mass with unclear margin in the uncinate process. (b) EUS-FNA proceeded using a 22G FNA needle.

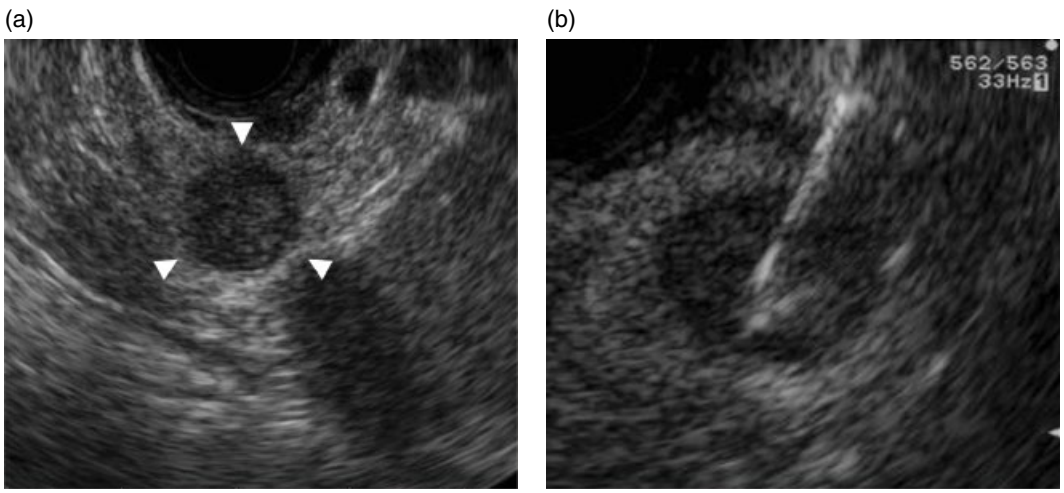

**Figure 96.3** Representative EUS findings of a neuroendocrine tumor. (a) EUS shows 6 mm low echoic mass with clear margin in the tail. (b) EUS-FNA proceeded using a 22G FNA needle.

rates are 12–14% and 0–5% [27,32–34], respectively. Although invasive, EUS is generally safe, as the range of total complication rates of EUS-FNA in a published series was 0–13% [35,36].

Complication rates determined in a multicenter study in the United States and a more recent prospective study were 0.28% [37] and 0.85% [35], respectively. The occurrence of complications was not definitively associated with the type and size of pancreatic lesions, number of passes, or history of chronic pancreatitis. The most frequent complications are bleeding (1–4%), pancreatitis (1–2%), and perforation (0.03%) [38]. Peritoneal tumor seeding is a rare complication that occurs less frequently after EUS-FNA than percutaneous biopsy [39]. Tumor seeding is a late complication that might be induced by EUS-FNA, and several case reports have indicated gastric and/or peritoneal dissemination in patients with cancer at the pancreatic body and tail [40–42]. However, several retrospective studies have not found definitive evidence that EUS-FNA increases levels of dissemination or worsens survival [43–45]. For example, Ngamruengphong et al. [43] analyzed data from 498 (24%) of 2,034 patients with surgically resected pancreatic cancer listed in the US Surveillance Epidemiology and End Results (SEER) medical database who underwent EUS-FNA between 1998 and 2009. The results revealed a marginally improved prognosis for the patients who underwent EUS-FNA compared with those who did not, even when the data were adjusted for the tumor site.

## Factors Affecting EUS-FNA Procedures

Most studies have shown that having a rapid on-site evaluation (ROSE) by a cytopathologist is beneficial, although this may be difficult in smaller hospitals [1,46]. The yield, accuracy, and complication rates do not differ among needle sizes including 19G, 22G, and 25G [1,46]. However, the 25G needle remains popular due to its flexibility in accessing the head of the pancreas and uncinate lesions [47]. Core biopsy needles do not appear to confer an advantage over 22G or 25G FNA needles except for reducing the number of passes required for an adequate sampling [1,46]. Furthermore, the use of stylets, suction, and various sampling techniques have not consistently increased the yield of FNA [1,46].

# Radiologic Diagnosis of Pancreatic Cancer: CT, MRI

*Siva P. Raman and Elliot K. Fishman*

*Department of Radiology, Johns Hopkins University, Baltimore, MD, USA*

## Introduction

Despite the large variety of advances in the surgical and oncologic treatment of pancreatic cancer over the course of the last decade, pancreatic adenocarcinoma still carries an extraordinarily poor prognosis with a high mortality, representing the fourth leading cause of cancer-related mortality in the United States. Fewer than 20% of patients are considered to be candidates for curative resection at the time of presentation, and unfortunately, even in patients considered to be candidates for curative resection, the overall survival rate is less than 15% [1,2]. Despite these poor numbers, it is worth remembering that imaging plays an extraordinarily important role in the evaluation of patients with pancreatic cancer, particularly when surgical resection is still considered a potential option. Not only does modern imaging (particularly CT and MRI) play an important role in identifying these aggressive malignancies in their earliest stages (when they are still potentially resectable), these imaging modalities also play a critical role in terms of properly staging these tumors and providing the information necessary to determine whether a patient is truly capable of undergoing an R0 surgical resection (i.e., complete surgical resection with negative tumor margins) [1,2].

This chapter will detail the two most important imaging modalities in the preoperative evaluation of pancreatic cancer, namely multidetector computed tomography (MDCT) and magnetic resonance imaging (MRI). MDCT is currently the most important modality for the evaluation of pancreatic cancer, playing a vital role in the initial identification of tumors and subsequently, allowing optimal staging of a tumor's local extension (including vascular involvement) and identifying the presence/absence of distant metastatic disease. MRI, alternatively, may allow the identification of tumors in difficult cases where tumors may be small or isodense to the pancreatic parenchyma on CT (and thus not adequately visualized), and can also be helpful in terms of staging distant metastatic disease in equivocal cases, particularly when evaluating indeterminate liver lesions [3]. This chapter will discuss standard protocol options for both MDCT and MRI, the typical imaging findings of pancreatic cancer on each of these two modalities, and the strengths and weaknesses of each of these modalities both in terms of lesion identification and tumor staging.

## Multidetector Computed Tomography

### Technique

The MDCT evaluation of the pancreas and biliary system makes the administration of intravenous (IV) contrast absolutely critical, as noncontrast images make adequate visualization of small tumors nearly impossible (with the vast majority of small pancreatic cancers appearing invisible on noncontrast imaging). Typically, roughly 100–120 cc of intravenous contrast media are administered through a peripheral IV, and a small amount of water (roughly 500–750 cc) is ingested by the patient immediately prior to the scan in order to distend the stomach and duodenum and allow the radiologist to distinguish duodenal or gastric pathology from a true pancreatic mass. Most standard pancreaticobiliary CT protocols employ a dual-phase technique, with the acquisition of both arterial and venous phase images. Arterial phase images are typically acquired at roughly 30 to 40 seconds, often using bolus tracking software, while venous phase images are typically acquired between 60 to 70 seconds, typically using a fixed delay.

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

Noncontrast and delayed images have little utility in the evaluation of pancreatic cancer and are usually not acquired as a part of these protocols [1,2].

Images on the most recent generation of CT scanners can be acquired with extremely thin collimation (0.625–0.75 mm), and these thin collimation images can subsequently be reconstructed into thicker axial images (3–5 mm) for standard radiology review, and facilitate the reconstruction of high-quality coronal and sagittal reformations directly at the CT scanner. In addition, the evaluation of pancreatic cancer is one instance where 3D reconstructions can be very helpful, particularly when evaluating vascular involvement by tumor. Thin collimation images are typically sent to an independent workstation where the radiologist can use advanced 3D visualization software to create 3D images in real time. The two most important 3D reconstruction algorithms being used widely today in clinical practice include maximum intensity projection imaging (MIP), a 3D technique that entails the acquisition of the highest attenuation voxels in a data set and their projection into a 3D image (a very important technique when seeking to evaluate a tumor's involvement of the adjacent vasculature), and volume-rendered imaging (VR), a complex computational algorithm that assigns a specific color and transparency to each voxel in a data set. Which of these two techniques is most useful will depend on the individual radiologist's preferences, the specific tumor being imaged, and the imaging feature being evaluated [1,2,4–6].

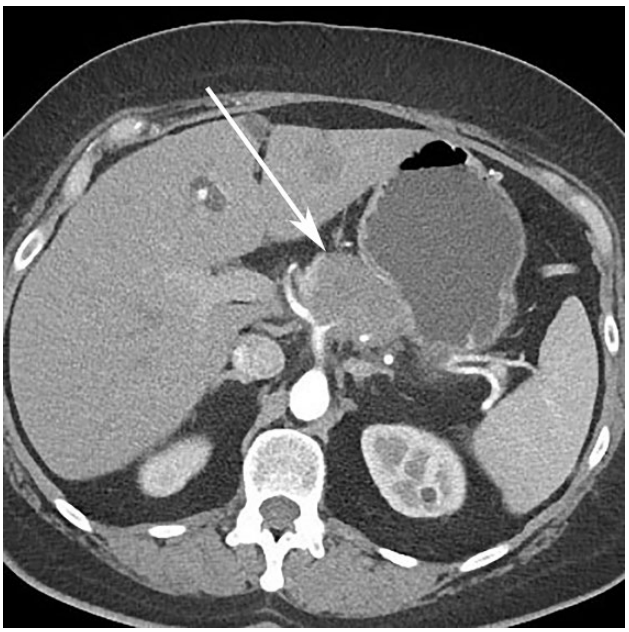

**Figure 97.1** Axial contrast enhanced CT image demonstrates a hypodense mass centered in the pancreatic body (arrow), with infiltrative, poorly defined margins, classic for pancreatic adenocarcinoma. Note that the tumor involves the celiac artery, hepatic artery, and splenic artery, and abuts the adjacent stomach.

## Diagnosis

Pancreatic adenocarcinoma appears as an infiltrative, hypodense, poorly marginated mass with frequent extension posteriorly into the retroperitoneum to involve critical vascular structures (Figs 97.1, 97.2, 97.3, and 97.4) [7–10]. The literature has shown that MDCT is an excellent modality for the identification of pancreatic cancer, with sensitivity rates well over 95%, and it is very likely that this underestimates the true sensitivity of CT, particularly given the rapid improvements in both temporal and spatial resolution seen with the most recent generation of CT scanners over the last several years. Much of the data we have regarding the efficacy of MDCT for pancreatic cancer is based on early generation scanners in the early multidetector era, and it is undoubtedly true that modern CT scanners have many additional features and improvements that have added to the efficacy of the imaging modality. In most cases, pancreatic cancer is most apparent in the venous phase, with the hypodense tumor nicely juxtaposed against the enhancing pancreatic parenchyma, although there are some cases where the tumor may be slightly more conspicuous on the arterial phase (as compared to the

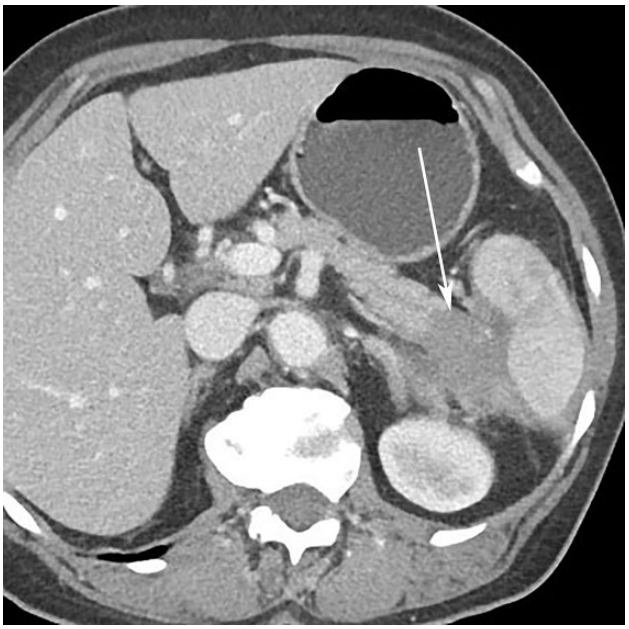

**Figure 97.2** Axial contrast enhanced CT image demonstrates a poorly defined hypodense mass (arrow) centered in the pancreatic tail, compatible with pancreatic adenocarcinoma. The tumor in this case is markedly infiltrative, involving not only the adjacent spleen but also extending to involve the adjacent left adrenal gland.

**Figure 97.3** Axial contrast enhanced CT demonstrates a subtle hypodense mass (arrow) in the uncinate process, a location in which pancreatic tumors are commonly missed on CT.

**Figure 97.4** Axial contrast enhanced CT demonstrates a large hypodense infiltrative mass (arrow) involving nearly the entirety of the pancreas, found at resection to represent pancreatic adenocarcinoma.

venous phase). Accordingly, the acquisition of images using a dual-phase technique does improve sensitivity, particularly when seeking to identify subtle or small tumors [11–13]. Nevertheless, it is worth remembering that there are small subcentimeter tumors (probably

**Figure 97.5** Axial contrast enhanced CT demonstrates a very subtle hypodense mass (arrow) in the pancreatic body segment, representing pancreatic adenocarcinoma. Noticeable is severe atrophy with a dilated pancreatic duct in the upstream pancreas, features that are highly suggestive of an underlying malignancy. The presence of a dilated pancreatic duct with pancreatic atrophy, even in the absence of a discretely visualized mass, should raise strong concern for an occult tumor.

representing less than 5% of all lesions) that are isodense to the pancreatic parenchyma on all phases of imaging, and can thus be very difficult to identify in the absence of secondary signs of malignancy [14].

Even if the primary tumor is not clearly visualized, secondary signs of malignancy can be extraordinarily helpful in terms of identifying subtle or small lesions. In particular, the most important secondary signs of malignancy include focal or upstream pancreatic atrophy, pancreatic ductal dilatation/obstruction with abrupt cut-off of the pancreatic duct, biliary ductal obstruction (especially with pancreatic head malignancies), and an abnormal contour of the pancreas [15,16]. In our own experience, many of the missed cases of pancreatic cancer that we have seen in our practice (or referred into our practice from outside institutions) have been due to one or more of these secondary signs of malignancy being ignored or disregarded. Of these secondary signs, by far the most important is the presence of a dilated pancreatic duct: A dilated pancreatic duct with abrupt cut-off should always be considered suspicious for an occult obstructing mass/tumor, even if the primary lesion is not clearly visible on CT, and should prompt further evaluation with another modality, usually endoscopic ultrasound (Figs 97.5 and 97.6) [17].

**Figure 97.6** Axial contrast enhanced CT demonstrates a hypodense pancreatic mass in the body (arrow) resulting in severe upstream pancreatic atrophy and abrupt obstruction of a dilated pancreatic duct.

**Figure 97.7** Sagittal contrast enhanced CT demonstrates a hypodense pancreatic mass, representing a pancreatic adenocarcinoma, resulting in 360° encasement of the superior mesenteric artery, a feature that makes this patient's tumor unresectable.

## Staging

CT currently represents the best modality for the local staging of pancreatic adenocarcinoma, including a tumor's involvement of adjacent retroperitoneal vascular structures and other organs. In particular, a tumor's involvement of several critical retroperitoneal vascular structures plays a crucial role in terms of determining whether a patient is capable of undergoing an R0 surgical resection. The five vessels that are most important in determining a patient's resectability include three major arteries (i.e., celiac artery, superior mesenteric artery, and hepatic artery), and two major veins (portal vein, superior mesenteric vein, and portal/SMV confluence). It should be noted that only these five major vessels are important in terms of dictating a patient's resectability, while smaller vascular structures (such as the gastroduodenal artery or inferior mesenteric vein) do not have the same presurgical significance.

When evaluating the central mesenteric arterial vasculature using CT, tumoral involvement is typically stratified using a quantitative system, with tumoral involvement delineated as either involving <180° or >180° of the vessel circumference. The ability of CT to distinguish such subtle degrees of vascular involvement by tumor has become increasingly critical, as the line between "resectable" and "unresectable" tumors has increasingly become blurred. At one time, tumors that demonstrated *any* significant involvement of the celiac, SMA, or hepatic artery were considered "unresectable," while a tumor was considered "resectable" only if it did not involve any of these major mesenteric arteries. Increasingly, however, it is possible to have some mild degree of arterial involvement and be considered "borderline resectable," and still undergo surgical resection following preoperative neoadjuvant chemoradiation [18]. However, placing the patient into this "borderline resectable" category requires very careful evaluation of tumoral involvement of the vessel, and making quite subtle distinctions between <180° and >180° involvement of the vessel, although these distinctions have become slightly easier given improvements in image quality on the latest generation of scanners (Figs 97.7, 97.8, 97.9, and 97.10).

Involvement of the central mesenteric venous vasculature has recently become less of a hindrance for complete surgical resection because of the increasing utilization of modern vascular surgical reconstruction techniques (such as interposition grafts or other vein reconstruction procedures). Accordingly, a strict numerical descriptor of tumoral involvement of the portal vein or SMV is less important than providing the surgeon with enough information to determine whether a surgical reconstruction of the vein is feasible (when involved by tumor). In other words, the radiologist's report should provide information regarding the length and degree of venous involvement and whether there is sufficient normal portal vein above or normal SMV below the tumor to allow an interposition graft to be placed (Fig. 97.11).

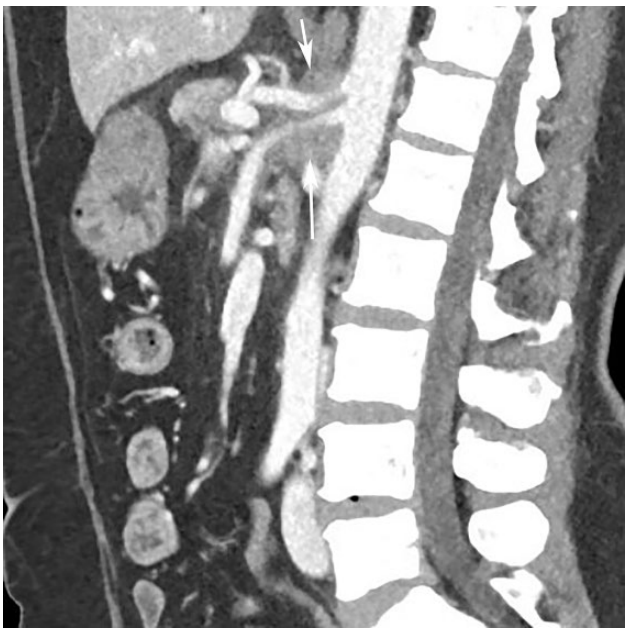

**Figure 97.8** Sagittal contrast enhanced CT demonstrates a poorly marginated hypodense pancreatic mass (arrows) resulting in 360° encasement of both the celiac artery and the superior mesenteric artery at their origins from the aorta.

**Figure 97.10** Coronal contrast enhanced CT demonstrates a hypodense infiltrative pancreatic mass (arrows) resulting in 360° encasement of the distal celiac artery and the hepatic artery.

**Figure 97.9** Axial contrast enhanced CT demonstrates an infiltrative hypodense mass (arrow) arising from the pancreatic uncinate process resulting in 360° encasement of the celiac artery.

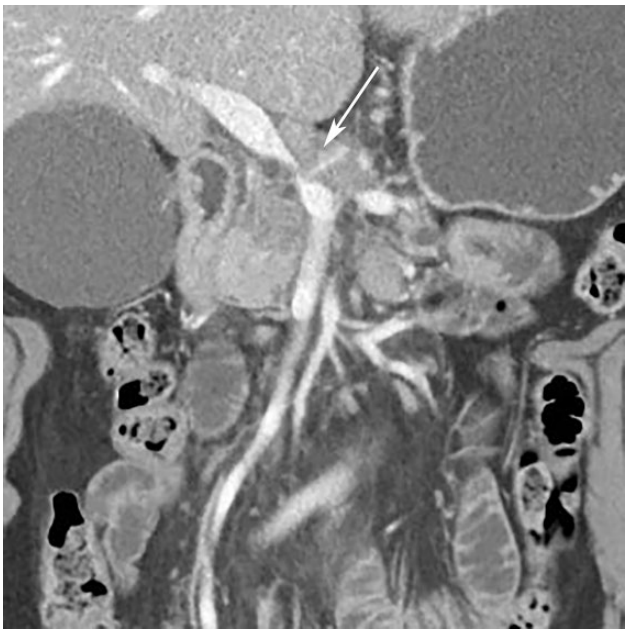

**Figure 97.11** Coronal contrast enhanced CT imaging the venous phase demonstrates a hypodense pancreatic adenocarcinoma (arrow) resulting in narrowing of the distal main portal vein near the portal/SMV confluence.

## Metastatic Disease

The most common sites of distant metastatic disease in patients with pancreatic cancer include locoregional lymph nodes, liver, and peritoneum, with metastatic disease to the lungs and bone relatively less common. As with many other malignancies in the abdomen/pelvis, the assessment of peripancreatic and retroperitoneal lymphadenopathy using CT is relatively limited, particularly given that CT

relies only on size criteria when delineating a node as "normal" or "suspicious." As one can imagine, normal size nodes can often harbor metastatic disease, while alternatively, enlarged nodes may be reactive and be histologically normal on surgical resection [19,20]. Accordingly, several studies looking at the sensitivity and specificity of CT for metastatic lymphadenopathy have shown that CT is relatively limited, with accuracy rates under 60% [1,2,21]. Fortunately, the accuracy of MDCT for metastatic lymphadenopathy is not of significant consequence, as locoregional lymph node metastases do not typically preclude a patient from undergoing surgical resection.

However, distant metastatic disease is critical in determining the patient's resectability, as the presence of distant metastases (most often to the liver or peritoneum) preclude surgical resection, making radiation or chemotherapy the only palliative options. The liver is, by far, the most common site of distant metastatic disease in patients with pancreatic cancer, and in virtually all cases, is the first site of distant metastatic disease (prior to the development of peritoneal, lung, or osseous metastatic disease). While the arterial phase of imaging may have some utility in the identification of liver metastases (demonstrating peripheral hyperenhancement around a lesion or perfusion abnormalities near a metastasis), the venous phase images are absolutely the most critical for the identification of liver lesions (Fig. 97.12). The overall sensitivity of CT for liver metastases is relatively good for lesions that measure over 1 cm, with sensitivity rates ranging above 75%. However, regardless of the type of primary tumor, the sensitivity of CT for smaller lesions (particularly lesions measuring under 1 cm in size) is relatively limited, probably with sensitivity rates under 50% [22]. In particular, part of the problem when assessing small liver lesions is accurately differentiating small benign lesions (such as cysts or hemangiomas) from truly malignant lesions, as standard imaging criteria can be very difficult to utilize for tiny too small to characterize liver foci. Nevertheless, the vast majority of these tiny nonspecific liver lesions (in the absence of clear morphologic features of malignancy) are benign, and MRI may be an additional helpful tool if it is absolutely necessary to further characterize these small lesions [23,24].

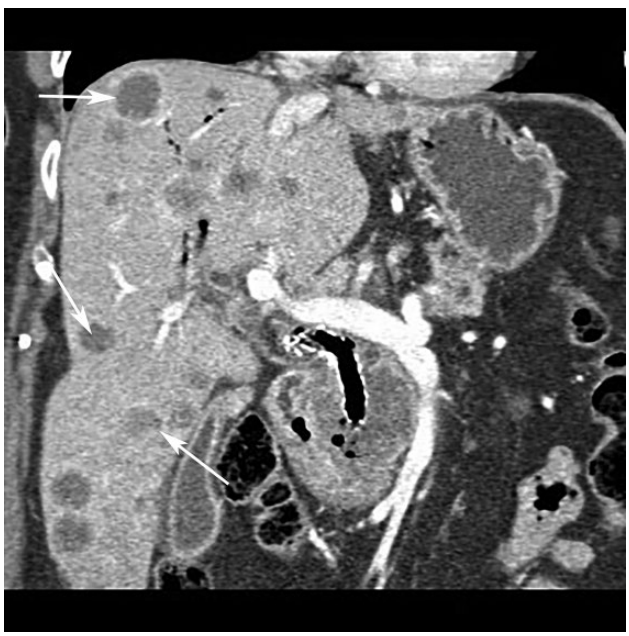

**Figure 97.12** Coronal contrast enhanced CT imaging a patient with a pancreatic head adenocarcinoma demonstrates multiple hypodense lesions (arrows) in the liver, some of which demonstrate peripheral enhancement, compatible with extensive metastatic disease to the liver.

The second most common site of distant metastatic disease in patients with pancreatic cancer is peritoneal carcinomatosis, and regardless of the primary tumor, CT is well known to struggle in the identification of early peritoneal metastatic disease. The overall sensitivity of CT for peritoneal disease is well under 50%, and the imaging appearance can be quite subtle in the earliest stages. The imaging appearance of peritoneal metastases can range from a subtle micronodular pattern (with tiny nodular foci in the omentum and adjacent stranding/induration) to the development of frank confluent omental soft tissue with an "omental caking" pattern. In most cases, peritoneal carcinomatosis is accompanied by the presence of ascites, so the presence of free fluid in a patient with pancreatic cancer should prompt a very careful, thorough search of the omentum and peritoneal cavity for tumor implants (Figs 97.13 and 97.14) [25].

## Magnetic Resonance Imaging

### Technique

While CT protocols for pancreatic imaging are relatively standardized across institutions (with some exceptions), there is a considerable variability in the types of MRI protocols utilized in different departments, in addition to a considerable amount of variation in the types of scanners being utilized at different institutions. Our own protocol for pancreatic imaging includes axial T2 FSE images with chemical fat saturation, coronal HASTE T2-weighted images, coronal T2 FIESTA images, magnetic resonance cholangiopancreatography (MRCP) images (both thick slab HASTE images and 3D volumetric T2 images), diffusion-weighted images (with ADC map), gradient echo sequences with in and out of phase imaging, as well as pre- and post-gadolinium T1-weighted images (with arterial, venous, and delayed phase acquisitions). One of the advantages of MR is that individual protocols can be tailored to the exact indication for the study and additional sequences can be added as necessary.

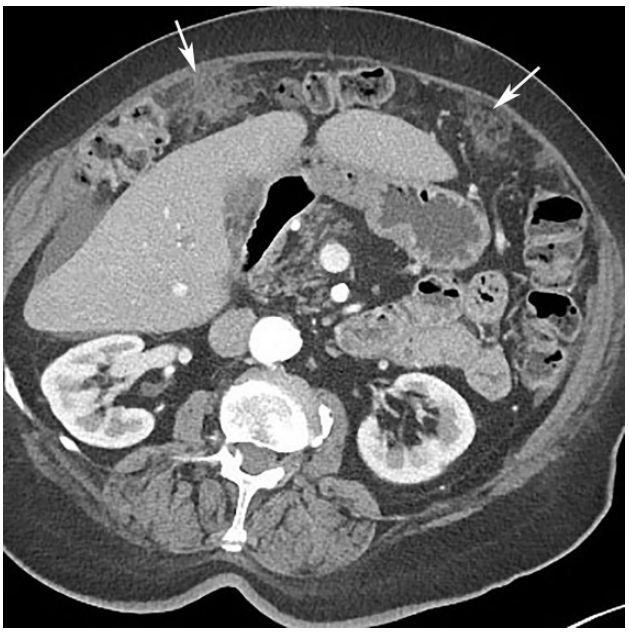

**Figure 97.13** Axial contrast enhanced CT imaging of a patient with known peritoneal carcinomatosis demonstrates a small amount of ascites, as well as ill-defined soft tissue and nodularity in the omentum (arrows), compatible with peritoneal carcinomatosis.

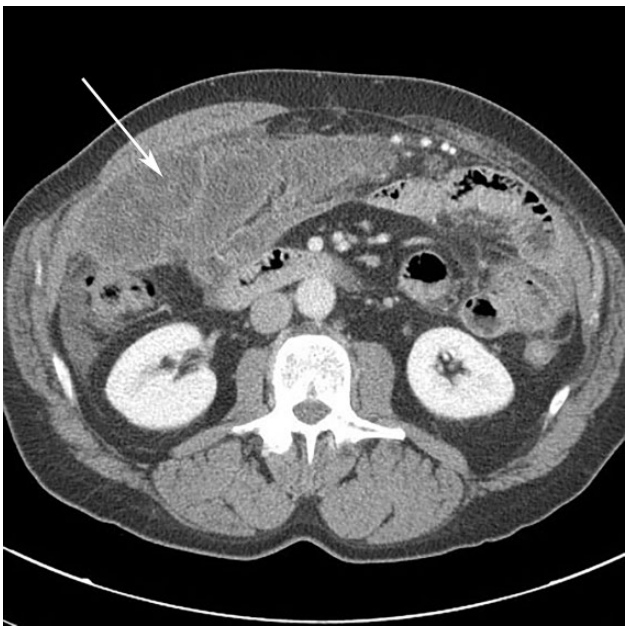

**Figure 97.14** Axial contrast enhanced CT demonstrates extensive hypodense soft tissue throughout the omentum, compatible with peritoneal carcinomatosis and "omental caking" in this patient with underlying pancreatic cancer.

## Lesion Identification

In most of the other organs of the abdomen, T2-weighted images are of critical importance, and often pathology will appear conspicuous as a result of its T2 hyperintensity. However, the pancreas is somewhat unique, given that its intrinsic T2 signal intensity can be quite variable depending on the age of the patient and the degree of fatty infiltration, and accordingly, pancreatic adenocarcinoma is often relatively inconspicuous on standard T2-weighted images. Alternatively, the pancreatic parenchyma contains a large amount of acinar protein, and in the absence of underlying chronic pancreatitis (which can reduce the T1 intensity of the pancreatic parenchyma), the pancreas is typically relatively T1 bright (roughly equal in signal intensity to the liver parenchyma). As a result, pancreatic cancers, which are usually relatively T1 hypointense and fibrotic, are often conspicuous when juxtaposed against the intrinsically T1 bright pancreatic parenchyma. T1-weighted images can, therefore, be relatively useful for lesion identification in patients who cannot receive gadolinium as a result of renal dysfunction or allergy. The pancreas upstream from the mass often appears atrophic and abnormally T1 hypointense as a result of fibrosis, and the upstream dilated/obstructed pancreatic duct is often nicely accentuated on T2-weighted images (Figs 97.15, 97.16, 97.17 and 97.18) [3,26,27].

Pancreatic adenocarcinoma on post-gadolinium images typically demonstrates an imaging appearance comparable to CT, appearing hypodense, infiltrative, and poorly marginated. While not reliably seen in all cases,

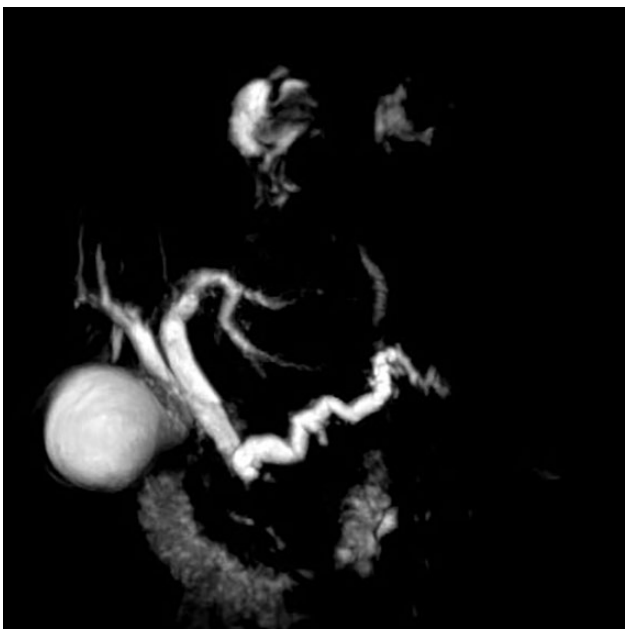

**Figure 97.15** Coronal MRCP images with maximum intensity projection reconstruction demonstrates a classic double duct sign of pancreatic adenocarcinoma, with marked dilatation of both the biliary tree and the pancreatic duct to the level of the pancreatic head, at the site of the patient's known pancreatic adenocarcinoma

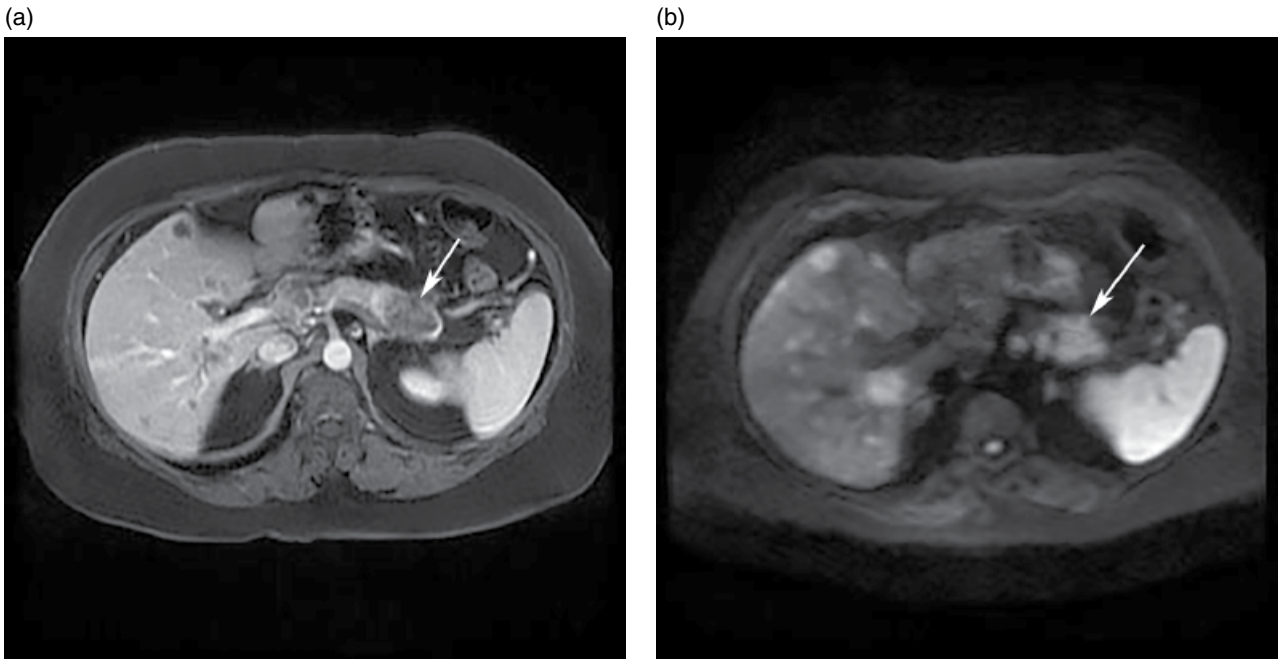

**Figure 97.16** Axial post-gadolinium T1-weighted image (a) and axial DWI (b) demonstrate a mass in the pancreatic tail (arrows), which demonstrates hypoenhancement on the post-gadolinium image and demonstrates restricted diffusion (i.e., bright on the DWI image). Notice the multiple metastases in the liver, which also demonstrate hypoenhancement and restricted diffusion.

many of these tumors do demonstrate restricted diffusion, offering another means of identifying subtle or small tumors that may be relatively inconspicuous on standard imaging sequences [3,26,28–32].

In most cases, MRI is not utilized for the initial screening or diagnosis of these tumors (although many sources suggest that it can be quite accurate when asked to do so), but rather as a troubleshooting tool to be used when a tumor is not adequately visualized on MDCT. In particular, MRI can be quite valuable in those cases where a primary tumor is strongly suspected on the basis of secondary signs (such as a dilated duct), but where the tumor is not seen on MDCT because it is too small or isodense to the pancreatic parenchyma.

## Tumor Staging

There is little doubt that MRI is generally inferior to multidetector CT in the local staging of pancreatic adenocarcinoma, and in particular, in evaluating a tumor's involvement of the critical retroperitoneal mesenteric vasculature. In general, CT is better for evaluating involvement of the mesenteric arteries and veins because of its superior temporal resolution, as CT images are much less likely than MRI to be plagued by motion artifacts or other technical artifacts that might make subtle determinations of vascular involvement difficult. Some authors have recently argued that technical advancements in MRI protocols and scanners may have made this gap less than was previously thought, but our own experience still argues for the superiority of CT in terms of staging vascular involvement [33,34].

MRI suffers from many of the same problems as CT in terms of evaluating locoregional lymph nodes, as MRI also largely relies on size criteria for the differentiation of benign from malignant lymph nodes. In some cases, as with CT, a lymph node can be delineated as abnormal based on morphologic characteristics (such as abnormal shape or central necrosis), but this is relatively comparable to CT. Unfortunately, while diffusion-weighted imaging was originally thought to hold some promise in terms of differentiating benign from malignant lesions, it is now clear that there is a significant overlap in the ADC values of benign and malignant lesions (including normal and abnormal lymph nodes), and the presence or absence of restricted diffusion within a lymph node is of little value in terms of making an absolute judgment as to whether or not a lymph node is infiltrated by tumor.

However, one area where MRI does have some clear advantages over CT is in the evaluation of indeterminate liver lesions. In particular, while CT struggles in terms of definitively characterizing lesions under 1 cm, this is an area where MRI may be a helpful troubleshooting tool, as multiple MRI pulse sequences can be used in conjunction together to make a more specific diagnosis, even in those cases where a lesion is under 1 cm, such as tiny cysts (which demonstrate a fluid signal on T2-weighted images) or small hemangiomas (which also demonstrate

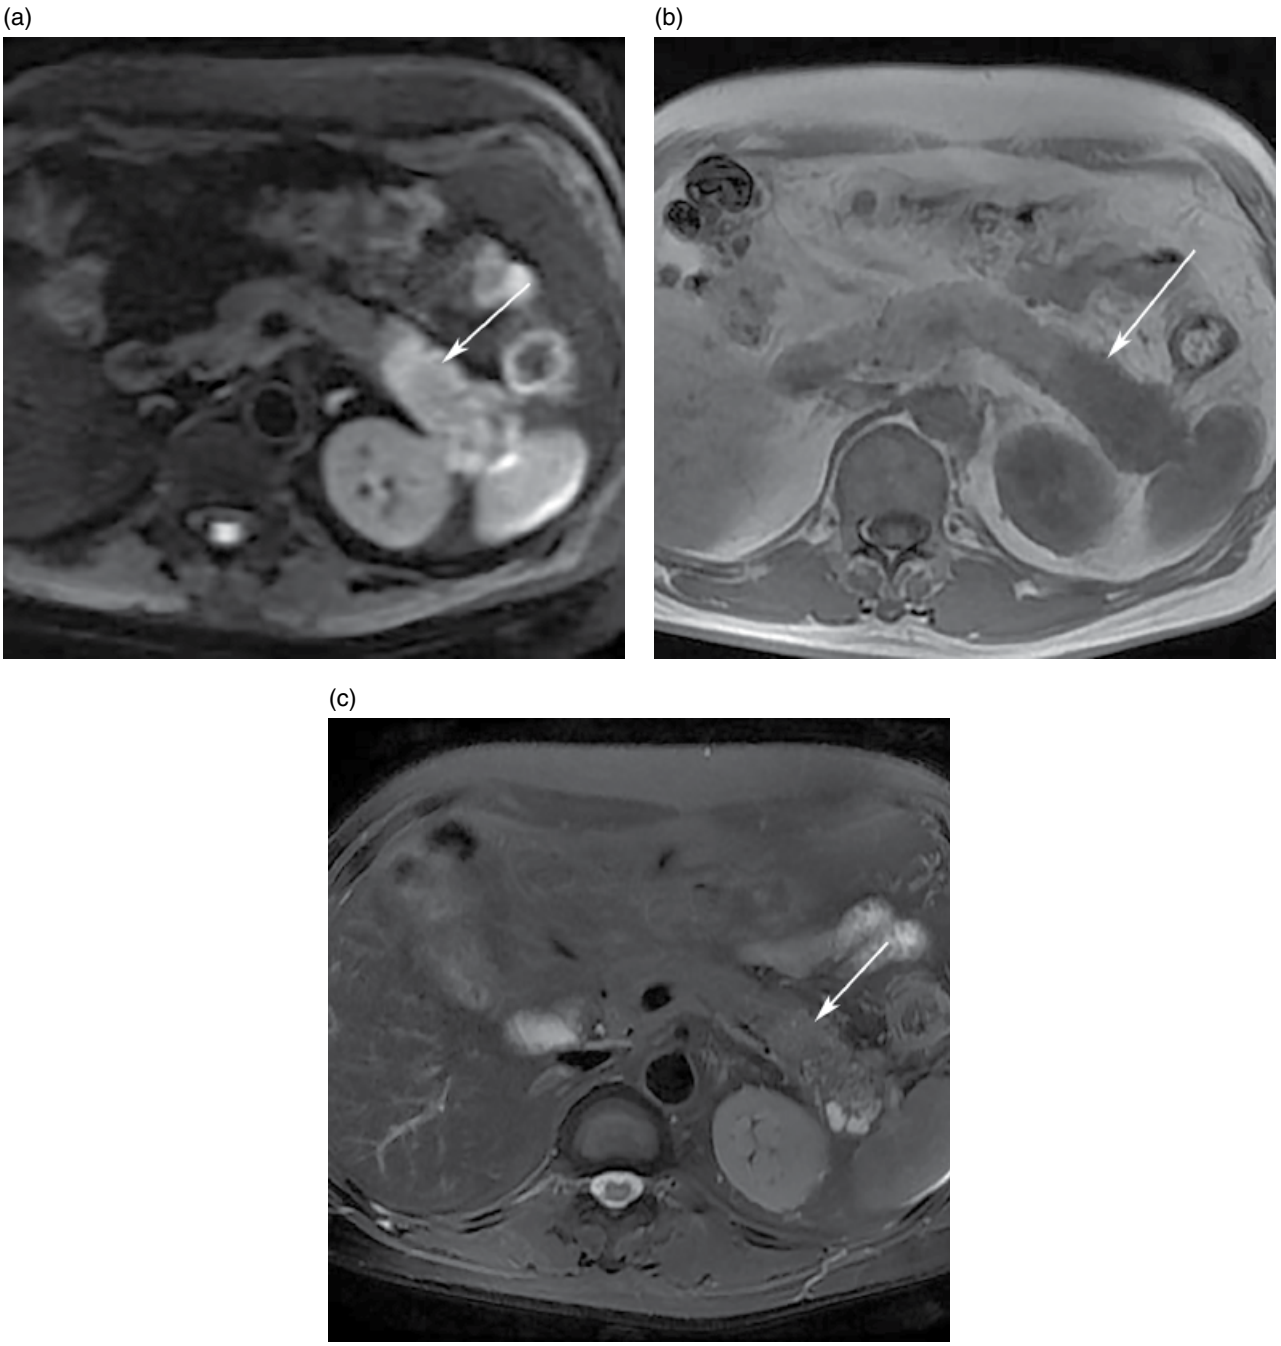

**Figure 97.17** Axial DWI (a), axial T1 without gadolinium (b), and axial T2 FSE with fat saturation (c) demonstrate a pancreatic adenocarcinoma (arrow) in the tail. Notice how the mass is relatively conspicuous on the pre-gadolinium T1-weighted images, juxtaposed against the T1 bright pancreatic parenchyma, and is also quite conspicuous on the DWI images as a result of restricted diffusion. However, as with many pancreatic adenocarcinomas, the mass is relatively inconspicuous on the T2-weighted images.

marked T2 hyperintensity). While not every patient with pancreatic adenocarcinoma requires evaluation of the liver with MRI, MRI may be a helpful tool in those few patients where an indeterminate liver lesion on CT may make a critical difference in terms of whether a patient is, or is not, a surgical candidate.

## Conclusion

There is little doubt that MDCT is currently the most important imaging modality for the identification of tumors, local tumor staging (including a tumor's involvement of adjacent retroperitoneal vasculature and

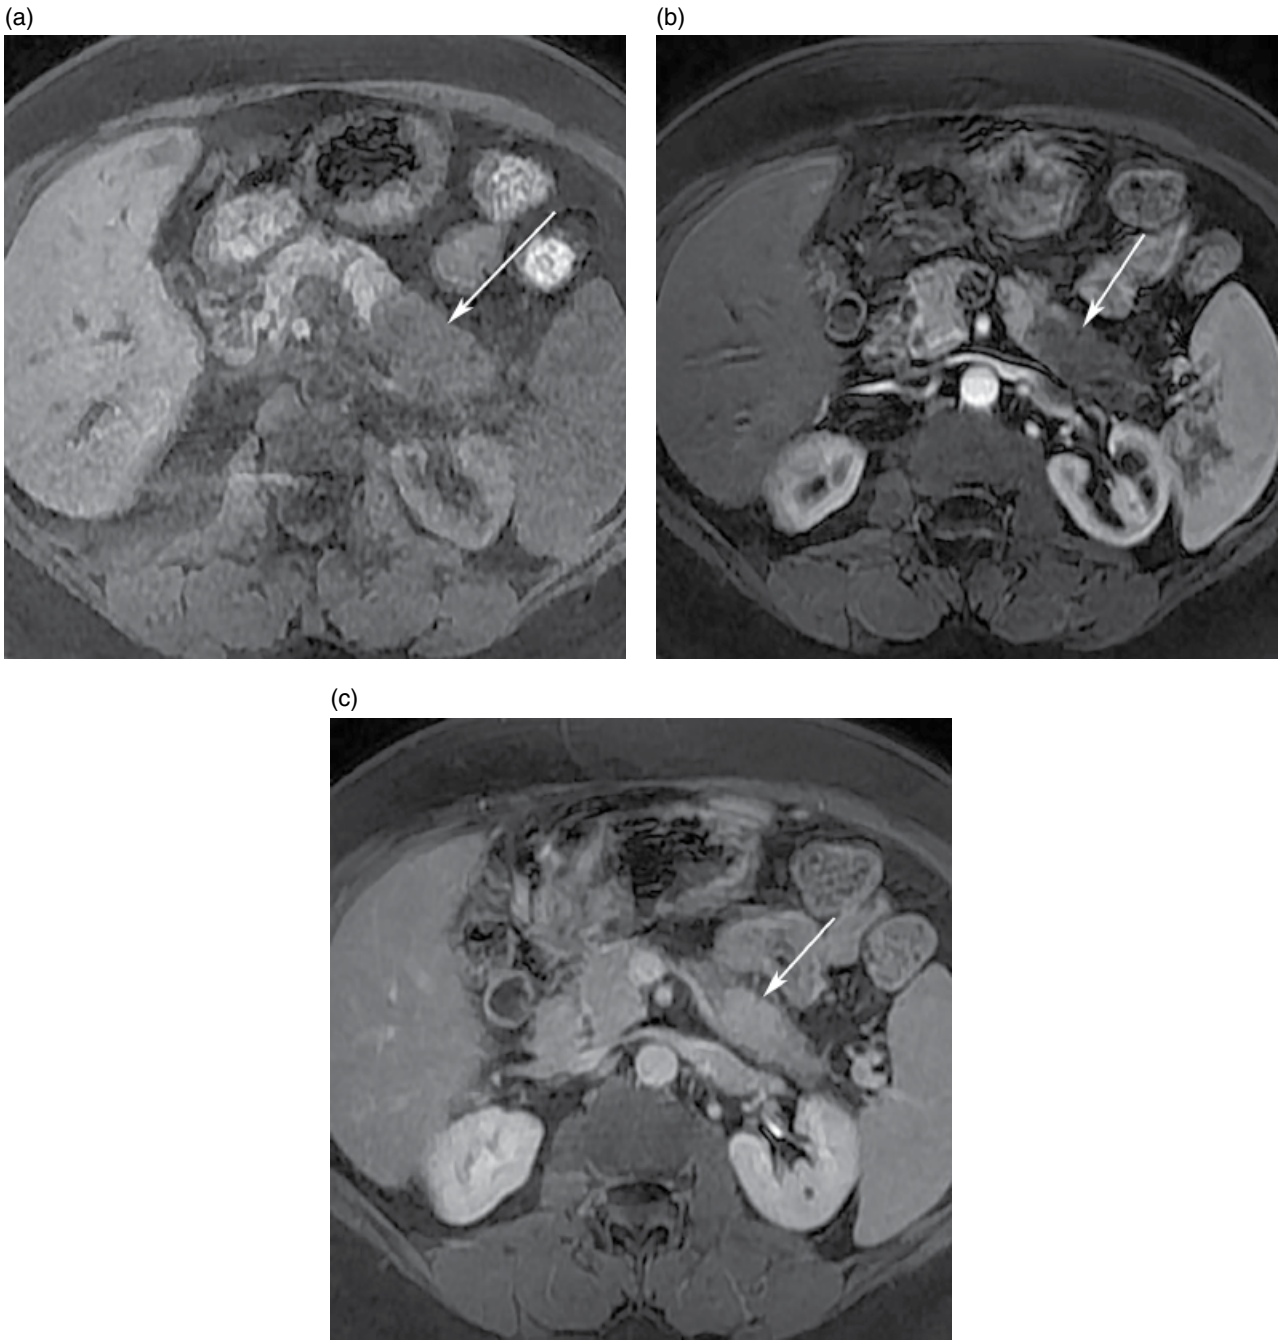

**Figure 97.18** Axial T1 without gadolinium (a), axial T1 post-gadolinium in the arterial phase (b), and axial T1 post-gadolinium in the delayed phase (c) demonstrate a hypodense mass (arrows) in the pancreatic tail, conspicuous on both the pre- and post-gadolinium images. The mass does demonstrate evidence of delayed enhancement, a relatively common feature with these tumors.

other organs), and the identification of distant metastatic disease (most commonly the liver and peritoneum). Every generation of CT scanners has brought additional improvements in terms of both temporal and spatial resolution, and it is likely that every new generation of CT scanners will allow us to better identify and stage these aggressive tumors [35]. While no one would argue that MRI should be a first-line modality in the identification and staging of pancreatic cancer, MRI does have a great deal of utility in terms of identifying lesions that may be occult or subtle on CT, and moreover, as a troubleshooting tool that might help provide more definitive answers when confronted with an indeterminate liver lesion on CT.

# Screening of Patients with Hereditary Pancreatic Cancer

## Pancreatic Cancer Risk and Pancreatic Screening

Pancreatic cancer is expected to be the second leading cause of cancer-related deaths in the USA by 2030 [1]. In the USA, the average lifetime risk of developing pancreatic cancer is ~1.4%. Since the long-term benefits of pancreatic screening are not known, screening is only offered to those individuals whose risk of pancreatic cancer is sufficiently high that the potential benefits are estimated to be greater than the potential risks of screening. Experts consider that pancreatic screening may be justified if the lifetime risk of developing pancreatic cancer is at least 5%, which is equivalent to a ~fourfold increased relative risk [2]. Estimating an individual's future cancer risk is an important step in deciding whether an individual should be considered for pancreatic screening.

The main tool used to quantify pancreatic cancer risk is the family history. A detailed cancer family history will determine whether or not individual is a first-degree relative of one or more subjects with pancreatic cancer and at what age pancreatic cancer developed in the family [3,4]. The estimates of pancreatic cancer risk in families have been achieved by following families long term in pancreatic cancer family registries [5]. Familial pancreatic cancer has been defined as kindred having two first-degree relatives with pancreatic cancer [6], although pancreatic cancer often runs in families who do not meet this definition. The risk of developing pancreatic cancer in first-degree relatives increases with the number of affected relatives [7]. This risk has been estimated to be 6.4-fold greater in individuals with two affected first-degree relatives (lifetime risk ~8–10%) and 32-fold greater in individuals with three or more first-degree relatives with pancreatic cancer (lifetime risk ~40%) [7]. Among kindred with familial pancreatic cancer, the risk of pancreatic cancer is higher in those with a young-onset pancreatic cancer (age <50 years, relative risk [RR] = 9.3) in their family compared to those without a young-onset case [4]. The increased risk of developing pancreatic cancer in pancreatic cancer families identified through prospective studies points to inherited factors, although it is suspected that in some families shared environmental factors plays a role in pancreatic cancer susceptibility.

Since the risk of developing hereditary pancreatic cancer is likely to be influenced by the same factors that influence the development of sporadic forms of the disease, in principle, pancreatic cancer risk factors such as smoking, obesity, diabetes, and pancreatitis history could be used to refine estimates of cancer risk [8–10]. However, to date these risk factors do not confer sufficient risk on their own to be useful in clinical practice [11].

Most patients with a family history of pancreatic cancer do not have an identifiable pancreatic cancer susceptibility gene mutation. However, identifying a cancer susceptibility gene mutation in a family can help identify which members of a family are at most risk of developing pancreatic cancer. Many pancreatic cancer susceptibility genes increase cancer risk at other organs and so knowledge of the genetic basis of a family's pancreatic cancer risk can help guide a patient's overall cancer surveillance. Gene testing to look for pancreatic cancer susceptibility genes is best performed on an affected individual with pancreatic cancer from a familial pancreatic cancer kindred. However, germline mutations in the known pancreatic cancer susceptibility genes explain only about 10% of the familial susceptibility to pancreatic cancer so most individuals with a family history of multiple pancreatic cancers who undergo gene testing will not have an identifiable susceptibility gene mutation.

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

The genes known to cause hereditary forms of pancreatic cancer when mutated in the germline include *BRCA2*, *ATM*, *PALB2*, *CDKN2A (p16)*, *STK11*, *PRSS1* [12–16], and the hereditary nonpolyposis colon cancer (Lynch) syndrome [17] susceptibility genes, which are associated with a significantly increased risk of developing pancreatic cancer. In addition, recent genome sequencing of ~600 pancreatic cancer families identified the pancreatitis susceptibility gene, *CPA1*, as a candidate pancreatic cancer susceptibility gene (deleterious mutations were found in 4/598 families) [18]. Among familial pancreatic cancer kindred, *BRCA2* is the gene most likely to have deleterious germline mutations (usually found in ~5–10% of such families [21–23]). Approximately 1% of individuals of Jewish ancestry have a deleterious founder mutation in *BRCA2* [24–26]. Approximately 10% of individuals with pancreatic cancer and Jewish ancestry carry the founder *BRCA2* gene mutation (even in the absence of a family history) [27,28]. Therefore, all such individuals should be considered for genetic counseling and testing [29,30]. The average lifetime risk of developing pancreatic cancer in *BRCA2* gene mutation carriers is estimated to be ~5% [31–34]. In contrast to *BRCA2*, the risk of developing pancreatic cancer among germline *BRCA1* gene mutation carriers is modest (RR 2.3-fold increased risk), which suggests that *BRCA1* mutation carriers generally do not warrant pancreatic screening [35].

Germline *ATM* mutations are the second most common known cause of hereditary pancreatic cancer [12,18]. Individuals with germline *ATM* mutations are at increased risk of developing multiple types of cancer. The protein product of *ATM* functions in DNA repair pathways and undergoes somatic mutation in a variety of cancers [36]. In a large multicenter study of familial pancreatic cancer kindred the prevalence of *ATM* mutations was ~2% [18]. The lifetime risk of pancreatic cancer among *ATM* mutation carriers has not yet been determined. Germline *CDKN2A (p16)* gene mutations cause familial atypical melanoma mole syndrome (FAMMM syndrome) [37,38]. The lifetime risk of developing pancreatic cancer among *CDKN2A* mutation carriers is estimated to be ~20% [39–41]. Germline *PALB2* (partner and localizer of Brca2) mutations are found in <1% of patients with familial forms of pancreatic cancer [42–46]. The risk of developing pancreatic cancer among *PALB2* gene mutation carriers is not known but given the similar functions of *BRCA2* and *PALB2*, the risk may be similar. Kindred of hereditary nonpolyposis colorectal cancer (Lynch syndrome), which arises from germline mutations in mismatch repair genes (*MLH1*, *MSH2*, *MSH6*, *PMS2*) gene mutations, have an estimated lifetime risk of pancreatic cancer of 3.7% [17,47]. The pathologic features of pancreatic cancers with mismatch repair defects can be characteristic [48]. The significance of identifying Lynch syndrome families with cancer is more important than ever, since not only are such mutation carriers targets for cancer prevention strategies, cancers with mismatch repair defects (which also occur in sporadic cancers) are more likely to respond to immunotherapy with checkpoint inhibitors [49].

It is known that long-standing chronic pancreatitis predisposes to the development of pancreatic cancer [9,10,15,50–52]. This is best illustrated by the ~40% average pancreatic cancer risk associated with hereditary recurrent acute pancreatitis [15], a risk that is even higher for smokers with hereditary pancreatitis [15]. The gene most commonly implicated in hereditary chronic pancreatitis is *PRSS1* [53], and affected individuals typically develop pancreatitis in their teens and have many decades of pancreatitis that often results in pancreatic insufficiency [54]. Pathologically, the pancreas of *PRSS1* mutation carriers undergoes progressive lipomatous atrophy with increasing age [55]. While other genes such as *CPA1* that have been identified as pancreatitis susceptibility genes are now suspected to be causes of hereditary pancreatic cancer [18], this has not been shown to be true for carriers of the pancreatitis modifier genes, *SPINK1* and *CFTR* [56] that increase the likelihood of developing pancreatitis [18]. Patients with long-standing chronic pancreatitis from hereditary causes likely benefit from pancreatic screening but the detection of pancreatic neoplasia in such individuals is often more challenging because of the effects of pancreatitis [57].

Patients with Peutz–Jeghers syndrome (PJS) (who generally carry germline *STK11* gene mutations) have a very high risk of developing pancreatic cancer (cumulative lifetime risk 11–36%) [58,59].

Other low-penetrance genetic variants associated with pancreatic cancer susceptibility have been identified through genome-wide association studies (GWAS) [60–62]. Thus, carriers of non-O blood groups have an approximately 1.4-fold elevated risk of developing pancreatic cancer relative to O-blood group carriers [64–66]. GWAS have also identified variants *PDX1*, *TERT*, and other loci as being associated with pancreatic cancer risk [60–64].

Many patients with germline susceptibility genes that predispose to pancreatic cancer do not present with evidence of familial cancer syndromes. Instead, incomplete or low penetrance is common [16,18–20]. For example, most patients with familial pancreatic cancer who carry germline *BRCA2* mutations do not have extensive histories of breast or ovarian cancer [30]. Indeed, germline mutations in pancreatic cancer susceptibility genes are not infrequently detected in patients with apparently sporadic pancreatic cancer [19,20,67].

## At What Age Should Pancreatic Screening Begin and End?

Although the lifetime risk of developing pancreatic cancer for many individuals undergoing pancreatic screening is 5–10%, the age-specific incidence of pancreatic cancer is much lower than the lifetime risk. Pancreatic screening protocols attempt to screen individuals over the period starting a few years before their peak incidence of pancreatic cancer (age 55–80) [2]. The average age of individuals at diagnosis for those with familial/inherited forms of pancreatic cancer is 68 [4], similar to sporadic pancreatic cancer although pancreatic cancer is thought to emerge at a younger age among hereditary pancreatitis gene mutation carriers [15]. For this reason, most screening programs recommend pancreatic screening at age 55, although many screening programs initially start screening patients from age 50 or earlier [68,69]. The Cancer of the Pancreas Screening program at Hopkins and collaborating centers initiates pancreatic screening at age 55 for individuals who are first-degree relatives of at least one person with pancreatic cancer and another first- or second-degree relative (clinicaltrials.gov NCT02000089). One reason for beginning pancreatic cancer screening a decade or more before the average age of pancreatic cancer diagnosis was to provide an opportunity to identify and manage the precancerous lesions in affected individuals [69]. For those individuals who are known pancreatic cancer susceptibility gene mutation carriers, the screening recommendations are tailored depending on the gene mutation. For germline *CDKN2A (p16)* mutation carriers and subjects with Peutz–Jeghers syndrome, pancreatic screening is generally initiated at age 50 or earlier [68]. *BRCA2* mutation carriers are generally recommended to undergo pancreatic cancer screening if they have at least one blood relative with pancreatic cancer. For individuals with a young-onset blood relative with pancreatic cancer in their family (age <55) who meet other family history or gene mutation criteria for screening, it is often recommended to begin pancreatic screening 10 years before the youngest pancreatic cancer in the kindred. Pancreatic screening guidelines developed from available evidence and expert opinion [2] are summarized in Table 98.1. Consensus guidelines developed in 2011 did not agree on when pancreatic screening should be discontinued in pancreatic cancer families [2]. Pancreatic screening often continues beyond age 75 in subjects who have pancreatic cysts but it is probably appropriate to discontinue pancreatic screening by age 75 or 80 in high-risk individuals without any evidence of pancreatic precancerous lesions on prior screening.

**Table 98.1** Pancreatic cancer screening guidelines [2].

## Pancreatic Screening Tests

Currently, pancreatic screening utilizes pancreatic imaging tests. In a head-to-head blinded comparison of pancreatic endoscopic ultrasound (EUS), MRI/MRCP and pancreatic protocol CT performed as part of the CAPS3 study of high-risk individuals, EUS had the highest rate of detection of pancreatic cysts, followed closely by MRI/MRCP [69]. MRCP provides the best visualization of cyst communication with the main pancreatic duct to determine the nature of the pancreatic cyst [70]. EUS has the advantage that it can identify subcentimeter solid lesions better than MRI, but it is more operator-dependent [71]. Pancreatic-protocol CT is currently less sensitive at detecting subcentimeter cysts [69] and also has the disadvantage of giving a low-dose of radiation, although the technology continues to improve. Pancreatic-protocol CT is also an excellent test to use to evaluate selected patients undergoing screening and surveillance when lesions of uncertain significance are identified.

## Lesions Identified by Pancreatic Screening

Pancreatic cysts are commonly identified in pancreatic screening cohorts. In the CAPS3 study the average age of the study population was 56 and over one third of the

study population had at least one pancreatic cyst with the prevalence increasing with advancing patient age [69]. Multiple other pancreatic screening studies of high-risk groups have reported a high prevalence of pancreatic cysts [68,69,72–80]. With improved pancreatic imaging in recent years, it is clear that pancreatic cysts are very prevalent in the general population, particularly among subjects in their 70s and older [81]. The high prevalence of pancreatic cysts in the general population and the recognition that most of these individuals are not going to develop pancreatic cancer has also raised questions as to the significance of pancreatic cysts in high-risk individuals. Although most pancreatic cysts identified in the screening population are branch-duct intraductal papillary mucinous neoplasms (IPMN), most of these are subcentimeter in diameter and the majority will not progress to invasive cancer [82]. To date, the number of pancreatic cancers detected by pancreatic screening in the literature is quite low (~1–5% of subjects under surveillance) [2], which is consistent with the expected age-specific incidence of pancreatic cancer of those undergoing screening.

Some patients who undergo pancreatic screening will have suspicious pancreatic cysts or solid lesions detected that are found at pancreatic resection to be nonneoplastic or of minimal malignant potential (such as serous cystadenomas, pancreatic neuroendocrine tumor, or lobulocentric parenchymal atrophy associated with PanIN) [80,83].

## Pancreatic Pathology not Detected by Current Screening Tests

Pancreatic cysts can be detected by pancreatic imaging even when they are quite small (~2 mm). But in the resected pancreata of patients who undergo pancreatic resection for pancreatic cysts, the most common neoplasm detected is the pancreatic intraepithelial neoplasia (PanIN) [83]. These lesions are generally too small (<5 mm diameter by definition) to be identified by current imaging modalities [84]. Although EUS can detect subtle changes like microcysts and hyperechoic foci that are often associated with the presence of PanIN, these EUS changes are not specific for PanIN [83,85]. PanIN-1 lesions are common in the population and have very low malignant potential [86], whereas PanIN-3 lesions are thought to have a significant risk of progressing to invasive cancer [84]. Most pancreatic cancers are thought to arise from PanIN and although pancreatic cysts (IPMN) are common in patients with hereditary forms of the disease, it is thought that most of the cancers that arise in these patients arise from PanIN [84,87–89]. Evidence for this comes from multiple sources. A blinded histologic review of hundreds of familial and sporadic pancreatic cancers found no significant differences in the histologic features of familial and sporadic cases, including no difference in the number of IPMN-associated cancers) [90]. Second, the genetic profiles of pancreatic ductal adenocarcinomas are similar to PanIN [91,92]. Finally, although ~66% of IPMN harbor *GNAS* mutations, *GNAS* mutations are not typically found in the pancreatic ductal adenocarcinomas of patients with a family history of pancreatic cancer [93–95].

## Surveillance

Because of the malignant potential of pancreatic cysts, their presence has been used to guide surveillance intervals. In recent years, surveillance recommendations for high-risk individuals have generally followed the recommendations used for subjects with pancreatic cysts without a familial susceptibility to pancreatic cancer [96] even though these recommendations were created from experience following patients with incidentally identified "sporadic" pancreatic cysts. However, the recognition that most pancreatic cysts (including those identified as IPMN) have low malignant potential [45,73,74,76,78] poses particular challenges in the high-risk setting. One the one hand, the cumulative cost and personal burden of annual pancreatic imaging tests is high. At the same time, it is understood that most pancreatic cancers arise from PanIN and it can be difficult to detect small pancreatic cancers. Indeed, among subjects that have had screen-detected pancreatic cancers, many have Stage II disease despite regular surveillance [97]. The recommendation that high-risk individuals undergo frequent (typically annual) surveillance reflects the underlying biology of pancreatic cancer and the limitations of current pancreatic imaging tests. Studies estimating the time to progression of pancreatic cancer predict that a cancer can progress from Stage I disease to Stage IV disease within approximately 1 year [98]. It may be appropriate to have longer surveillance intervals (several years apart) when the risk of pancreatic cancer is lower (such as for subjects in their 50s) increasing it to annually for older subjects, but more evidence is needed.

The choice of surveillance test is often influenced by practical considerations such as patient preference and insurance. Surveillance protocols often alternate EUS and MRI to provide complementary imaging and limit the burden of annual EUS [68]. Subjects who have large pancreatic cysts, pancreatic duct abnormalities, or solid lesions undergo fine-needle aspiration of any focal concerning lesion(s) and close surveillance.

## Surgery for Lesions Identified by Pancreatic Screening

As clinicians have gained experience with pancreatic screening, the indications for pancreatic resection in the screening setting have become more defined. Pancreatic resections are usually undertaken once there is evidence that a pancreatic cyst has features concerning for invasive cancer or for a cancerous solid mass or suspicious mass. Most patients are likely to develop their cancer from PanIN that will grow into a solid mass and not a cystic lesion. The strategy of waiting for the emergence of a cancer risks missing opportunities for cure as most patients who present with resectable cancers will not be cured, but operating on subjects with IPMN without a cancer or strong suspicion of cancer often results in overtreatment (the detection of PanIN-1 and low-grade dysplasia in IPMN). The rationale for performing pancreatic resection for high-risk patients with multiple medium-sized pancreatic cysts that do not individually meet criteria for resection is that some of these patients have PanIN-3 in their resected pancreata [80,83].

The choice of operation for high-risk patients with lesions identified by pancreatic screening can be challenging since some patients will have concerning cysts or other lesions in both the head and the tail of the pancreas. However, total pancreatectomy is only occasionally undertaken in this setting because of the potential morbidity associated with diabetes after total pancreatectomy. Instead, patients usually undergo partial pancreatectomy for screen-detected lesions and are then recommended to continue surveillance postoperatively. These cases are evaluated on a case-by-case basis preferably by an experienced multicenter team and at a high-volume center [99,100].

## Developing Better Pancreatic Screening Tests

The limitations of currently available pancreatic screening tests highlight the need for better tests. The most optimal test would be a simple blood test able to detect Stage I pancreatic cancers with high diagnostic accuracy. A screening test that performs well at detecting more advanced pancreatic cancers (even resectable cancers) would not have a major impact on survival since the median survival of patients with Stage II pancreatic cancer is less than 2 years [101,102]. Many candidate blood markers of pancreatic cancer have been developed, and most are not sufficiently useful for pancreatic screening. Screening blood tests need to have very high diagnostic performance since they can generate a lot of downstream testing with the risks of complications, worry, and cost. Serum CA19-9 has good performance characteristics but among patients with resectable pancreatic cancers only ~60% of these have elevated CA19-9 [103]. Some studies have identified elevated CA19-9 levels in a small fraction of prediagnostic blood samples from patients who subsequently develop pancreatic cancer [104,105]. Overall, it is the occasional false-positive elevations of CA19-9 that have limited its potential as a screening test [106]. Perhaps the best test identified to date is circulating *KRAS* mutations, but less than half of patients with resectable pancreatic ductal adenocarcinoma have detectable circulating tumor DNA [107,108]. Other markers such as glypican-positive exosomes and thrombospondin-2 have been reported to be potential markers of pancreatic cancer, but further evaluation of these markers is needed [109,110]. Most other circulating markers that have been reported as potential pancreatic cancer markers do not have the diagnostic characteristics that would make them suitable for pancreatic screening [111,112].

The inability of current pancreatic screening tests to detect PanIN-3 lesions means that we cannot identify patients most likely to progress to cancer. If this could be done reliably, screening intervals could be shortened for those with PanIN-3 and lengthened for those without PanIN-3. Approaches that have been used to identify PanIN by pancreatic screening include pancreatic juice analysis and molecular imaging. Analysis of secretin-stimulated pancreatic juice collected endoscopically from the duodenum of patients enrolled in the CAPS trials revealed that *KRAS* mutations are often detected in the pancreatic juice of high-risk individuals without pancreatic cysts or pancreatic cancer; these mutations are thought to arise from small PanIN lesions [113]. Similarly, *GNAS* mutations are detected in the pancreatic juice of over half of patients with evidence of IPMN (close to what would be expected if one directly analyzed their IPMN) [82,114,115]. Next-generation sequencing analysis of pancreatic juice can be used to detect low-abundance mutations affecting multiple genes (such as *KRAS*, *TP53*, *SMAD4*, *GNAS*, *CDKN2A*, and *RNF43*) from the pancreata of patients with pancreatic ductal adenocarcinoma [97]. Improvements in how pancreatic juice is collected may be needed to improve the diagnostic yield of this sample [114].

Molecular imaging offers the possibility to detect these lesions in the future [116], but the molecular targets and imaging approaches needed are still under investigation (such as more IPMN-associated cancers) [117].

## Evaluating the Long-Term Outcomes of Patients who Undergo Pancreatic Screening

Large multicenter studies involving patients followed for many years will be required to prove the benefit of pancreatic screening. The goal of pancreatic screening is to demonstrate it can reduce the risk of pancreatic cancer death. Although such trials are needed, it is clear we still do not have optimal screening tests so such large studies probably need to await for better screening tests. Such studies need to await improvements in our ability to identify individuals at most risk of developing pancreatic cancer. For now, surrogate endpoints (such as the detection of Stage I pancreatic cancer, resectability rate, PanIN-3 lesions, and IPMN with carcinoma *in situ*) are used to define the success of pancreatic screening. Since most patients who have their pancreatic cancer diagnosed by screening will have advanced disease, and since the 5-year survival of patients with Stage I pancreatic cancer is considerably higher than for those with advanced disease, the detection of Stage I pancreatic cancer is a good surrogate endpoint [118,119]. Treating Stage I pancreatic cancer is likely to improve patient outcome for most patients, although lead-time bias could also cause this. In one prospective screening study of high-risk germline *p16* mutation carriers using MRI/MRCP, nine invasive pancreatic cancers were detected and treated in 79 patients followed for a median of 4 years. The number of patients who needed to be screened to detect and treat one patient's pancreatic cancer in this cohort was 11 [76]. A more recent study from this group found that pancreatic screening resulted in downstaging (more resectable cancers) and improved 5-year survival (24%) compared with patients who present with symptomatic pancreatic cancer [120].

## Summary

Pancreatic screening of subjects who have an inherited predisposition to develop pancreatic cancer frequently detects pancreatic neoplasms in these individuals, but the long-term benefits of screening remains to be determined. Pancreatic cancers are detected in a very small percentage of patients and the early detection of these cancers provides an opportunity to improve patient outcome. Similarly, resecting precancerous neoplasms in patients who have high-grade dysplasia (PanIN-3 or high-grade dysplasia in IPMN) is likely to be beneficial in preventing cancer in many cases. Managing concerning but indefinite pancreatic lesions identified by screening is best done by experienced multidisciplinary teams. There are major unanswered questions about pancreatic screening. There is a need to better define pancreatic cancer risk so as to improve the targeting of individuals who most need pancreatic screening. There is also a need to develop better screening tests. Current pancreatic imaging tests do not reliably detect PanIN, which are the most common precursor lesion. With the development of more accurate blood tests it may ultimately be possible to detect small potentially curable Stage I pancreatic cancers.

## Introduction

Positron emission tomography (PET) is a noninvasive functional imaging technique that is used to observe metabolic processes in the body. The patient is given a radioactive glucose analog carrying a positron emitter. During the radioactive decay of the so-called radiotracer positrons are emitted. The positrons next collide with electrons, which cause the release of photon pairs. Detectors arranged in a circle around the patient then can record the latter. Thereby, PET can analyze both the localization and the intensity of the radioactive tracer in the patient's body. Compared with morphologic imaging, PET therefore provides functional data of the investigated tissue, which can also be measured quantitatively. Different radiotracers can be applied depending on the clinical problem. Currently, the radiotracer 2-[$^{18}$F]-fluoro-2-deoxy-D-glucose (FDG) is most commonly used. Its uptake reflects glucose metabolism in the cells which is significantly increased in malignant tumors. However, FDG is not a cancer-specific agent and its uptake has been described in a number of nonneoplastic inflammatory lesions as well. Thanks to consequent technical improvements, integrated PET-computed tomography (PET-CT) was introduced in 1999 [1]. These PET-CT scanners provide a simultaneous acquisition of both high-resolution anatomic CT data and high-resolution metabolic PET information. However, as PET-CT is still a cost-intensive diagnostic tool with limited availability, reliable data evaluating the actual benefit of PET and PET-CT is of crucial importance. Therefore, this chapter gives an overview on currently available data of PET and PET-CT imaging in pancreatic cancer, summarizing its value and possible indication in the setting of primary diagnosis, staging, detection of tumor recurrence, and therapy monitoring. Finally, the potential value of recently introduced integrated whole-body PET-magnetic resonance imaging (MRI) into clinical practice is outlined.

## The Role of PET and PET-CT in Primary Tumor Diagnostic of Pancreatic Carcinoma

Despite excellent registration of anatomic and pathologic structures, morphologic imaging is unable to distinguish malignant from benign processes unconditionally. The sensitivity of multidetector CT (MDCT) has improved over the past few years. According to data from the literature, sensitivity of MDCT in pancreatic carcinoma was reported to be between 75% and 100% in so-called multiphase scans with a specificity of 70% to 100%. However, concerning lesions smaller than 2 cm, the sensitivity reaches values of no higher than 77% [2,3], which demands for complementary histopathologic investigation of suspicious lesions. MRI appears to be of outstanding impact in detection and assessment of tumor lesions of the pancreas, which cannot be directly depicted in CT imaging because of isoenhancing [4]. Concerning magnetic resonance cholangiopancreaticography (MRCP) in primary tumor diagnostics, Fusari et al. demonstrated sensitivity, specificity, accuracy, and positive and negative predictive values (describing the probabilities of FDG-positive lesions to be malignant and of negative lesions not to be malignant) to be 100%, 88%, 98%, 97%, and 100%, respectively [5]. For comparison purposes, sensitivity and accuracy of endo-ultrasound for lesions smaller than 2 cm are reported to be as high as 100% and 95%, respectively [3].

Tumor detection and assessment of tumor dignity with FDG-PET encounter problems of a different nature. As FDG-PET displays areas of increased glucose metabolism within the body, those tissues with a high metabolism by nature and all hypermetabolic processes are depicted regardless of its dignity. This might lead to false-positive diagnosis in, for example, inflammation. The differentiation of pancreatic lesions is complicated, whenever a local pancreatitis is present at the time of FDG-PET examination [6]. The glucose oxidation of activated leukocytes in inflammatory sites is highly increased, which causes an intense FDG uptake in this area as well. Additionally, within autoimmune pancreatitis an increased FDG uptake can be demonstrated in up to 100% of the cases [7]. Contrary, in patients with chronic pancreatitis without active inflammatory components, PET shows a FDG uptake in only 13% of the patients [8]. Therefore, the pancreatic carcinoma can be distinguished from chronic pancreatitis, because most pancreatic adenocarcinomas show a relatively high FDG uptake (Fig. 99.1). However, recent studies prove difficulties in the differentiation between metastasis-free pancreatic carcinoma and mass-forming pancreatitis because of an overlap of the maximum standardized uptake value of both diseases [9]. Further, FDG uptake in tumor tissue and normal tissue is influenced by the dietary state, as FDG is a glucose analog. The investigator has to ensure a well-controlled serum glucose concentration in the examined patient to allow for adequate PET diagnostics. This is especially important in diabetic patients, because glucose concentrations above 8.4 mmol/L significantly reduce the detection rate of pancreatic carcinoma [6].

Kauhanen et al. reported on a higher diagnostic accuracy of PET-CT compared to conventional MDCT and MRI in primary diagnosis of pancreatic cancer [10]. In their analysis including 38 patients the pooled sensitivity and specificity turned out to be 85% and and 94%, respectively. For comparison, sensitivity and specificity were 85% and 92% for MDCT, and 85% and 72% for MRI. In two prospective studies on primary diagnostics of pancreatic cancer the sensitivity of PET-CT (89%) turned out to be comparable to both CT [11] and endo-ultrasound [12]. However, no homogeneous consent has been reported so far concerning any superiority of PET or PET-CT compared with MDCT and MRI, respectively. A 2014 published meta-analysis including 35 studies reports on a pooled sensitivity (SN), specificity (SP), positive predictive value, and negative predictive value of 90%, 76%, 90%, and 76% for PET and 90%, 76%, 89%, and 78% for FDG-PET-CT, respectively. In contrast, sensitivity and specificity of CT and MRI are 91% and 85% versus 84% and 82%. Therefore, Rijkers and colleagues could not derive any superiority or additional benefit of both FDG-PET and FDG-PET-CT in primary diagnosis of pancreatic carcinoma [13]. These data therefore support the current guidelines of the NCCN, which do not recommend PET-CT for standard primary diagnostics in patients with pancreatic carcinoma. Taken together, PET-CT is a useful diagnostic method *in addition* to conventional imaging procedures, especially when the results are inconclusive or show cystic and complex lesions in the pancreas [14]. Therefore, currently, the role of PET and PET-CT in diagnostics of primary pancreatic carcinoma cannot be finally rated.

## The Role of PET and PET-CT in Oncologic Staging of Pancreatic Carcinoma

Whereas primary diagnostics exclusively aim for the detection and proof of a pancreatic carcinoma, TNM-staging focuses on gathering information on the oncologic extent of the primary tumor and its potential metastases, which is essential for the individual evaluation of therapeutic options. Regarding tumor resectability and reasonableness of surgical procedures both local tumor infiltration of vessels and detection of distant metastases have crucial impact on the therapeutic

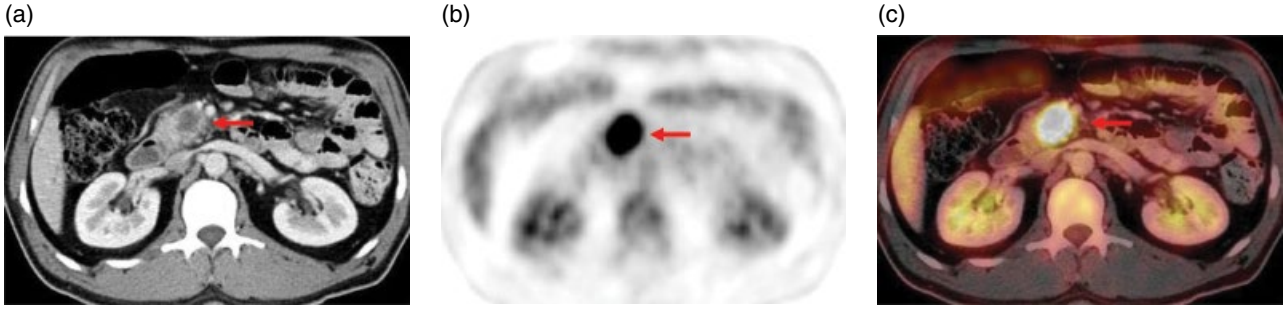

**Figure 99.1** (a–c) FDG PET-CT examination of a patient with primary diagnosis of pancreatic cancer presenting with an intense, focal FDG uptake in the pancreatic head.

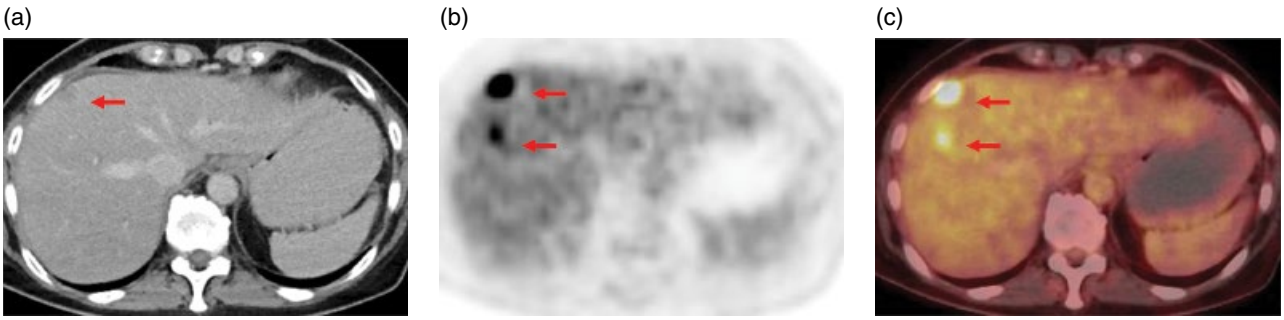

**Figure 99.2** FDG PET-CT of a patient presenting with two liver metastases of pancreatic cancer with high, focal FDG uptake (b,c). However, note, that only one of them was visible with diagnostic CT (a).

strategy. As a result of high surgical standards and improvements in downstaging of pancreatic carcinomas, the classification of *resectable*, *borderline resectable*, *locally advanced/irresectable*, and *metastasized* tumors has just recently gained increasing attention. MDCT and MRI are the most commonly used methods in staging of pancreatic carcinomas. Here, T-staging is of special importance because unresectability of pancreatic cancer is defined morphologically as infiltration of the superior mesenteric artery and/or the celiac trunk. The preference of either method depends on both the local availability and the experience of the investigator. The NCCN practice guides support both contrast-enhanced pancreatic CT and MRI and the International Study Group of Pancreatic Surgery (ISGPS) recommends the investigation of the pancreas by use of contrast-enhanced CT imaging. Nevertheless, the assessment of local resectability remains difficult even with these tools. In ambiguous cases the decision has to be forwarded to a pancreatic surgery reference center. A study of Strobel et al. revealed that the use of enhanced FDG PET-CT as a 1-stop-shop imaging protocol for assessing the resectability of pancreatic cancer is feasible and accurate. In their study, enhanced PET-CT was significantly superior to PET alone and although not being significant, there was a trend for enhanced PET-CT to be superior to unenhanced PET-CT [15]. Therefore, PET-CT should always include a diagnostic contrast-enhanced CT as unenhanced PET-CT has limited value in T-staging.

During the last years combined FDG PET-CT made distinct progress in terms of staging of malignant pancreatic tumors. The advantage of this whole-body examination especially concerns the M-staging where its specificity reaches up to 100%, for example in the detection of lung and bone metastases [15]. Heinrich et al. could prove that in patients with known metastatic spread more metastases became visible by PET compared with CT scan alone [11]. In addition, the authors evaluated the oncologic impact of PET-CT on further therapeutic decision making. In 16% of the patients investigated the detection of metastasis prompted the physicians to refrain from surgical therapy. This is concordant with the results of Bang et al. who revealed that PET scan increased the tumor stage in approximately a quarter of the investigated patients because metastases had not been visible with CT imaging alone [16]. Another study demonstrated the superior sensitivity of FDG-PET (88%) compared to MDCT (38%) and MRI (38%) regarding the detection of liver metastases. This study also reports a change of therapeutic strategy in 29% of the patients as the then palliative situation made surgical procedures unnecessary [10]. These results could be augmented by a recently published meta-analysis, which reports an increased sensitivity of PET-CT compared to PET alone (82% vs. 67%) regarding the detection of liver metastases [17]. The sensitivity of PET-CT in the detection of lymph node metastases has been reported to be as low as 21% to 38% [10,11]. Conversely, other studies underline the role of PET-CT in staging of locoregional and distant lymph node metastases. Here, PET-CT has been reported to be more accurate than CT or PET alone with regard to locoregional N-staging. However, the differences turned out to be rather small (85.3% vs. 83.8% and 79.4%) [18]. Because of the contrary results published in the literature, the value of PET-CT regarding N-staging has to be questioned. In summary, PET seems to be more sensitive in detection of distant metastases but has not achieved significance in routine staging and has not given proof of cost-effectiveness yet [19] (Fig. 99.2).

## Therapy Control and Diagnostics of Malignant Pancreatic Tumor Recurrence by PET and PET-CT

The impact of FDG-PET and PET-CT in terms of response prediction after neoadjuvant chemotherapy in patients with pancreatic adenocarcinoma is promising. They are particularly expected to allow for decision

making in tumors that were initially described as a borderline situation. Both the depiction of metabolic processes and the morphologic evaluation of lesions are highly difficult because of neoadjuvant chemotherapy-induced regional alterations around the tumor. Katz and co-workers demonstrated imposingly, that the resectability of a tumor could be predicted on the basis of imaging procedures in only 0.8% of the investigated patients after intended downstaging. However, tumors actually turned out to be resectable in 66% of the patients during surgical exploration [20]. The ISGPS consecutively postulates the explorative laparotomy in all patients without proof of metastatic spread or other indicators of tumor progress after neoadjuvant therapy.

FDG-PET and PET-CT show a significant advantage compared with CT and MRI in the detection of local recurrence after initially performed surgical resection of pancreatic carcinoma. Tumor recurrence could be approved in 96% of the patients by use of FDG-PET but in only 39% when CT or MRI imaging were performed [21]. In another study proof of tumor recurrence by FDG-PET was successful in 96.8%, whereas CT scan was accurate in only 55.6% of the cases [22]. Therefore, PET gains some significance in monitoring of surgical patients after resection of pancreatic cancer.

However, pancreatic tumors are often unresectable when diagnosed. FDG-PET served as therapy control of pancreatic carcinoma in several investigations. Advantages of PET-CT compared with CT scan could be demonstrated in terms of decreasing standardized uptake values in case of a tumor response in both follow-up monitoring after radiotherapy [23] and after chemotherapy [24], respectively. These findings allow for some prognostic assessment concerning survival of every single patient. Nevertheless, the correlations between metabolic response and prognosis remain under debate because of very heterogeneous results. However, new therapeutic agents and their effectivity can be tested and validated by use of FDG PET-CT within studies.

## Potential Value of PET-MRI in Patients with Pancreatic Cancer

With the recent introduction of integrated whole-body PET-MRI into clinical practice, a novel metabolic–anatomic imaging technique is now available with the opportunity to perform multiparametric oncologic imaging that reflects different aspects of tumor biology (tumor diffusion, perfusion, and glucose metabolism). Hereby it also combines the strengths of PET (metabolic imaging) with the advances of MR (soft-tissue contrast, functional imaging, e.g., using diffusion-weighted imaging and dynamic contract-enhanced imaging) (Fig. 99.3).

This multiparametric approach allows for noninvasive phenotyping of tumor biology which, by combining

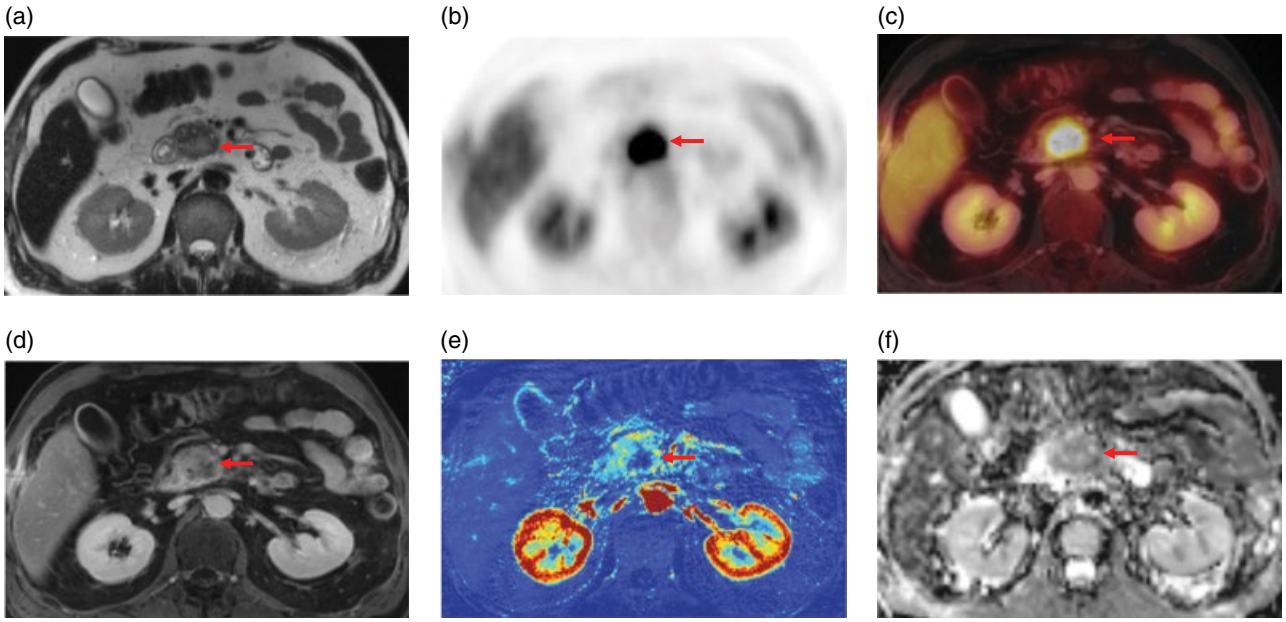

**Figure 99.3** Multiparametric FDG PET-MRI of a patient with primary diagnosis of pancreatic cancer. The MR image shows an inhomogeneous, hypointense tumor in the pancreatic head (a) with a high, focal FDG uptake (b,c). Dynamic contrast-enhanced (DCE) MRI shows peripheral hypervascularity (d) and the parametric map of iAUC60 (initial area under the DCE-MRI contrast agent concentration-time curve after 60 s) confirmed a high wash-in rate (e). Corresponding diffusion-weighted imaging presents low ADC values within the tumor indicating low cellularity (f).

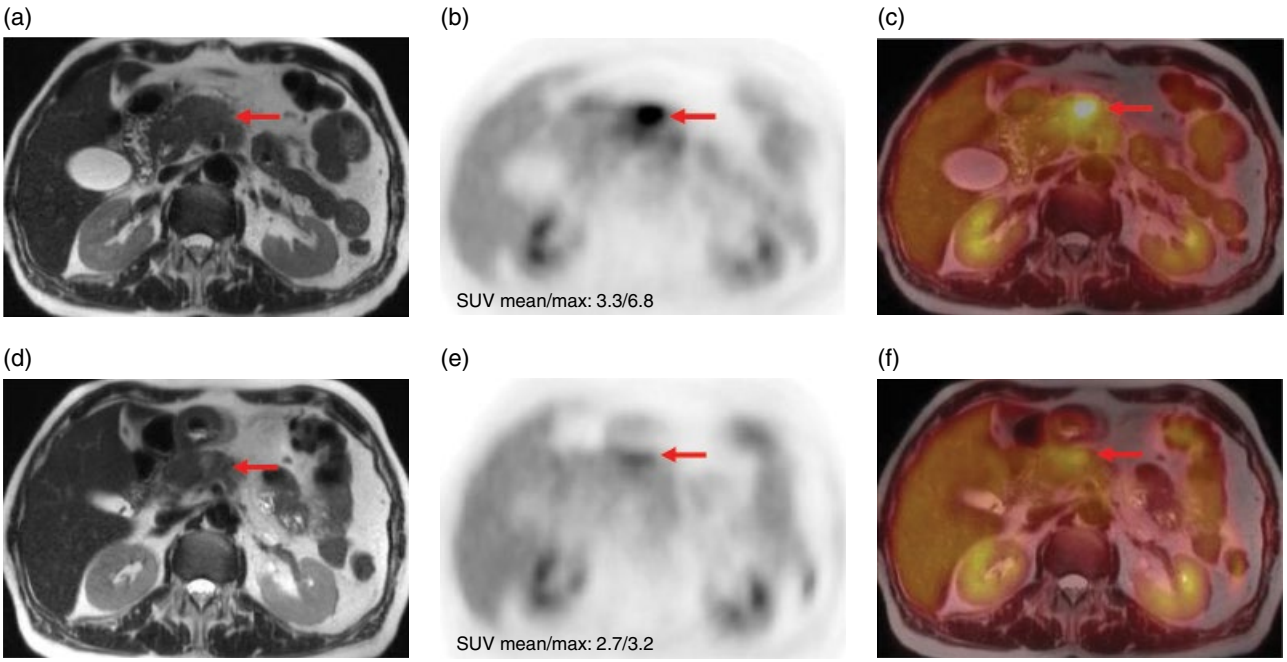

**Figure 99.4** FDG PET-MRI of a patient with pancreatic cancer before (a–c) and 6 weeks after beginning of chemotherapy (d–f). Note the decrease of SUV values (b,e) after chemotherapy indicating a tumor response (decrease of SUV mean/max 18% and 53%).

different functional and molecular imaging methods, might lead to a higher accuracy for tumor detection and differentiation as well as response (Fig. 99.4).

First studies suggest that PET-MRI seems to be highly accurate in T-staging of tumor entities for which MRI has traditionally been favored, such as squamous cell carcinomas of the head and neck [25]. By adding functional MRI to PET, PET-MRI may further improve diagnostic accuracy in the differentiation of scar tissue from recurrence of tumors such as rectal cancer. With regard to N-staging, PET-MRI does not seem to provide a considerable benefit as compared with PET-CT but provides similar N-staging accuracy when applied as a whole-body staging approach [25]. M-staging will benefit from MRI accuracy in the brain and the liver and allows visualization of the biologic heterogeneity of tumors. However, regarding M-staging it has to be noted that the detection rate of small lung lesions in PET-MRI is still inferior compared with PET-CT with diagnostic CT of the chest [26]. For neuroendocrine tumors in the pancreas a first preliminary study has shown an added value of PET-MRI compared with PET-CT [27].

However, organ-specific data on the diagnostic performance of PET-MRI in pancreatic cancer are not available yet. There is only one study evaluating retrospective FDG PET-MRI fusion to PET-CT in various pancreatic tumors (96 cancers and 23 benign lesions) showing a significantly improved accuracy (96.6% vs. 86.6%) [28]. Therefore, the simultaneous acquisition of multiparametric MRI and PET data is awaited to create new options in molecular tumor imaging by improving tumor detection and delineation as well as biologic characterization.

## Conclusion

The final appraisal of the patient-relevant benefit of PET and PET-CT with regard to primary diagnostics, diagnostics of tumor recurrence, or staging cannot be based on a comparison with the standard methods only. In fact, the major matter of interest is the question of the impact of an improved diagnostic tool on therapy and therefore patient morbidity, mortality, and quality of life, respectively. Randomized studies have to be initiated to investigate the impact of findings from PET and PET-CT in all those cases where they indicate different results or tumor stages compared with standard methods. At the moment there are no studies that allow for any statement concerning PET and PET-CT in this respect. However, many studies validate the quality of PET and PET-CT by scrutinizing the improvement in primary diagnostics, diagnostics of tumor recurrence, and tumor staging of pancreatic carcinoma compared with the standard methods without PET. The current literature does not obligatorily recommend the use of PET-CT within primary diagnostics of pancreatic carcinoma, but it is considered to be a useful modality. However, PET-CT

plays a promising role in the assessment of borderline resectable tumors and locally advanced tumors. Furthermore, the additional use of PET scanners demonstrated auspicious results within the staging of locally resectable lesions with synchronous CT- and MRI-morphologically occult metastases. Nevertheless, the sensitivity concerning the detection of lymph node metastases is rather low. The impact on therapeutic consequences in tumor therapy will play a relevant role in future socioeconomic concerns, however, while sparing patients unnecessary surgical procedures. Finally, PET-CT already plays an important role in detection of tumor recurrence after surgical resection and therapeutic monitoring in unresectable pancreatic cancer.

PET-MR is a new and increasingly used multimodal imaging technique, which is expected to improve diagnostic performance especially in oncology patients. The combination of PET and MR in hybrid whole-body PET-MRI systems has the potential to combine excellent morphologic, functional, and biologic information in one imaging session with precise image co-registration. Contrary to PET-CT, the MR part of PET-MRI provides superior soft-tissue contrast and imposes no ionizing radiation. So far, studies evaluating the performance of PET-MRI in pancreatic cancer are pending; therefore, the potential benefit of PET-MRI in comparison to PET-CT and conventional imaging modalities has still to be validated.

## Conventional Tumor Markers for Pancreatic Cancer

### CA 19-9

There are several tumor markers for pancreatic cancer. The usefulness and efficacy of these markers for clinical decision making are well established, but several pitfalls need to be kept in mind. CA 19-9 is a sialyl-Lewis A antigen, which is recognized by a mouse monoclonal antibody NS 19-9 established by Koprowski et al. [1]. Indispensable roles of CA 19-9 are described in recent clinical guidelines for pancreatic cancer, such as NCCN Guidelines for Patients®, Pancreatic Adenocarcinoma, Version 1.2013, or ESMO-ESDO Clinical Practice Guidelines [2,3]. Currently, the clinical usefulness of CA 19-9 is mainly for follow-up after surgery, assessment of chemotherapy effect, and prognosis. Patients with a low postoperative CA 19-9 value have a better prognosis [4]. Similarly, patients with low CA 19-9 before surgery or adjuvant chemotherapy also have a better prognosis [4]. Another study reported that decrease of CA 19-9 during gemcitabine-based chemotherapy could predict better median survival, suggesting the possibility as a determinant factor of chemotherapy continuation [5]. Based on this line of evidence, measurement of CA 19-9 before and after surgery or during chemotherapy is strongly recommended. However, CA 19-9 is not a suitable marker for "early" detection of pancreatic cancer in the general population. According to a recent meta-analysis, the pooled diagnostic sensitivity of CA 19-9 was around 80% [6]. In addition, the diagnostic sensitivity of CA 19-9 was only 55.6% in Stage I [7].

False-positive and false-negatives of CA 19-9 should also be taken into consideration. Elevation of CA 19-9 is observed in several conditions besides pancreatobiliary cancers. Obstructive jaundice causes CA 19-9 elevation, regardless of the etiology of the biliary stricture. Adequate biliary drainage then leads to a decrease of CA 19-9 [8], and NCCN Guidelines recommend measurement of CA 19-9 after the normalization of serum bilirubin by biliary drainage [2]. Patients with liver cirrhosis sometimes have nonspecific elevation of CA 19-9 [9]. Synthesis of CA 19-9 sialyl-Lewis A epitope requires α-1,4-fucosylation of sialyl-Lewis C precursor, which is regulated by the *Le* gene encoding fucosyl transferase [10]. Individuals lacking this enzymatic activity are unable to synthesize CA 19-9 epitope, therefore CA 19-9 levels become undetectable. Measurement of CA 19-9 is performed in patients with suspicious lesions for pancreatic cancer found by imaging. Initial measurement of CA 19-9 will identify Lewis-negative individuals. After a definitive diagnosis of pancreatic cancer, changes in CA 19-9 value will be monitored after surgery or during chemotherapy. Continuous elevation after surgery suggests tumor spread or resistance to chemotherapy, needing additional imaging studies to detect progression of the initial lesion or the development of new lesions. The algorithm for CA 19-9 measurement is summarized in Fig. 100.1. Measurement of CA 19-9 in high-risk individuals might have some benefit for early diagnosis of pancreatic cancer. Intraductal papillary mucinous neoplasm (IPMN) of the pancreas may progress to pancreatic cancer in a small proportion of individuals. Elevated CA 19-9 in patients with branch-duct IPMN may be associated with concomitant pancreatic cancer [11].

### DU-PAN-2 and SPan-1

DU-PAN-2 is a sialyl-Lewis C antigen, which is a precursor of CA 19-9. Mouse monoclonal antibody against DU-PAN-2 was established by immunizing mice with the HPAF human pancreatic cancer cell line [12]. Since Lewis-negative individuals can synthesize this antigen [10], DU-PAN-2 becomes an alternative marker of pancreatic cancer in patients with low levels of CA 19-9 (typically less than 2.0 KU/L). SPan-1 is recognized by a monoclonal antibody raised against mucins purified from the SW1990 pancreatic cancer cell line [13], which therefore recognizes both sialyl-Lewis A and C antigens [14]. False-positives for DU-PAN-2 and SPan-1 can also be seen in patients with obstructive jaundice, liver cirrhosis, or chronic hepatitis [15,16].

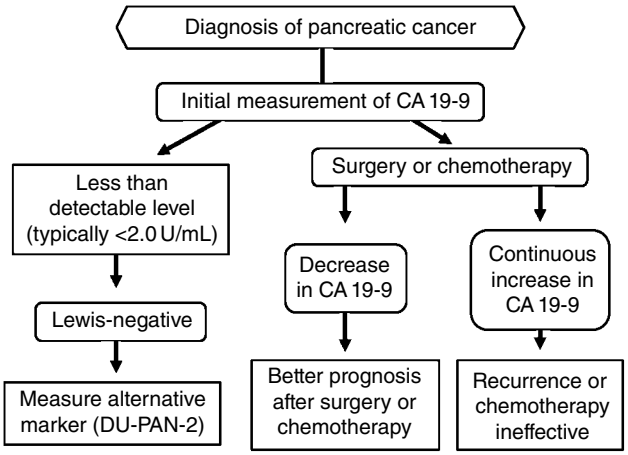

**Figure 100.1** Clinical flow-chart for CA 19-9 measurement in patients with pancreatic cancer.

## Other Markers for Pancreatic Malignancies

### Markers for Rare Pancreatic Malignancies

Acinar cell carcinoma is a rare type of pancreatic cancer. Elevation of alpha-fetoprotein (AFP) has been reported in cases of acinar cell carcinoma, and a decrease of serum AFP levels after therapeutic intervention has also been described [17,18]. Measurement of AFP in patients with pancreatic tumor suggestive of acinar cell carcinoma by imaging studies or pathologic diagnosis will be beneficial for follow-up after surgery and during and after chemotherapy.

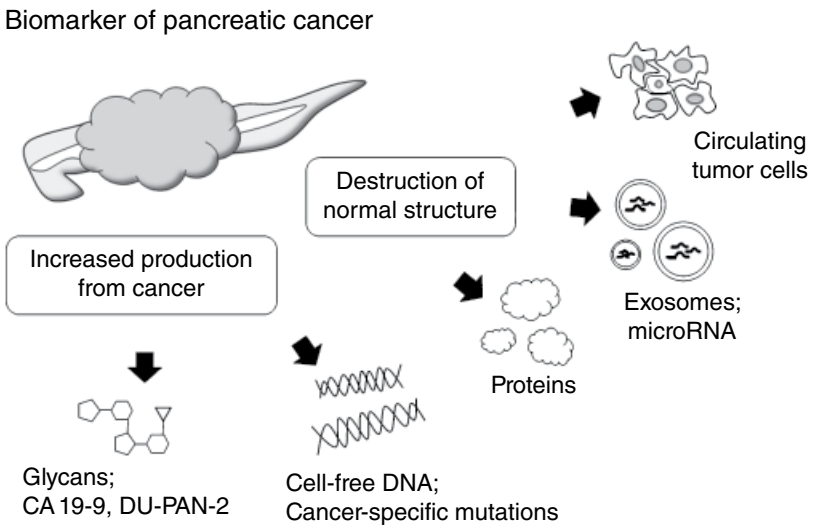
Production of granulocyte colony-stimulating factor (G-CSF) has been reported in various types of cancer, such as gastric cancer or hepatocellular carcinoma [19,20] and also pancreatic cancer with a poor prognosis [21,22].

## Novel Markers for Pancreatic Cancer

### New Candidates for Pancreatic Cancer Marker

Currently, conventional markers of pancreatic cancer are not suitable for early detection or screening so novel markers are being investigated (summarized in Fig. 100.2). Circulating tumor cells (CTC) are detectable in blood samples from some patients with pancreatic cancer, especially in patients with advanced disease and a poor prognosis after surgery [23]. Cell-free DNA sequencing by next-generation sequencer (NGS) may identify cancer-specific gene in some cases [24]. Mass-spectrometry-based proteomics has identified serum

**Figure 100.2** Current biomarker of pancreatic cancer and future candidates for novel biomarker.



LAMC2, a constituent of basement membrane, as a potential marker of CA 19-9 [25].

MicroRNA, which are normally protected from degradation by nucleases by extracellular vesicles such as exosomes, are detectable in various body fluids [26]. Elevated expression of miR-21 in pancreatic cancer tissues has been correlated with clinical outcome and gemcitabine resistance [27]. Stool detection of miR-21 may differentiate patients with pancreatic cancer from those with chronic pancreatitis patients and from healthy controls [28]. A 70% diagnostic sensitivity and specificity for pancreatic cancer was found for elevated miR-3679-5p and miR-940 levels in salivary samples [29]. Urinary miR-143, miR-223, and miR-30e are elevated in patients with pancreatic cancer of which miR-143 could differentiate Stage I pancreatic cancer patients from healthy controls, with sensitivity of 83.3% [30].

### Markers for Personalized Medicine

The expression levels of deoxycytidine kinase was correlated with progression-free survival in patients who have received gemcitabine therapy after surgery [31]. Severe neutropenia is a limitation in using FOLFIRINOX [32] and may be linked to a specific genotype of *UDP-glucuronyltransferase 1A1* (*UGT1A1*) that is required for elimination of active metabolite of irinotecan [33]. A blinded analysis of the human equilibrative nucleoside transporter 1 (hENT1) levels was undertaken in microarrays from 434 patients randomized to chemotherapy in the ESPAC-3 trial plus controls from the ESPAC-1 and ESPAC-3 trials [34]. Multivariable analysis confirmed hENT1 expression as a predictive marker in gemcitabine-treated but not 5-fluorouracil-treated patients [34]. Prospective validation, is now underway to evaluate the roles of hENT1 expression in the use of gemcitabine versus gemcitabine-based regimens.

# The Role of Laparoscopy and Peritoneal Cytology in the Management of Pancreatic Cancer

*Kyoichi Takaori and Shinji Uemoto*

*Division of Hepatobiliary-Pancreatic Surgery and Transplantation, Department of Surgery, Kyoto University Hospital, Kyoto, Japan*

## Introduction

Pancreatic cancer is either systemic or local disease and in approximately 90% of patients, it is complicated by systemic disease according to previous autopsy studies [1,2]. However, about 40% of patients with pancreatic cancer are diagnosed as having local disease only at the time of initial diagnosis [3,4]. The discrepancy in the ratio of local versus metastatic disease between the autopsy and initial diagnosis suggests that some local disease may progress toward metastatic disease after the initial diagnosis and that others may harbor "occult" metastatic disease. In the active treatment of pancreatic cancer, surgery and/or radiation therapy in combination with chemotherapy may be used for local disease, while chemotherapy is currently the choice of treatment for systemic disease [5,6]. Therefore, it is of vital importance to define the disease as systemic or local before initiation of active treatment. In patients complicated by peritoneal metastasis, cancer cells may be disseminated as a number of small nodules in the peritoneal cavity that are often not visible even with state-of-the-art multidetector CT. Moreover, small metastasis on the surface of the liver is also hard to detect with the present imaging technologies. To identify such metastatic disease, efforts by means of staging laparoscopy and peritoneal cytology have been made. The role of laparoscopy and peritoneal cytology in the management of pancreatic cancer is described in this chapter.

## Laparoscopy

The usage of laparoscopy for pancreatic cancer dates back to 1970s. Cuschieri et al. started to use laparoscopy in patients with suspected pancreatic cancer in 1973 and found "metastatic deposits elsewhere in the abdomen" in 2 of 15 patients with obstructive jaundice [7]. Ishida et al. have used a two-channel laparoscope in patients with pancreatic cancer and pancreatitis since 1976 and succeeded in obtaining biopsy specimens of the pancreatic tissue [8]. Observation of the peritoneal cavity by a laparoscope provided physicians with information about peritoneal dissemination and superficial liver metastasis, both of which are determinant factors for staging of the disease. Thus, diagnostic laparoscopy became widely called staging laparoscopy or laparoscopic staging. One of the advantages of staging laparoscopy is detection of peritoneal dissemination and superficial liver metastasis, which are not detectable with CT and other imaging studies. This advantage has contributed to avoiding unnecessary laparotomy as demonstrated in many retrospective studies [9–13]. However, the development of high-resolution imaging technologies such as multidetector CT has led to a decline in the role that staging laparoscopy should play. Nevertheless, small nodules, for example, those <0.5 cm, are often invisible even with state-of-the-art CT and there is a role for staging laparoscopy in selected patients. Selection criteria vary among the previous reports partly because of the diverse accuracy of imaging studies in different eras. In general, high value of serum CA 19-9, large tumor, location in the body-tail, and any suspected metastatic lesions on imaging support the use of staging laparoscopy [14,15]. Moreover, staging laparoscopy is widely used in the setting of neoadjuvant chemoradiation therapy in order to rule out metastatic disease. Recently, advantages of "extended" staging laparoscopy over standard staging laparoscopy have been advocated [16]. By simply observing the peritoneal cavity without intracorporeal surgical manipulation, it is impossible to explore the lesser cavity

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

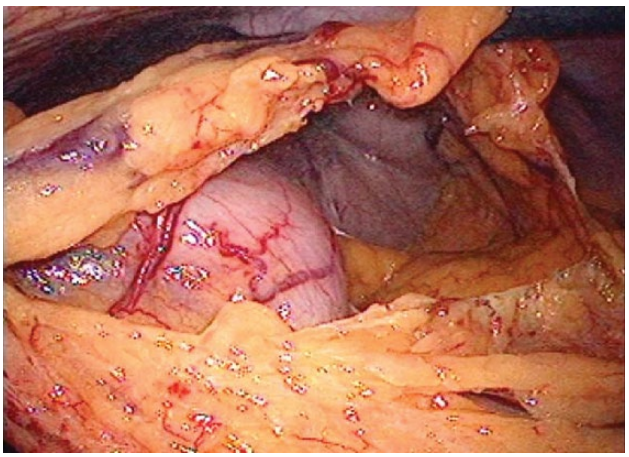

**Figure 101.1** Observation of the lesser sac through a division of the gastrocolic ligament during "extended" staging laparoscopy.

and some parts of the liver surface in dead angles. Since the early era, the lesser sac has been explored by using various techniques [7,8]. In order to explore the lesser cavity during staging laparoscopy, surgeons have to divide the gastrocolic ligament with surgical instruments such as ultrasonic coagulation dissectors or bipolar vessel sealing systems (Fig. 101.1). To visualize the liver surface more thoroughly, the liver must be retracted medially and caudally by retractors and/or atraumatic forceps and the superior, posterior, and lateral surface of the right lobe can be visualized with an angled laparoscope of 30° or 45° or a flexible videoscope. For these maneuvers during "extended" staging laparoscopy, three or four trocars for a laparoscope and laparoscopic surgical instruments are needed [15], while only one or two trocar(s) are used for standard staging laparoscopy. Cytologic examination of peritoneal washing with saline can be done during staging laparoscopy [16] and the role of peritoneal cytology is described later. For the purpose of evaluating tumor involvement around major vessels and detecting subsurface lesions of the liver, laparoscopic ultrasonography is utilized by some surgeons [17]. Furthermore, some interventional procedures can be carried out in conjunction with staging laparoscopy. As examples of interventional staging laparoscopy, a radiographic marker, Visicoil® fiducial, for target tracking radiation therapy can be implanted [18] and the common hepatic artery can be ligated laparoscopically to ensure collateral blood flow from the superior mesenteric artery to the proper hepatic artery via the gastroduodenal artery before a distal pancreatectomy with celiac artery resection for a locally advanced tumor [19] (Fig. 101.2).

## Peritoneal Cytology

Peritoneal cytology is a method of pathocytologic examination to collect spread cells in the ascites or in the liquid after peritoneal cavity lavage with saline and to make a diagnosis of potential spread of cancer cells (Fig. 101.3). In patients with cancers of abdominal organs including the ovary, stomach, and pancreas, peritoneal cytology has been used as a prognostic indicator. Peritoneal cytology can be performed either by laparotomy or laparoscopy [20]. In the Classification of Pancreatic Cancer by the Japan Pancreas Society, it is recommended to gently irrigate the pelvic cavity with 100 mL of saline for peritoneal

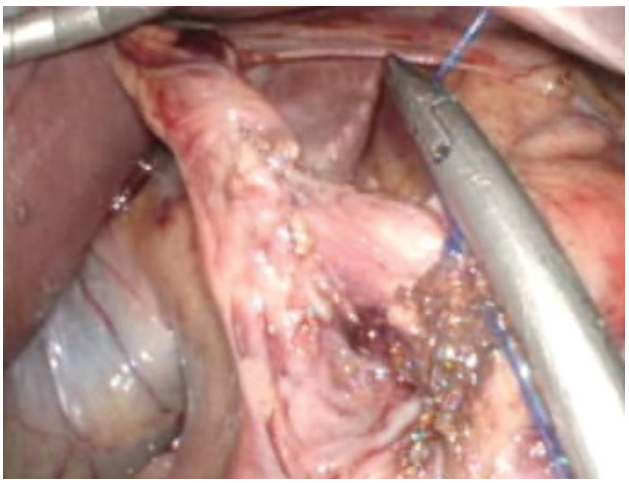

**Figure 101.2** Ligation of the common hepatic artery during interventional staging laparoscopy.

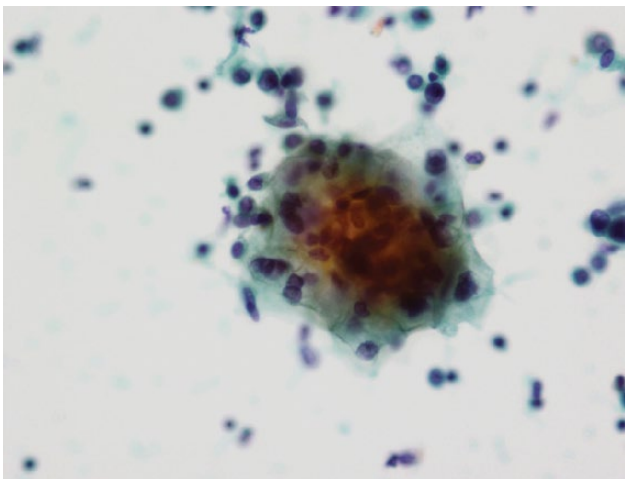

**Figure 101.3** Example of a cell cluster in peritoneal washing fluid. The cluster consists of atypical cells with remarkable nuclear dysplasia and mucin in the cytoplasm, suggesting intraperitoneal spread of cancer cells. (Papanicolaou stain, original magnification × 400)

cytology [21]. Positive peritoneal cytology of pancreatic cancer indicates spread of cancer cells in the peritoneal cavity and is associated with higher incidence of invasion into the anterior pancreatic capsule [22,23]. Accordingly, large tumors are risk factors for positive cytology. It has been well demonstrated that positive cytology is a significant negative prognostic factor [24] and, in the National Comprehensive Cancer Network (NCCN) guidelines, it is stated that positive cytology from washings obtained at laparoscopy or laparotomy is equivalent to M1 (metastatic) disease. However, there are debates about whether or not all positive cytology patients are complicated by peritoneal metastasis. In a cohort of 134 patients who underwent surgical resection after cytologic examinations of peritoneal washings, Yachida et al. have shown that there were no significant differences in cumulative survival rates between patients with negative cytology ($n = 114$) and those with positive cytology but no macroscopic peritoneal metastasis ($n = 19$) [22]. In another cohort of 523 patients with pancreatic cancer including 390 who underwent resection, Yamada et al. demonstrated that multivariable analysis of 12 clinical pathologic parameters including peritoneal cytology identified tumor size, portal vein invasion, plexus invasion, and lymph node metastasis as independent predictive factors but not peritoneal cytology as such [23]. While patients with positive cytology tended to develop peritoneal metastasis, the correlation was not statistically significant and the first site of tumor recurrence in some patients with positive cytology was other than peritoneal metastasis [23]. Thus, positive peritoneal cytology does not directly predict peritoneal metastasis. Besides, there are many long-term survivors who underwent surgical resection despite positive cytology [22,23]. Positive peritoneal cytology may not be a contraindication of surgical resection if the patient can tolerate surgery. Nevertheless, those patients with positive cytology are complicated by more advanced disease and likely to develop systemic metastasis. Therefore, adjuvant treatments for systemic disease are strongly recommended. In the setting of neoadjuvant chemotherapy and neoadjuvant chemoradiation therapy, the significance of peritoneal cytology should be further studied.

# Clinical Assessment and Staging of Advanced Pancreatic Cancer

*Jennifer LaFemina, Ann K. Friedrich, and Giles F. Whalen*

*Division of Surgical Oncology, Department of Surgery, University of Massachusetts Memorial Health Care, Worcester, MA, USA*

## Introduction

Pancreatic adenocarcinoma (PDAC) is now the fourth leading cause of cancer deaths in the United States, with 5-year survival of 7%. Recent data suggests that incidence and mortality rates are increasing [1,2]. Some predict that PDAC will surpass colorectal cancer to become the second leading cause of cancer death by 2020. Unfortunately, because of the vague symptoms at presentation, fewer than 10% of patients will be diagnosed in the earliest stages when tumors are resectable [1].

This chapter serves to highlight the clinical assessment and staging of those who are diagnosed with PDAC with a focus on those diagnosed with advanced cancers.

## Clinical Presentation

The dismal prognosis associated with PDAC is partly related to a lack of symptoms until late in the disease course. The earliest symptoms may be associated with tumor location such as painless jaundice for tumors arising in the head of the pancreas and obstructing the biliary and pancreatic ducts. Earlier signs of biliary obstruction include choleuria, acholic stools, and pruritus. Chronic obstruction of the pancreas can result in exocrine and endocrine insufficiency, manifested by steatorrhea and new/worsening diabetes. Body and tail lesion tumors more commonly result in nonspecific symptoms of abdominal pain that may radiate, appetite loss, weight loss, nausea, and possibly vomiting and consequently, are more likely to be diagnosed at a later stage [3].

Examination can confirm signs of biliary obstruction with scleral icterus and jaundice. For obstructing right-sided tumors, a distended and palpable gallbladder may be appreciated. The presence of ascites, confirmed with a distended abdomen and fluid wave, raises suspicion for peritoneal disease. Involved supraclavicular (Virchow's node) or umbilical (Sister Mary Joseph node) nodes or peritoneal implants found in the pelvic cul de sac on rectal exam (Blummer's shelf lesions) are consistent with metastatic disease.

## Evaluation for Pancreatic Cancer

### Serologic Evaluation

Serologic workup may include a comprehensive metabolic panel inclusive of liver function tests, complete blood count, amylase, lipase, coagulation studies, and albumin. Right-sided tumors may result in biliary obstruction with a conjugated hyperbilirubemia. Elevations in transaminases may be absent or mild. For those who are newly diabetic, hemoglobin $A_{1c}$ ($HbA_{1c}$) may be grossly elevated or demonstrate a rapid rate of rise, similar to those with type 1 diabetes [4].

CA 19-9 is the only FDA-approved serologic tumor marker for PDAC. Initially described in colon cancer, the test is based on a sialyl-Lewis A antigen ($Le^A$) produced by epithelial cells on the surface of erythrocytes and in the mucin produced by pancreatic cancer cells [5]. The sensitivity and specificity is up to 81% and up to 90%, respectively. There is an approximately 10% risk of a false negative (i.e., Lewis-negative patients). False positives occur in the setting of biliary obstruction and pancreatitis [6].

In secretors of the antigen, this marker can serve as a marker of tumor burden to guide management. Studies have demonstrated that preoperative CA 19-9 levels correlate with stage of disease and oncologic outcome. Ferrone et al. suggested that postoperative reduction in

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

CA 19-9 and a postoperative CA 19-9 < 200 U/mL were strong predictors of survival [7]. Evaluation of postresection CA 19-9 within the setting of the phase III trial, RTOG 9704, also supported this finding, reporting a 72% reduction in risk of death in patients with a postresection CA 19-9 < 180 [8]. Others have proposed that a preoperative CA 19-9 130 U/mL is a predictor of unresectability and should prompt a diagnostic laparoscopy [9].

CEA and CA-125 have a limited role in the management of PDAC, though may have utility in patients whose tumors do not secrete the Lewis antigen [10]. Recently published work suggests that panels based on microRNA expression (miR-145, miR-150, miR-223, miR-636, miR-26b, miR-34a, miR-122, miR-126, miR-505, miR-885.5p) were significantly different in patients with PDAC compared to normal controls [11]. Other potential screening tests involve promoter DNA methylation of *BNC1* and *ADAMTS1* [12]. However, no serologic markers beyond CA 19-9 have been approved for PDAC management.

## Radiologic Evaluation

Abdominal ultrasound is the first diagnostic tool commonly employed for a patient with obstructive jaundice and abdominal pain. The study may demonstrate intra- and/or extrahepatic biliary ductal dilation, pancreatic dilation, and possibly a pancreatic mass. However, it has only a limited role in the diagnosis and staging of advanced PDAC except to guide percutaneous biopsy of liver metastases.

A dedicated pancreatic computed tomography (CT) using a multidetector CT with angiography and with thin, axial sections is the preferred method to diagnosis and stage PDAC [1,13]. These scans assess arterial and venous phases using water as the oral contrast agent (Fig. 102.1). CT has a high predictive value for unresectability (up to 100%) but a lower predictive value for resectability, primarily because small liver lesions and peritoneal implants may be missed [14]. The presence of ascites can be an indicator of peritoneal metastases.

Magnetic resonance cholangiopancreatography (MRCP) may be particularly useful in assessing soft tissue contrast and ductal structures, particularly for early tumors that may not be visible on a CT [15]. Additionally, MRCP may better detect small tumors and/or evaluate focal fatty infiltration, a hypertrophied pancreatic head, and isoattentuating pancreatic cancer [16]. MRI may also be used to characterize CT-indeterminate liver lesions or in the setting of patients with an iodinated intravenous contrast allergy.

The utility of positron emission tomography (PET) with [$^{18}$F]-fluoro-2-deoxy-D-glucose (FDG) in assessing stage and resectability for PDAC is unclear. Studies

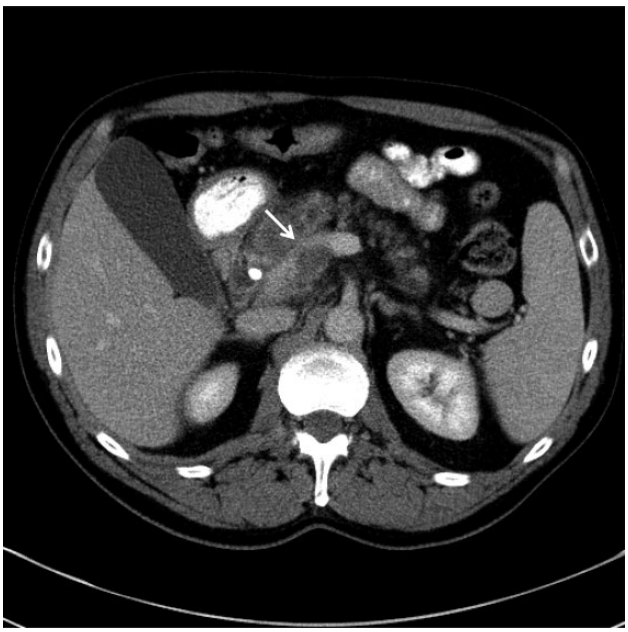

**Figure 102.1** CT pancreatic protocol, with representative venous phases, demonstrating encasement of the portal vein (arrow). This patient's carcinoma was deemed locally advanced as it had not only encasement of the portal SMV, but also nonreconstructable encasement of the hepatic artery.

demonstrate that PET has a lower specificity and positive predictive value compared to CT and MRI [17]. However, it demonstrates a sensitivity and specificity that is superior to that of CT and MRI for evaluation of metastatic disease [17,18]. One may consider PET in specific situations: to assess those at high risk for distant metastatic disease (i.e., large regional lymph nodes, large primary tumors, a markedly elevated CA 19-9, or borderline resectable or locally advanced disease) [19] and to assess response to treatment [20].

## Endoscopic Evaluation and Treatment of Advanced Pancreatic Cancer

Endoscopic techniques, such as endoscopic retrograde cholangiopancreatography (ERCP) and endoscopic ultrasound (EUS), are increasingly utilized for diagnosis and to complement imaging. Historically, ERCP allowed for cytology via brushings. ERCP has been largely replaced by EUS with fine-needle aspiration (FNA) for diagnostic purposes as it offers an opportunity to obtain specimens for histopathology diagnosis, with a sensitivity and specificity of 87% and 96%, respectively [21]. EUS is considered one of the most accurate means by which to diagnose small, focal tumors of the pancreas and is associated with a lower risk of complications, particularly in those with obstructive jaundice, compared to ERCP [20].

Endoscopic procedures remain a mainstay of management for PDAC, particularly for its role in palliating symptoms, such as obstructive jaundice. Endoscopic stenting, with either plastic or metallic stents, is commonly employed at diagnosis to relieve jaundice and pruritus and to permit treatment with neoadjuvant therapy in locally advanced PDAC. Endoscopic stenting has been thoroughly studied in the palliative setting. Studies have demonstrated that in patients presenting with obstructive jaundice due to malignant obstruction and who require palliative decompression, palliative biliary stenting, compared to surgical bypass, is associated with no difference in technical or therapeutic success, fewer total complications, lower procedure-related mortality, greater quality of life scores, and lower total cost. While there are more reocclusions in those stented, total hospital days are reduced in whom stents are employed [22–26]. A recent randomized controlled trial evaluated the cost efficiency of self-expandable metal stents (SEMS) compared to those with plastic stents for palliation. The study demonstrated that while the up-front costs of SEMS are greater than plastic stents, SEMS have a longer functional time and no significant difference in cost at 1 year [27]. Advances in endoscopic technology with regard to approach (transgastric, transduodenal) and techniques (rendez-vous, hepaticogastrostomy, and choledochoduodenostomy) lead to success rates approaching 100% [28]. In the event of failure, hepaticojejunostomy or radiologically placed percutaneous biliary drainage may be considered.

Symptoms attributable to gastric outlet obstruction (GOO) can also be addressed particularly in patients with advanced PDAC. This has been reported to occur in up to 25% of patients with unresectable disease [29]. Mehta et al. found no difference in survival for patients with malignant GOO undergoing laparoscopic gastrojejunostomy versus endoscopic duodenal stent placement. In that study, patients who underwent endoscopic stenting had fewer complications and shorter length of stay, suggesting that duodenal stenting may be preferable to surgical bypass [30].

Lillemoe et al. originally reported that intraoperative celiac plexus neurolysis (CPN), compared to placebo in patients with unresectable PDAC considerably reduced mean pain scores and led to a substantial survival improvement in those patients with significant preoperative pain [31]. With modern imaging, CPN is now more commonly performed endoscopically or radiologically. A recent randomized trial of early EUS-guided CPN demonstrated that early EUS-CPN provided improved pain control for patients with inoperable PDAC with pain and may avoid progressive increase in morphine use [32].

Emerging data is now available evaluating the role of EUS-guided radiofrequency ablation, intratumoral drug delivery, and radiation therapy. Larger studies are needed to determine the safety and impact on survival of these techniques but may serve as future endoscopic options available to patients with advanced PDAC.

### Surgical Evaluation and Treatment in Advanced Pancreatic Cancer

The principal role of surgical evaluation for advanced PDAC is the further assessment of resectability and palliation. Staging laparoscopy with peritoneal washings may be employed prior to neoadjuvant therapy or embarking upon a laparotomy to attempt resection. The presence of positive peritoneal cytology is considered M1 disease.

Surgical bypass with either hepatojejunostomy and/or gastrojejunostomy have been surgical mainstays for palliation of advanced tumors in the head of the pancreas. The incidence of these procedures has decreased in recent years with the emergence of endoscopic stenting. Nevertheless, laparoscopic or open bypass remains a viable palliative option, particularly when endoscopic stenting is not feasible, or when an attempted resection is aborted well into the dissection. Limited data suggest that laparoscopic gastrojejunostomy is feasible and successful, including in situations in which duodenal stenting fails [33]. Laparoscopic gastrojejunostomy seems to be associated with a reduction in time to oral intake and a trend toward reduced delayed gastric emptying and length of stay compared to open operation [34].

Up to 33% of patients who appear resectable by radiologic criteria will be found to have metastatic or unresectable disease at the time of exploration [29]. Early studies suggested that prophylactic bypass at the time of laparotomy reduced the risk of late GOO [35–37]. Contemporary studies suggest prophylactic bypass may not be necessary due to dismal overall survival [38,39]. However, celiac plexus blockade done prophylactically at this time can both improve quality of life and survival [31].

Operative biliary bypass and CPN have been discussed previously.

## Staging for Advanced Pancreatic Cancer

The American Joint Cancer Committee (AJCC) TNM Staging System, Seventh Edition, is a commonly employed staging system for PDAC. The staging system incorporates status as it relates to tumor size (T), regional lymph nodes (N), and the presence/absence of distant metastatic disease (M). The staging correlates with overall survival and, to some extent, with treatment guidelines (Table 102.1).

While the AJCC TNM staging correlates with prognosis (Table 102.1), it does not correlate with treatment guidelines as well since it does not satisfactorily define tumor resectability. It is well established that surgical resection provides the only opportunity for long-term survival for patients with PDAC.

Pancreatologists commonly employ a surgical and radiologic staging system that more properly defines whether tumors are resectable. Originally described by MD Anderson, with modification from the NCCN most recently in 2017, tumors are defined as resectable, borderline resectable, and unresectable, based on relationships to the relevant vascular structures (Table 102.2; Fig. 102.1) [4,19,40,41].

While there is some controversy about the role of neoadjuvant therapy for resectable tumors, patients with borderline resectable PDAC are frequently treated with neoadjuvant chemotherapy and/or chemoradiation followed by restaging and assessment for resection, often requiring a vascular resection and reconstruction [4].

**Table 102.1** Summary of AJCC Staging, 7th edition, with correlation to overall survival.

| TNM staging | Median survival (mo) |
|---|---|
| Stage IA T1N0M0 | 10.0 |
| Stage IB T2N0M0 | 9.1 |
| Stage IIA T3N0M0 | 8.1 |
| Stage IIB T1-3N1M0 | 9.7 |
| Stage III T4N0-1 M0 | 7.7 |
| Stage IV T1-4 N0-1 M1 | 2.5 |

*Source:* Modified from [2,42].

A tumor staged as "locally advanced" in the MD Anderson/NCCN system is unresectable even if not metastatic. There is no role for surgery beyond that for palliation unless the tumor responds dramatically to chemotherapy or chemoradiotherapy. This degree of response occurs less than 10% of the time. The role of radiation in this setting is unclear. The LAP-07 trial evaluated patients with locally advanced PDAC with stable or responsive disease after 4 months of chemotherapy (gemcitabine ± erlotinib). Patients were randomized to chemoradiotherapy compared to ongoing chemotherapy. There was no difference in overall survival reported [43]. Recently multidrug regimens (FOLFIRNOX and gemcitabine-*nab*-paclitaxel) have produced favorable responses in the locally advanced setting, similar to what is seen in the Stage IV disease [44]. These chemotherapy regimens are now considered the standard for systemic treatment of Stage IV PDAC because they have improved median survival as well as quality of life and global health status, compared to best supportive care and gemcitabine [45,46].

An understanding that a tumor is locally advanced or metastatic may also appropriately lead to management decisions involving palliative care. Temel et al. published a landmark randomized study evaluating patients with newly diagnosed nonsmall cell lung cancer and demonstrated that early palliative care resulted in significant improvements in quality of life, mood, and survival (in spite of less aggressive interventions) [47]. While there are no studies of its kind evaluating the role of early palliative care in the setting of advanced PDAC, some institutions do employ an early palliative care approach, particularly in the locally advanced and metastatic settings to achieve a balance of quality of life and survival.

## Conclusion

In spite of extensive research in PDAC, it remains a highly lethal malignancy in part due to the high percentage of patients presenting with advanced tumors at diagnosis.

**Table 102.2** Surgical staging system of NCCN and MD Anderson.

| Stage | Superior mesenteric artery (SMA) | Celiac axis (CA) | Hepatic artery (HA) | Superior mesenteric vein (SMV)/portal vein (PV) |
|---|---|---|---|---|
| Resectable | No contact | No contact | No contact | No contact with SMV/PV or ≤180° contact without irregularity |

*Criteria as noted or with distant metastases.

Management of these patients involves a comprehensive clinical, radiologic, and endoscopic approach to define the tumor and stage. Treatment involves a multidisciplinary approach, and many times, the tools employed for clinical workup, as summarized here, can also be extrapolated for palliative care of symptoms in the advanced setting.

# Surgical Treatment of Pancreatic Cancer

## 103

## Pancreatic Cancer: Indications for Resection

*Akimasa Nakao*

*Nagoya University and Nagoya Central Hospital, Nagoya, Japan*

## Introduction

Pancreatic cancer has the worst prognosis of all gastrointestinal neoplasms. An estimated 39,590 people will die of pancreatic cancer during 2014 in the United States [1]. This type of cancer is the fourth most common cause of death among the malignant neoplasms in the United States and Japan. The prognosis of pancreatic cancer is still poor, despite developments in surgical techniques and chemotherapy. Surgical resection offers the only possibility of a cure. The morbidity and mortality of pancreaticoduodenectomy (PD) were high about 30–40 years ago. However, the morbidity and especially the mortality of PD have been greatly reduced, and operative mortality rates had fallen to 2.8% in 2014 in Japan [2].

## Clinical Criteria for Resection

### Age and Concomitant Diseases

The peak incidence of pancreatic cancer occurs in the seventh and eighth decades of life. In our experience and that of high-volume centers, the morbidity and especially the mortality of pancreatic resection have been greatly reduced, and there is no difference in mortality rates between patients >70 years of age and those <70 years of age [2,3]. Patient age, comorbidity, performance status, and frailty are all topics for discussion during multidisciplinary review. One of the few medical contraindications for PD is liver cirrhosis with ascites and portal hypertension.

### Diagnosis and Staging

Diagnosis of pancreatic cancer will be discussed in another chapter. Preoperative staging is usually performed with multidetector computed tomography (MDCT) [4,5]. Endoscopic ultrasound (EUS) is also sometimes used in staging and diagnosis of pancreatic cancer. Laparoscopy is another potentially valuable diagnostic tool for cancer staging.

### Biopsy

Confirmation of the malignancy by biopsy is considered necessary before proceeding with surgical resection. Histologic diagnosis of adenocarcinoma of the pancreas is often made using fine-needle aspiration biopsy with either CT or EUS guidance. Pancreatic ductal blushing or biopsies can also be obtained at the time of endoscopic retrograde cholangiopancreatography. However, histologic or cytologic diagnosis of the malignancy is not required before surgical resection when the clinical suspicion of pancreatic cancer is high.

### Tumor-Associated Antigens

Tumor-associated antigens, such as carcinoembryonic antigen, carbohydrate antigen (CA) 19-9, DU-PAN-2, and SPan-1 have been studied in connection with pancreatic adenocarcinoma. CA 19-9 1000 U/mL may correlate with distant metastasis or unresectable tumor in pancreatic cancer [6].

## Surgical Criteria for Resection

### Preoperative Staging for Extent of Disease

There are no universally accepted criteria for resection. However, it is clear that patients with hepatic, peritoneal, and pleural metastases derive no benefit from resection. Therefore, preoperative staging to assess the extent of disease is important. The initial staging procedure is MDCT with contrast imaging [4,5]. This technique is reported to predict a high resectability rate. Factors contraindicating resection are extrapancreatic disease, obstruction of portal or superior mesenteric veins, and direct tumor extension to the celiac axis and superior mesenteric artery (SMA), which are assessed by MDCT. It is generally convenient to consider a clinical staging system based on whether the disease is resectable or borderline resectable, locally advanced unresectable, or disseminated. The criteria defining resectability status according to National Comprehensive Cancer Network (NCCN) Guidelines (Table 103.1) are generally used [7]. EUS is believed to be complementary to CT, providing additional information for patients in whom CT shows no lesions, or who have questionable involvement of major vessels or lymph nodes. Laparoscopy can reveal peritoneal or hepatic metastasis that might be missed even with the use of MDCT.

## Surgery for Pancreatic Cancer

The ideal operation for pancreatic cancer is isolated pancreatectomy. "Isolated" means en bloc resection using a non-touch isolation technique. It is easy to perform isolated distal pancreatectomy for cancer of the pancreatic body or tail compared with isolated PD. Isolated PD is difficult because of the complex vascular anatomy of the pancreas head region. However, isolated PD is also possible using a mesenteric approach [8], and catheter bypass of the portal vein [9] if necessary. Indication for

**Table 103.1** Criteria defining resectability status.

| Resectability status | Arterial | Venous |
|---|---|---|
| Resectable | No arterial tumor contact (celiac axis [CA], superior mesenteric artery [SMA], or common hepatic artery [CHA]). | No tumor contact with the superior mesenteric vein (SMV) or portal vein (PV) or ≤180° contact without vein contour irregularity. |
| Borderline resectable | Pancreatic head/uncinate process:<br>• Solid tumor contact with CHA without extension to celiac axis or hepatic artery bifurcation allowing for safe and complete resection and reconstruction<br>• Solid tumor contact with the SMA of ≤180°<br>• Presence of variant arterial anatomy (ex: accessory right hepatic artery, replaced right hepatic artery, replaced CHA and the origin of replaced or accessory artery) and the presence and degree of tumor contact should be noted if present as it may affect surgical planning.<br>Pancreatic body/tail:<br>• Solid tumor contact with the CA of ≤180°<br>• Solid tumor contact with the CA of ≥180° without involvement of the aorta and intact and uninvolved gastroduodenal artery (some members prefer this criteria to be in the unresectable category). | • Solid tumor contact with the SMV or PV of >180°, contact of ≤180° with contour irregularity of the vein or thrombosis of the vein but with suitable vessel proximal and distal to the site of involvement allowing for safe and complete resection and vein reconstruction.<br>• Solid tumor contact with the inferior vena cava (IVC). |
| Unresectable | • Distant metastasis (including nonregional lymph node metastasis).<br>*Head/uncinate process*:<br>• Solid tumor contact with SMA >180°<br>• Solid tumor contact with the CA >180°<br>• Solid tumor contact with the first jejunal SMA branch.<br>*Body and tail*:<br>• Solid tumor contact of >180° with the SMA or CA<br>• Solid tumor contact with the CA and aortic involvement. | *Head/uncinate process*:<br>• Unreconstructible SMV/PV due to tumor involvement or occlusion (can be due to tumor or bland thrombus)<br>• Contact with most proximal draining jejunal branch into SMV.<br>*Body and tail*:<br>• Unreconstructible SMV/PV due to tumor involvement or occlusion (can be due to tumor or bland thrombus). |

total pancreatectomy or PD in pancreatic head cancer is one of the key problems in pancreatic cancer surgery. Recent studies using histopathologic and immunohistochemical analysis of total pancreatectomy specimens have clarified that carcinoma development from head to body or tail of the pancreas is continuous [10–12]. Therefore rapid intraoperative histopathologic diagnosis using frozen sections is important for diagnosis of intrapancreatic carcinoma development, for PD for pancreatic head cancer as well as distal pancreatectomy for pancreatic body or tail cancer [13]. Pylorus-preserving PD was intended to improve delayed gastric emptying and provide nutritional benefit [14]. However, no consistent data suggest that pylorus preservation leads to better quality of life or nutritional status after resection [15]. The superiority of laparoscopic or robotic surgery compared with open surgery for pancreatic cancer has not yet been clarified surgically and oncologically.

## Local Invasion

Invasion of the distal bile duct, duodenum, stomach, or mesocolon can often be dealt with by en bloc resection. The retroperitoneal margin, which includes the connective tissues behind the pancreas and those adjacent to the SMA, which are composed of extrapancreatic nerve plexuses, is often involved with a tumor. The mesenteric approach is ideal to obtain surgical free margins at this location. A negative margin is an important prognostic factor in survival [16,17].

## Extrapancreatic Nerve Plexus Invasion

Pancreatic carcinoma often invades the extrapancreatic nerve plexus [18–20]. There is no clear explanation for invasion of the extrapancreatic nerve plexus in the Union for International Cancer Control classification [21]. In the Japan Pancreas Society classification [22], the precise anatomy of the extrapancreatic nerve plexus is explained (Fig. 103.1). The grade of intrapancreatic neural invasion correlates with extrapancreatic nerve plexus invasion, and the manner of neural invasion has no relationship with lymph node metastasis [20]. In pancreatic head carcinoma, complete dissection of the extrapancreatic nerve plexus, especially the second portion of pancreatic head nerve plexus, is necessary to obtain a carcinoma-free surgical margin (Fig. 103.2). However, complete resection of the nerve plexus around the SMA causes severe diarrhea after surgery, and the prognosis for pancreatic carcinoma invading the extrapancreatic nerve plexus is poor [16]. The main cause of carcinoma-positive surgical margins is

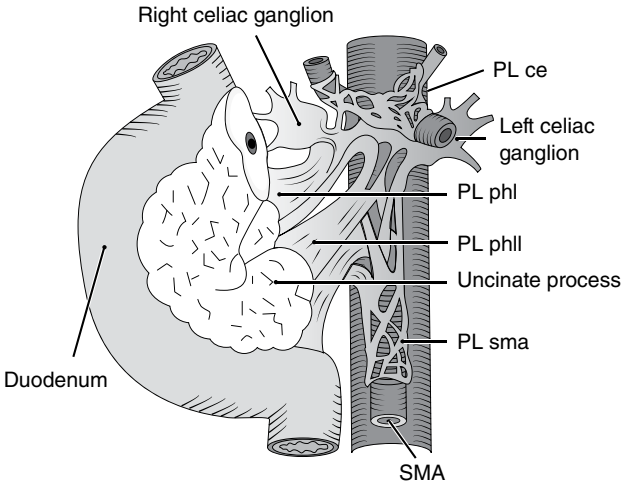

**Figure 103.1** Extrapancreatic nerve plexus (Japan Pancreas Society, Classification of Pancreatic Carcinoma, 3rd English edn, 2011). PL ce, celiac plexus; PL phI, first portion of pancreatic head nerve plexus; PL phII, second portion of pancreas head nerve plexus; PL sma, nerve plexus around the superior mesenteric artery; SMA, superior mesenteric artery.

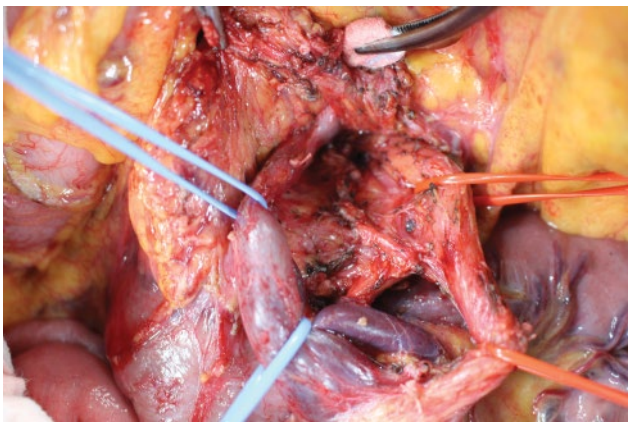

**Figure 103.2** Exposure of the mesopancreas (second portion of the pancreatic head nerve plexus) using the mesenteric approach. The nerve plexus around the superior mesenteric artery is completely preserved in this case.

extrapancreatic nerve plexus invasion [16,18,20]. The term mesopancreas has been used recently [23]. However, it is better to use the second portion of pancreatic head nerve plexus (PLphII) instead of mesopancreas (Fig. 103.3).

## Vascular Invasion

Cancer invasion of the superior mesenteric and portal veins is common in pancreatic head cancer. Over the past 35 years, the operative mortality rate of PD combined with portal vein resection has decreased, and portal vein resection in pancreatic cancer surgery has become a safe procedure [24].

From 1981 to 2014, 463 patients with pancreatic carcinoma underwent tumor resection in our department, and vascular resection was performed in 297 (64.1%) of these. Arterial resection with portal vein resection was undertaken in 16 patients. Operative mortality was 2.4% (11/463) in resected patients, 0.6% (1/166) in patients without vascular resection, 1.8% (5/281) in patients with portal vein resection without arterial resection, and 31.3% (5/16) in patients with portal plus arterial resection. Survival in patients is shown in Fig. 103.4 [24]. The combined portal and arterial resection group had a high operative death rate, more advanced stage, and high incidence of positive carcinoma invasion on the dissected peripancreatic margin. Carcinoma invasion to the SMA, celiac artery, and common hepatic artery is a contraindication for resection [25]. One of the exceptions is pancreatic body cancer that invades the celiac axis. This cancer should be resected by distal pancreatectomy with celiac axis resection [26]. Vascular resection is indicated when carcinoma-free surgical margins are necessary. There is no indication for extended resection in patients in whom surgical margins will become cancer positive if such an operation is done.

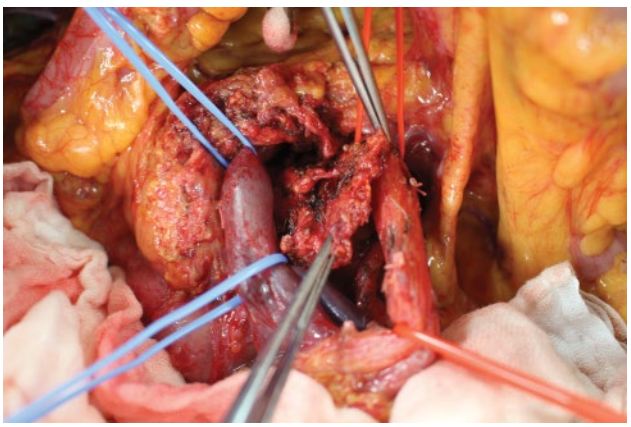

**Figure 103.3** Total mesopancreas excision along the superior mesenteric artery.

## Lymph Node Metastases

Lymph node dissection is one of the important components in pancreatic cancer surgery. The high incidence of 56–77% [27–30] in resected specimens of pancreatic cancer is the reason for extensive dissection of lymph nodes in pancreatic cancer surgery. There are few reports about para-aortic lymph node metastasis: the incidence of para-aortic lymph node metastasis in pancreatic head carcinoma is reported to be 16% [29] and 26% [30], while that in pancreatic body and tail carcinoma is reported to be 13% [31] and 17% [32], respectively. Although the efficacy of extended lymph node dissection in pancreatic cancer surgery was suggested, this issue was not clarified in recent prospective controlled studies [33–37] for pancreatic cancer surgery. The extended dissection of lymph nodes, including para-aortic lymph nodes, should not be considered as a routine part of PD, and although it does not contribute to survival, it does allow accurate staging.

## Peritoneal Metastases

Peritoneal dissemination is frequent in pancreatic cancer and is one of the contraindications for resection. Peritoneal metastases are too small to diagnose by CT or ultrasound, if the patients have no ascites. Therefore, diagnosis of peritoneal dissemination is done by direct visualization using laparoscopy or at the time of surgical exploration. Using conventional staining, the incidence of cancer cells ranges from 0% to 17% [38–42]. However, high incidences of 58% [43], 39% [44], and 22% [42] have been reported by immunocytochemical staining using monoclonal antibodies against tumor-associated antigens and cytokeratins. Controversy exists about prognosis with regard to positive and negative cytology [45]. Further study is necessary to determine whether positive cytology without macroscopic dissemination from washings

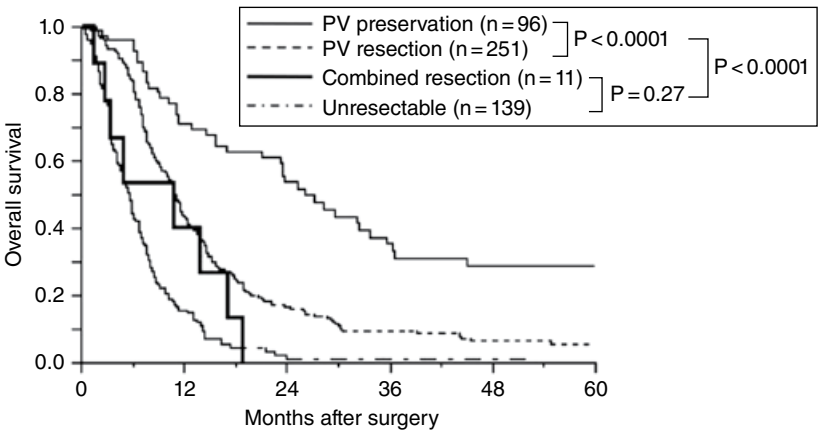

**Figure 103.4** Cumulative survival rates of the portal vein (PV) preservation and resection groups. Combined resection means the group with both portal vein and artery resection. *Source:* Nakao et al. 2012 [24]. Reproduced with permission of Wolters Kluwer Health.

obtained at laparoscopy or at the time of surgical exploration is a contraindication for resection.

## Liver Metastases

Liver metastases are also common in pancreatic cancer, and survival is so short that resection of the primary tumor is contraindicated. Metastases are usually multiple, and there are no data showing longer survival by pancreatectomy, with or without resection of liver metastases.

## Other Distant Metastases

Occasional distant metastases to the lungs, bone, and supraclavicular lymph nodes are also contraindications for resection of a primary tumor.

## Effect of Clinical Volume

Several studies have reported the effect of institutional volume on patient outcomes. In 1995, Lieberman et al. [46] assessed 1972 pancreatectomies, including total pancreatectomy, from 184 institutions in New York State. High-volume centers with >40 cases per year had significantly less mortality than low-volume centers (4% vs. 12.3%). Several other studies have also reported decreased mortality, length of hospital stay, and overall cost at high-volume compared with low-volume centers [47–49]. Furthermore, negative margin status and 5-year survival rates are higher in high-volume centers [50]. The definition of high and low volume varied among all these studies. The NCCN Panel recommendation is that pancreatic resections should be done at institutions that perform at least 15–20 cases of pancreatic resections annually [7].

# Pancreaticoduodenectomy for Pancreatic Cancer, Short- and Long-Term Outcomes After Kausch–Whipple and Pylorus-Preserving Resection

*Jin He and John L. Cameron*

*Department of Surgery, The Johns Hopkins Medical Institutions, Baltimore, MD, USA*

## Introduction

Dr. William Stewart Halsted performed the first successful resection of a periampullary tumor in 1898 [1,2]. The first successful regional resection of the head of the pancreas was performed by Kausch and was reported in 1912 [3]. The operative procedure of pancreaticoduodenectomy was popularized by Whipple, when he presented three patients to the American Surgical Association in 1935 [4,5]. During this era, and extending into the 1970s, pancreaticoduodenectomy was performed only infrequently because of a hospital mortality in the range of 25% [6]. Beginning in the 1980s, and extending up until the present, pancreaticoduodenectomy has become a safe procedure, performed in virtually any age group in high-volume centers, with a hospital mortality rate less than 5% [2,7,8]. The 30-day mortality in our hospital has been below 1% over the last decade [9].

Pancreatic cancer (PDAC) is a common cause of cancer death and is difficult to treat because of late presentation, disease heterogeneity, and treatment resistance. Long-term overall survival remains poor with a 5-year survival rate of 5% and virtually unchanged over the last three decades. For PDAC in the head of the pancreas, pancreaticoduodenectomy with curative intent is the only treatment modality that offers a chance of cure. With the development of effective neoadjuvant chemotherapy and significantly reduced surgery-related mortality, more patients with PDAC will have a chance for pancreaticoduodenectomy.

An accurate diagnosis of PDAC is required before any treatment plan. High-resolution computed tomography (CT) with pancreas protocol is the choice of imaging. Tissue diagnosis is necessary if neoadjuvant chemotherapy is part of the treatment plan. This can be achieved by endoscopic ultrasound (EUS) guided fine-needle aspiration (FNA).

The definition of resectability is categorized in Table 104.1. PDAC without visible distant metastasis is classified as resectable, borderline resectable (BRPC), or locally advanced cancer (LAPC) based on the preoperative CT imaging.

Several randomized studies have shown equivalent outcome between pylorus-preserving pancreaticoduodenectomy and the classic Whipple procedure [10,11]. In this chapter, we will discuss the short- and long-term outcomes after pancreaticoduodenectomy (classic and pylorus-preserving) for pancreatic cancer.

## Short-Term Outcome

Approximately 20% of patients with PDAC present with resectable disease. Surgery with curative intent should achieve an R0 resection with negative margins. The 5-year overall survival rate for all-comers after a successful resection is approximately 20% and is higher for those with negative nodes and margins [9].

Whether patients with borderline resectable pancreatic cancer (BRPC) will benefit from neoadjuvant chemotherapy remains controversial [12]. Konstantinidis et al. showed that patients undergoing an R1 resection have an improved survival compared with patients with locally advanced unresectable pancreatic cancer. Survival after resections with a 1 mm margin or less (169 patients) was similar to R1 resections (157 patients) [13]. There are currently two Alliance trials on the topic of the benefit of neoadjuvant chemotherapy and/or radiation therapy (A201101 and A201501). We are expecting results of these randomized clinical trials in a few years. These hopefully will settle the controversy over neoadjuvant treatment for patients with BRPC.

**Table 104.1** Definition of resectability of pancreatic cancer.

| | Resectable | Borderline resectable | Locally advanced |
|---|---|---|---|
| **MD Anderson** | SMV/PV abutment or encasement w/o occlusion; No abutment of SMA/CHA/celiac | SMV/PV short segment occlusion; Abutment of SMA/CHA/celiac | SMV/PV not reconstructible; Encasement of SMA/CHA/celiac |
| **NCCN** | SMV/PV no abutment; SMA/CHA/celiac no abutment | SMV/PV abutment, short segment occlusion but reconstructible; Abutment of SMA/CHA; No abutment of celiac | SMV/PV not reconstructible; Encasement of SMA/CHA/celiac |

CHA, common hepatic artery; NCCN, National Comprehensive Cancer Network; PV, portal vein; SMA, superior mesenteric artery; SMV, superior mesenteric vein.
Abutment: less than 180° of vascular circumference.
Encasement: more than 180° of vascular circumference.

Locally advanced pancreatic cancer (LAPC) is often treated with systemic neoadjuvant chemotherapy with the hope of a surgical resection. Case reports [14] and small series have been published showing the feasibility of surgical resection of LAPC after neoadjuvant chemotherapy. Faris et al. reported 22 patients with LAPC treated with FOLFIRINOX (5-fluorouracil [5-FU], oxaliplatin, irinotecan, and leucovorin). Five patients (23%) subsequently underwent R0 resections. Although the chemotherapy was associated with a 23% conversion to resectability, 3 of these 5 patients had distant metastasis by 5 months [15]. Ferrone et al. reported 40 patients with BRPC/LAPC who received FOLFIRINOX and surgery. Although 19 patients still had LAPC after FOLFIRINOX, 35 patients (92%) had R0 resections. The short-term outcomes such as length of stay, readmission, and mortality rate were similar when compared with patients with no neoadjuvant FOLFIRINOX [16]. Bickenbach et al. reported 36 resected patients with LAPC who received neoadjuvant chemotherapy. Their median overall survival was similar to those who presented with resectable PDAC [17]. Kadera et al. summarized their experience of 49 patients with LAPC. After a median of 7 months of neoadjuvant chemotherapy, 37 of 49 patients were lymph node negative (75.5%) and 42 (85.7%) had negative resection margins. They reported 45.8% with a complete pathologic response, the highest in the literature [18]. In a systemic review of 57 studies (median BRPC/LAPC patients per study = 27), Gillen et al. reported that 33.2% of patients were resected after neoadjuvant therapy. Resection after neoadjuvant chemotherapy or chemoradiation appears to give patients similar overall survival rates as those with resectable PDAC [19].

Regardless of the indications for pancreaticoduodenectomy as discussed earlier (resectable vs. BRPC vs. LAPC), factors affecting the short-term surgical outcome include patient age, history of neoadjuvant therapy, vessel resection and reconstruction, extension of lymph node dissection, and methods of reconstruction. These factors will be discussed here:

- Compared with age <80 years, patients aged 80 or over are associated with higher morbidity (55% vs. 44%) and hospital mortality (4% vs. 1%) [2]. Younger patients (<45 yrs) have fewer complications after curative resections and better survival compared with older patients (over 70 yrs) [20].
- History of neoadjuvant therapy has been associated with lower operative morbidity. Ferrone et al. reported no pancreatic fistula in her series of 40 patients with BRPC/LAPC who received FOLFIRINOX and surgery [16]. Motoi et al. reported a large series of 388 patients who received neoadjuvant therapy. There were no significant differences in postoperative morbidity rate between the neoadjuvant and no neoadjuvant groups [21].
- Resection of the portal vein/superior mesenteric vein is occasionally necessary to achieve an R0 resection. Riediger et al. reported their experience in 53 patients with vein resection. Thirty-two percent were segmental resections; 40% had no tumor infiltration of the vein on final pathology. Compared with patients without vein resection, patients with vein resection had similar morbidity rates (23 vs. 35%) [22].
- Arterial resection and reconstruction after neoadjuvant chemotherapy may be required to achieve an R0 resection. The most common resected artery during pancreatectomy is the celiac axis. The procedure came to be known as the modified Appleby procedure where a distal pancreatectomy and splenectomy with en bloc celiac axis resection is performed, and arterial perfusion of the liver is maintained by retrograde collateral blood flow from the superior mesenteric artery (SMA) via the gastroduodenal artery (GDA). Numerous small series have shown the safety and feasibility of this surgery [23–28]. The short-term outcome including postoperative morbidity of the modified Appleby procedure is similar to that of distal pancreatectomy.
- Hepatic artery and SMA are infrequently resected during pancreaticoduodenectomy because of the technical challenge of arterial reconstruction and poor

short-term outcome. Rehders et al. reported their experience with arterial vascular resection for PDAC and argued that arterial vascular involvement is an indicator of unfavorable topography, instead of adverse tumor biology. They claimed vascular resection is warranted if an R0 resection can be achieved by experienced surgeons [29]. Although a few small series have shown the safety of an en bloc resection of the hepatic artery or SMA [30], the benefit has not been proved by any large study or meta-analysis [31].

- Extended lymphadenectomy is not widely utilized as many randomized trials and systemic reviews have shown no benefit and more postoperative complications [32–36].
- After resection, pancreaticojejunostomy is preferred at our hospital. Postoperative pancreatic fistula (POPF) can be significantly reduced by meticulous anastomosis with optimization of blood supply at the pancreaticojejunostomy [37].

In our recent series of pancreaticoduodenectomy for 1,687 patients with PDAC, the overall complication rate was 41%, with the most common complications including delayed gastric emptying (DGE) (16%), wound complications (11%), and POPF (6%) (Table 104.2) [9]. DGE and wound complications are often related to POPF. In the absence of POPF, the management of DGE is mainly supportive. A nasogastric tube is often used to decompress the stomach. Parental nutrition support is necessary. Patients with DGE might benefit from prokinetics such as metoclopramide and erythromycin. The antecolic location of gastrojejunostomy has been shown to reduce the incidence of DGE in several publications [38,39]. In a recent series of 160 pancreaticoduodenectomies, Nakamura et al. showed a side-to-side anastomosis of gastrojejunostomy on the greater curvature could significantly reduce the incidence of DGE (2.5% vs. 21% from end-to-side anastomosis) [40]. It seems that an antecolic side-to-side gastrojejunostomy has the lowest chance of DGE in our practice.

**Table 104.2** Trends of the three most common postoperative morbidities after Whipple for pancreatic cancer.

| | POPF | DGE | Wound complications |
|---|---|---|---|
| 1980s ($n$ = 66) | 0 (0%) | 2 (3%) | 1 (2%) |
| 1990s ($n$ = 507) | 18 (4%) | 74 (15%) | 33 (7%) |
| 2000s ($n$ = 1115) | 75 (7%) | 190 (17%) | 151 (14%) |
| Total ($n$ = 1688) | 93 (6%) | 266 (16%) | 185 (11%) |

DGE, delayed gastric emptying; POPF, postoperative pancreatic fistula.

## Long-Term Outcome

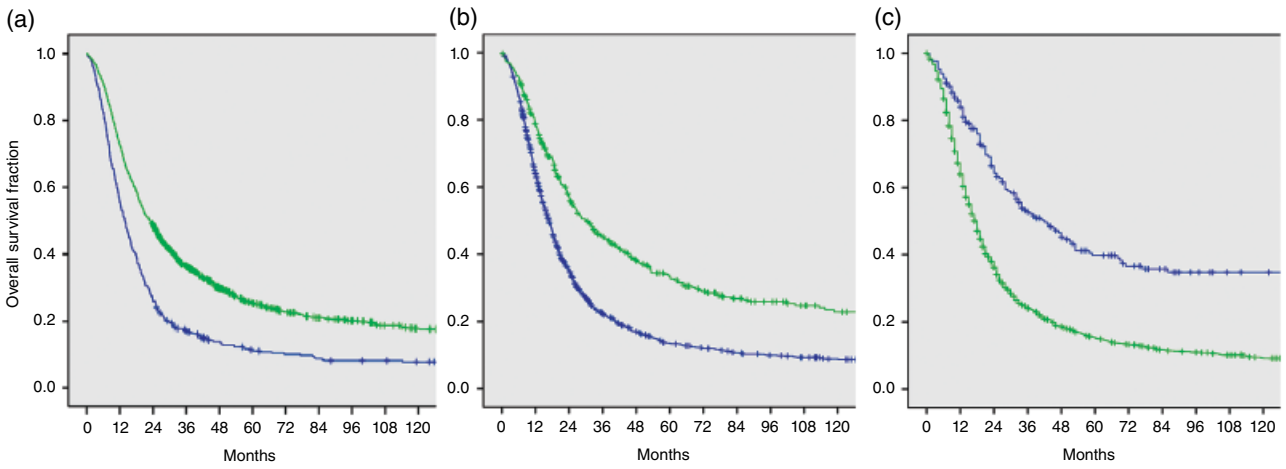
Long-term overall survival after Whipple surgery for patients with PDAC is not optimistic. Although the 30-day mortality after Whipple surgery has been low at 1% since the 1990s, the median survival for PDAC remained at 19 months in our recent analysis of PDAC patients from 1981 to 2011 [9]. In this series of 1,687 patients with PDAC, resection margin status and lymph node positivity were associated with overall survival (Fig. 104.1). For those patients with negative resection margin and negative lymph node metastasis, the estimated overall survival was 42 months compared with 18 months for patients with either positive margin or nodal metastasis.

The commonly used prognostic factors for 5-year survival include tumor size, lymph node status, margin status, tumor differentiation, lymphovascular and perineural invasion, and adjuvant chemotherapy. Whether these factors can predict the 10-year survival rate remains unknown. We reviewed the clinicopathologic characteristics of patients who underwent pancreatectomy for PDAC at the Johns Hopkins Hospital between 01/2000 and 12/2010. The estimated disease-specific survival at 5 and 10 years was 20.4% and 15.1%, respectively. Using the Aalen's linear hazards model to study time-varying effect, the commonly used prognostic factors for 5-year survival were not important for survival after 5 years. Among 119 patients who survived >5 years, 30 (25%) had positive margins, 13 (11%) had tumor size >4 cm, 8 (7%) had >5 positive nodes, 36 (30%) had poor tumor differentiation, 38 (32%) had lymphovascular invasion, and 95 (80%) had perineural invasion. Among 27 patients who survived >10 years, 8 (30%) had positive margins, 4 (15%) had tumor size >4 cm, 2 (7%) had >5 positive nodes, 12 (44%) had poor tumor differentiation, 6 (22%) had lymphovascular invasion, and 24 (89%) had perineural invasion. The reported prognostic factors for PDAC are time-dependent and restricted to the first 5 years following pancreatectomy.

Completion of the full course of adjuvant chemotherapy was an independent prognostic factor for survival, but time to treatment initiation after surgery was not [41].

Neoadjuvant chemotherapy has significantly increased the chance of resection of PDAC. Although no phase 3 trial data has been published about the use of neoadjuvant chemotherapy in PDAC, neoadjuvant chemotherapy and/or chemoradiation therapy is widely used especially for patients with BRPC/LAPC [15,16,42].

A meta-analysis of more than 4,000 patients with PDAC showed that 32% of patients with locally advanced disease would have surgical resection after neoadjuvant chemoradiation therapy. The survival rate is similar to patients with resectable disease [19]. The most commonly



| | Margin positive ($n=440$) | Margin negative ($n=1247$) | Node positive ($n=1277$) | Node negative ($n=410$) | Margin/Node negative ($n=214$) | Other ($n=1473$) |
|---|---|---|---|---|---|---|
| Median overall survival (months) | 14 | 23 | 17 | 30 | 42 | 18 |

(a) Overall survival of PDAC patients with margin negative resection (green line) vs. margin positive resection (blue line). (median survival 23 vs. 14 months, $P<0.001$)
(b) Overall survival of PDAC patients with negative lymph node metastasis (green line) vs. positive lymph node metastasis (blue line). (median survival 30 vs. 17 months, $P<0.001$)
(c) Overall survival of PDAC patients with negative lymph node metastasis and negative margin (blue line) vs. other (green line). (median survival 42 vs.18 months, $P<0.001$)

**Figure 104.1** Overall survival curve of patients with PDAC.

used regimen for neoadjuvant chemotherapy is FOLFIRINOX if the patient has good performance status. The rationale to use FOLFIRINOX is based on the data extrapolated from the metastatic setting where FOLFIRINOX showed better improvements in both median progression-free survival (PFS) (6.4 months vs. 3.3 months; $P<0.001$) and median overall survival (11.1 months vs. 6.8 months; $P<0.001$) compared to gemcitabine [43].

Another regimen for neoadjuvant chemotherapy is gemcitabine and nab-paclitaxel. This is also based on the data extrapolated from the metastatic setting where the combination of both drugs improved overall survival (8.7 months vs. 6.6 months; $P<0.0001$; HR, 0.72) and PFS [44].

Several national trials are enrolling patients with resectable PDAC (SWOG S1505), BRPC (Alliance A201101 and A201501), or LAPC (RTOG 1201) to determine the benefit of neoadjuvant chemotherapy and/or radiation. A phase 2 study of FOLFIRINOX plus a short course of radiation therapy is being explored in the neoadjuvant setting to determine the rate of R0 resection (NCT01591733). We are expecting level 1 evidence in the next few years regarding the benefit of neoadjuvant chemotherapy and/or radiation therapy.

Recently, stereotactic body radiotherapy (SBRT) has been used for patients with BRPC/LAPC in both neoadjuvant and adjuvant settings [45]. SBRT can deliver a high dose of radiation to the tumor area while sparing radiation damage to surrounding tissue [46]. SBRT targeting of the tumor bed outlined by surgical clips is being explored in a prospective single-arm clinical trial in combination with a pancreatic tumor cell vaccine and FOLFIRINOX in the adjuvant setting (NCT01595321) [45]. Chuong et al. reported the combination of gemcitabine, docetaxel, and capecitabine (GTX) and SBRT in 57 patients with BRPC. Of these patients, 32 (56.1%) underwent successful surgical resection, with a 96.9% rate of R0 resection, a 9.4% rate of pathologic complete response, and a median overall survival (OS) of 19.3 months [47]. Whether the benefit of using SBRT to achieve better local control can be translated into longer overall survival is still unknown.

Other surgical factors affecting the long-term outcome of pancreaticoduodenectomy may include margin status and vessel resection/reconstruction. Data have shown if an R0 resection is obtained with vein excision, overall survival appears similar to those with R0 resections without venous involvement, with no significant increase in morbidity and mortality [48]. Venous involvement is an

indicator of tumor location rather than aggressive tumor biology. Kelly et al. reported the experience of 71 patients with vein resection. The long-term outcome is not worse for patients with Whipple and vein resection compared with patients who had Whipple without vein resection (overall survival 12 vs. 19 months; $P = 0.05$) [49]. Tseng et al. reported a similar experience of 110 patients who underwent Whipple with vein resection. Median survival was 23.4 months in the group that required vein resection and 26.5 months in the group that underwent standard Whipple surgery ($P = 0.177$) [50].

Although retrospective studies have shown that in selected patients Whipple with vein resection can achieve low mortality and median survival of 2 years, aggressive resection with both arterial and venous resection and reconstruction does not lead to long-term survival [31,51].

Although data are rare, prospective data are being collected for patients with limited liver metastasis (less than 3) and response to a full course of neoadjuvant chemotherapy (6 months). The outcome of these patients who are treated with diagnostic laparoscopy and then surgical resection is pending.

## Future Trends

Minimal invasive pancreaticoduodenectomy including total laparoscopic [52,53] or robotic-assisted approach [54,55] has shown promising short-term outcomes such as shorter hospital stay and faster recovery. This could be translated into timely adjuvant chemotherapy. Total laparoscopic approach has also been shown to have a longer PFS compared to that of open pancreaticoduodenectomy. Early detection, minimal invasive surgery, and more effective chemotherapy will lead to a better outcome for patients with PDAC in the future.

# Left Pancreatectomy for Body and Tail Cancer

*Georgios Gemenetzis and Christopher L. Wolfgang*

*Department of Surgery, Johns Hopkins University School of Medicine, Baltimore, MD, USA*

## Introduction

Patients with cancer of the pancreatic body and tail typically present in a more advanced stage, because of the initial lack of symptoms. By the time clinical signs occur, disease is usually present outside of the pancreatic parenchyma and infiltration of adjacent vascular structures or organs is often observed [1]. Moreover, lymphatic metastasis in locoregional lymph nodes and dissemination to distant organs may also be present at the time of diagnosis, leading to less than 15% of body and tail located malignant tumors being resectable at initial presentation [2].

Treatment modalities are optimally decided by a multidisciplinary team, based on imaging studies, cancer biomarker values, and patient performance status. Surgical resection of the malignant lesion is the treatment of choice and provides the highest chance of cure. Patients who are eligible for surgery undergo a left pancreatectomy (LP), also known as distal pancreatectomy [3]. It is a standardized surgical procedure that has been performed with improved postoperative outcomes over the years [4]. LP involves resection of the distal portion of the pancreas, to the left of the superior mesenteric vessels, and the spleen when malignancy is involved. Resection of adjacent organs, such as the ipsilateral adrenal gland or the stomach may be necessary, due to local advancement of the tumor or inflammatory adhesions [5].

The combination of advanced disease and technical challenges, such as extensive retroperitoneal surface area, has led to increased rates of postoperative morbidity and positive margin resections accompanying the procedure [6].

## Tumor Staging and Resection Eligibility

Multidisciplinary consultation at a high-volume center for pancreatic surgery is optimal for diagnosis, assessment of resectability, and management of left-sided pancreatic cancer [7]. High-quality imaging studies are essential in evaluating the extent of the disease at presentation and should include a pancreas protocol multidetector CT or an MRI (Fig. 105.1). Radiologic findings and laboratory values of cancer biomarkers (CA 19-9) allow the categorization into resectable, locally advanced, and metastatic disease. Additional diagnostic modalities, such as endoscopic ultrasound and fine-needle aspiration biopsy (EUS-FNA), are utilized when radiologic and clinical findings are suggestive of additional differential diagnosis apart from pancreatic solid tumor [8]. Proof of malignancy via biopsy is not required in candidates for surgical resection and a diagnostic biopsy should not delay definitive treatment, when clinical findings indicate high probability of pancreatic cancer [9]. Resectability status criteria for solid tumors of the pancreatic body and tail are shown in Table 105.1.

## Surgical Technique

### General Considerations

Left pancreatectomy is performed as an oncologic procedure with the goal to achieve R0 resection and regional lymph node dissection. Detailed knowledge of the anatomy, including anatomic spaces and major vascular structures is mandatory. The pancreatic body and tail lie

|---|---|
| **Borderline resectable** | • Tumor contact with the celiac artery of ≤180°<br>• Tumor contact with the celiac artery of >180°, without involvement of the aorta and with intact gastroduodenal artery<br>• Tumor contact with the inferior vena cava<br>• Tumor contact with the superior mesenteric vein or portal vein of >180° or ≤180° with contour irregularity or vein thrombosis |
| **Unresectable** | • Tumor contact with the superior mesenteric artery or celiac artery of >180°<br>• Tumor contact with the celiac artery and aortic involvement<br>• Unreconstructable superior mesenteric vein or portal vein due to occlusion |

in the retroperitoneum in an oblique position behind the lower portion of the gastric greater curvature; in the same left anterior pararenal space in which the duodenum, the root of the mesocolon, and the splenic flexure also lie. Medially, the pancreatic body relates to the superior mesenteric artery, the celiac artery, and the portal-splenic-superior mesenteric vein confluence; all surrounded by connective tissue. Therefore, development of malignant tumors in the left part of the pancreas can penetrate the pancreatic capsule and invade any of the afore-mentioned surrounding structures.

A combined pancreatosplenectomy is usually performed, since spleen preservation is generally not indicated in pancreatic adenocarcinoma. When the tumor involves adjacent organs beyond the spleen, a wider en bloc resection is indicated. Direct tumor invasion to the splenic vessels constitutes a T3 pathologic stage (extension beyond the pancreas); further vascular involvement increases the probability of unresectability.

Patients who are eligible for surgery should undergo diagnostic laparoscopy at the beginning of the operation to exclude possible distant metastases (liver) or carcinomatosis, missed by the imaging studies [10]. In the presence of metastatic disease, a lesion biopsy is performed.

## Retrograde Left Pancreatosplenectomy

After initial laparoscopy, a long midline skin incision from the xiphoid to 8–10 cm below the umbilicus is created; in patients with normal weight this incision provides satisfactory exposure for mobilization of the pancreatic body and tail. Alternatively, a left subcostal incision is suitable in obese patients.

Exposure of the pancreatic body and tail follows after a thorough exploration of the abdominal cavity for signs of metastatic disease. Initially, the omentum is detached from the transverse colon, and the peritoneal layer that surrounds the pancreas is incised along the inferior border, starting from the tail. Care must be taken to avoid injury to the inferior mesenteric vein that lies deep in the peritoneal layer. Palpation of the left-sided pancreas allows a precise evaluation of tumor extension. Ligation of the splenic artery follows, close to its point of origin from the celiac artery; palpation of the hepatoduodenal ligament prior to ligation secures that the hepatic artery has not been occluded.

The traditional retrograde approach continues with mobilization of the spleen, by incision of the splenorenal and splenocolic ligaments with electrocautery or Metzenbaum scissors. The spleen can now be elevated away from the ipsilateral adrenal gland and kidney. Division of the short gastric and the left gastroepiploic vessels allows the detachment of the spleen from the greater curvature of the stomach and the free inspection of the posterior pancreatic surface (Fig. 105.2). The splenic vein is identified and ligated distal to the confluence with the inferior mesenteric vein with two 2-0 silk ligatures.

The final step involves the division of the pancreatic parenchyma. This can be accomplished by numerous methods. Traditionally, the pancreas is divided sharply or with electrocautery followed by the placement of figure of eight sutures to occlude the superior and inferior pancreatic arteries. Once hemostasis is achieved, the pancreatic duct is identified and oversewn with a fine

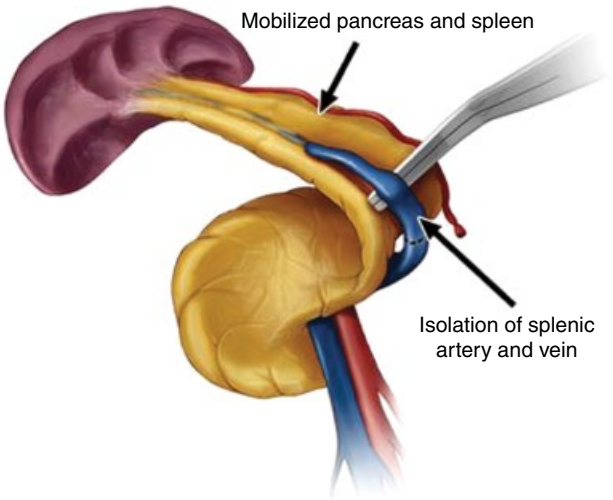

**Figure 105.2** Mobilization of the pancreatic body and tail and visualization of the posterior pancreatic surface. *Source:* Reprinted with permission from the American Journal of Roentgenology.

absorbable suture. This is followed by the placement of mattress sutures over the entire transection line. Alternatively, a more modern approach is to use a 48–55 mm linear stapler that is applied across the pancreatic transection line. Prior to closure, closed suction drains are usually placed near the transection margin.

### Radical Antegrade Modular Pancreatosplenectomy

In 2003, Strasberg et al. described a modification of LP for malignant tumors that relied on early control of major blood vessels, improved visualization of the posterior resection margin, and extensive lymph node dissection [11]. In radical antegrade modular pancreatosplenectomy (RAMPS) the dissection takes place in an antegrade fashion (from right to left). The parenchyma is dissected first at the pancreatic neck using a stapler and the underlying vascular structures are exposed. The splenic vessels are ligated and extended dissection of celiac and superior mesenteric artery nodes follows. The final resection plane is decided based on tumor extension. The anterior renal fascia is always excised; if the pancreatic lesion invades the ipsilateral adrenal gland or further, the resection plane extends towards the anterior surface of the kidney, behind the perinephric fat (posterior RAMPS) [4].

Improved 5-year survival has been reported in patients with pancreatic adenocarcinoma of the left pancreas who underwent RAMPS [12,13]. Modifications of the surgical procedure can also be found in the literature [4,14]. Randomized trials comparing standard LP and RAMPS will be needed to support the improved oncologic outcome of the latter.

### Distal Pancreatectomy with en Bloc Celiac Artery Resection

Vascular involvement of the celiac axis in pancreatic cancer is considered an indicator of unresectability. In the last decade, a modified Appleby procedure has been adopted for resection of locally advanced tumors of the pancreatic body [15]. The operation is a left pancreatectomy with en bloc splenectomy and resection of the celiac axis. In the modified Appleby procedure, once the celiac trunk and common hepatic artery are resected, the liver receives adequate blood supply from the superior mesenteric artery via retrograde flow, through the inferior pancreaticoduodenal artery, the arcade within the pancreatic head, and finally the gastroduodenal artery to the proper hepatic artery.

Few small series of patients who underwent a modified Appleby operation have been published [16–18]. Appropriate patient selection is necessary and consideration on anatomic variations of hepatic circulation must be given. Neoadjuvant chemotherapy or chemoradiation is necessary in stage III borderline patients [19]. The procedure has a postoperative morbidity rate similar to LP [20]. The median overall survival of these patients is improved, compared with chemotherapy or chemoradiotherapy alone, and is similar to that of stage I/II patients, who undergo resection [21].

## Minimally Invasive Left Pancreatectomy

Laparoscopic and robotic surgery of the distal pancreas has developed rapidly over the last few years. The first laparoscopic LP was reported in a patient with chronic pancreatitis, early in the development of laparoscopic surgery [22]. Utilization of laparoscopic technique in dissection of malignant tumors of the pancreatic body and tail progressed slower. The surgical principles remain the same as in the open pancreatectomy: margin-negative resection and an adequate lymphadenectomy. Both the standard retrograde [23] and the RAMPS technique [24–26] are amenable to the laparoscopic approach. Although operating time is reported to be longer on average, several publications demonstrated a lower estimated blood loss compared to open LP [27–29]. Additionally, R0 resection and number of dissected lymph nodes in laparoscopic LP are similar to the open approach [30,31], which leads to comparable long-term oncologic outcomes. Moreover, the reported overall survival was similar in the open and laparoscopic approach [30,32,33]. Interestingly, some have suggested that postoperative complication rates are improved compared to the open approach, including hemorrhage and pancreatic fistulas

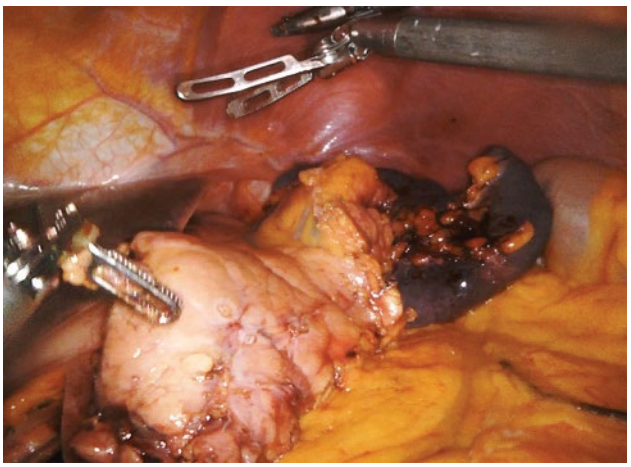

**Figure 105.3** Robotic left pancreatectomy for pancreatic adenocarcinoma.

[34,35]. Others have reported that shorter length of stay, lower postoperative costs, and shorter time for initiation of adjuvant therapy are observed in patients who undergo laparoscopic LP [35–37].

Robot-assisted resections were the next step in minimally invasive pancreatic surgery. In 2003, three cases of robot-assisted laparoscopic LP for adenocarcinoma were reported by Giulianotti et al. [38]. Since then, utilization of robotic surgical systems (Fig. 105.3) has increased significantly and major case series have been published [39–44]. Main comparisons are made against the laparoscopic resection. A recent systematic review and meta-analysis found no statistically significant difference in blood loss, operative time, and conversion rates between the two approaches; postoperative morbidity was also similar [45]. It appears that robot-assisted laparoscopic LP is as feasible and safe as the laparoscopic approach.

The advantages of laparoscopic and robot-assisted LP are evident: smaller incisions, decreased blood loss, less postoperative pain, shorter length of hospital stay, and faster recovery. However, reported conversion rates of 10–15% [46] indicate that these operations are feasible in well-selected patients and substantial surgeon experience in minimally invasive techniques is required [46,47]. Randomized controlled trials are recommended to evaluate further the feasibility and long-term outcomes of these approaches.

## Postoperative Considerations

### Postoperative Pancreatic Fistula

Postoperative pancreatic fistula (POPF) is the most common major complication of left pancreatectomy with a reported incidence of 20–30% [48,49]. The impact of the closure technique on POPF rates following LP has been extensively studied. Multiple prospective studies and randomized trials have compared the suturing and stapling technique [50–53] and a trend favoring use of stapler for remnant closure is observed. However, Bilimoria et al. reported that identification and direct ligation of the main pancreatic duct is associated with reduced pancreatic leak rates in left pancreatectomy [54]. The most recent meta-analysis identifies lower overall POPF incidence with use of stapler, but no difference in clinically relevant POPF [53]. Other risk factors for development of pancreatic fistula include size of the pancreatic gland [55], location of parenchymal transection [56], and extensive lymphadenectomy [57].

Placement of a postoperative drain on the surgical bed and time of its removal is an ongoing debate. The goal of drain placement is to recognize a pancreatic leak early and allow controlled drainage of the pancreatic fluid, which invariably resolves within 3–4 weeks. However, drains have been associated with retrograde intra-abdominal infections, peripancreatic vessel and hollow viscera erosion, and increased possibility of promoting pancreatic fistula formation, especially with closed suction drainage [58–60]. Utilization of drains is highly dependent on the surgeon's preferences and clinical experience.

Pancreatic fistula diagnosis is clinical; nonspecific symptoms such as anorexia, nausea, and abdominal discomfort or pain are usually present. Secondary delayed gastric emptying can also be observed, and mildly elevated WBC count and C-reactive protein levels should raise clinical suspicion for POPF. Definitive diagnosis is placed with an abdominal CT, where a peripancreatic collection is seen. In the vast majority of cases, management of POPF is a combination of support with enteral nutrition [61,62] and image-guided percutaneous drainage of peripancreatic fluid collection [63]. Recent studies indicate that utilization of somatostatin analogs in POPF does not provide significant advantage in fistula closure rate [64].

### Postoperative Diabetes Mellitus

New-onset pancreatogenic diabetes (type 3c) is a complication of a varying rate between 5% and 50%, depending on preexisting pancreatic disease and extension of parenchyma resection [65,66]. With the improved survival achieved after resection of body and tail adenocarcinoma, postoperative diabetes can become a lifelong complication. In a recent meta-analysis, the cumulative risk for new-onset diabetes after LP for malignancy is 7–28%, with an increased chance of insulin dependency [67]. Patients who will be submitted to LP should be informed preoperatively about the possibility of developing diabetes.

## Conclusions

Patients diagnosed with cancer of the pancreatic body and tail usually present with locally advanced or metastatic disease. In those cases where the tumor is manageable surgically, a left pancreatectomy with negative margins provides the best chance for curative treatment. Postoperative morbidity rates are relatively high, but the majority of them are self-limited and the surgical mortality remains low. Utilization of laparoscopic and robotic techniques allows faster recovery and timely initiation of adjuvant therapy.

## Total Pancreatectomy

Total pancreatectomy (TP) was first described by Rockey in 1943 [1], and the popularity of this procedure increased during the 1960s [2]. The rationale for TP was to avoid pancreatic anastomosis-related complications and to optimize oncologic surgery in pancreatic cancer patients. After the initial enthusiasm for TP, results of large series of TP for pancreatic cancer were published in the late 1980s and 1990s [3–8]. They showed that TP could not improve the rates of R0 resections for pancreatic cancer, had perioperative mortality rates similar to or higher than partial pancreatic resections (13–27%), and no survival advantage was found [3–8]. Furthermore, TP was complicated by permanent pancreatic endocrine and exocrine deficiencies [9]. These results led surgeons largely to abandon TP and no longer consider it as a viable option for pancreatic disease.

However, recent advances in surgical techniques, perioperative management, and the development of high-volume surgical centers demonstrate that TP can be performed with lower mortality rates than in the past [10–13]. Furthermore, improvements in long-acting insulin formulations and high-quality enzyme replacement formulations for managing brittle diabetes mellitus and malabsorption from exocrine insufficiency enable more effective control of these conditions after TP [10–14].

In this chapter, recent indications and limitations of TP are considered, based on short- and long-term outcomes after TP reported in the literature.

## Elective Total Pancreatectomy and Salvage Completion Pancreatectomy

TP can be classified into elective TP and salvage completion pancreatectomy for complications after partial pancreatectomy [12,15,16].

An elective TP includes primary TP and two-stage TP after previous partial pancreatic resections. Primary elective TP is performed in cases of central tumor location in the pancreas or multifocal tumors with preoperatively planned TP, the intraoperative finding of an extended tumor other than preoperative imaging finding, or tumor positive intraoperative frozen pancreatic transection margin with the need for extension of the pancreas. Two-stage elective TP is performed in cases of tumor recurrence or of new tumors developing in the remnant pancreas after partial pancreatic resection.

Salvage completion pancreatectomy is indicated in the clinical situation of a patient with a severe complication after a pancreatic resection, such as pancreatic fistula or abdominal hemorrhage, and when conservative treatment strategies have been exhausted [12,16].

## Perioperative Outcomes After Total Pancreatectomy

### Elective TP

High perioperative mortality and morbidity rates after TP have long been reported [3–8]; however, a dramatic decrease has been achieved in recent years due to improvements in surgical techniques and postoperative management [10–13,15,16]. Recent single-institution series have reported perioperative mortality rates ranging from 3% to 12.5%, and perioperative morbidity rates ranging from 25% to 54% (Table 106.1) [10,12,15–20]. Advanced age (>70 years), the presence of comorbid conditions, lengthy operative time (>420 min), high blood loss (>2,000 mL), and/or arterial resections were reported as independent risk factors for mortality following TP [20,21].

Surgical complications after TP include delayed gastric emptying, intra-abdominal abscess, abdominal hemorrhage, anastomotic leakage, and wound infection. Several studies report that rate of delayed gastric emptying is the most frequent perioperative complication following TP [12,19,20], and that the relationship between delayed gastric emptying and surgical technique (i.e., with or without preservation of the pylorus ring of the stomach) was unclear [12,20].

Although mortality rates following TP have decreased, perioperative morbidity rates remain high. Therefore, careful patient selection, surgical procedure, and postoperative management are essential to decrease morbidity rates after this procedure.

### Salvage Completion Pancreatectomy

High mortality rates after emergent complete pancreatectomy have been reported, ranging from 39% to 48%, and morbidity rates were also high, ranging from 79% to 91% [12,16]. Furthermore, the postoperative outcomes after salvage completion pancreatectomy, including complications, hospital stay, and survival, were significantly worse than those after elective TP [12,16]. The poor outcomes are associated with conditions such as severe abdominal sepsis or hemorrhage after partial pancreatectomies, when conservative treatment strategies have been exhausted.

With advances in interventional radiology techniques, including drainage of pancreatic fistula or intra-abdominal abscess, and arterial embolization for abdominal hemorrhage, complications from salvage TP after partial pancreatectomies should become more avoidable [22,23].

## Long-Term Outcomes After Total Pancreatectomy

With the increasing number of long-term survivors after TP [20,25,26], management of late complications and evaluation of quality of life (QOL) are important, although there have been few reports about long-term outcomes [10,12,15,18–20,24,27]. Late complications after TP include anastomotic ulcer at gastrojejunostomy and hepatic steatosis as well as diabetes mellitus and malabsorption caused by endocrine and exocrine insufficiency. Furthermore, long-term QOL may be associated with postoperative symptoms, such as diarrhea, inappetence, and weight loss [10,12,20,27].

### Diabetes Mellitus After Total Pancreatectomy

Diabetes mellitus after TP is caused by a complete lack of endogenous insulin and glucagon, leading to frequent and deep states of hypoglycemia and hyperglycemic episodes that can be difficult to control (brittle diabetes) [9].

**Table 106.1** Perioperative mortality and morbidity rates after an elective total pancreatectomy reported in the main literature.

| Author | Period of time | Total number | Disease PDAC | IPMN | Others | Mortality rate (%) | Morbidity rates (%) |
|---|---|---|---|---|---|---|---|
| Billings et al. [10] (2005) | 1985–2002 | 99 | 33 | 26 | 40 | 5% | 32% |
| Müller et al. [12] (2007) | 2001–2006 | 124 | 67 | 18 | 39 | 4.8% | 24% surgical<br>14.5% nonsurgical |
| Stauffer et al. [17] (2009) | 2002–2008 | 47 | 10 | 31 | 6 | 2% | 37% |
| Casadei et al. [18] (2010) | 2006–2009 | 20 | 7 | 8 | 5 | 5% | 25% |
| Crippa et al. [15] (2011) | 1996–2008 | 65 | 19 | 31 | 15 | 0% | 38.5% |
| Barbier et al. [19] (2013) | 1993–2010 | 56 | 4 | 39 | 13 | 3.6% | 45% |
| Hartwig et al. [20] (2015) | 2001–2012 | 434 | 289 | 75 | 70 | 7.8% | 37.3% surgical<br>37.6% nonsurgical |
| Almond et al. [16] (2015) | 1987–2013 | 98 | 45 | 12 | 41 | 12.5% | 46% |

**Table 106.2** Long-term outcomes after total pancreatectomy reported in the main literature.

| Author | Total number | $HbA_{1c}$ | Diabetes | Weight loss % of patients | Digestive symptoms |
|---|---|---|---|---|---|
| Billings et al. [10] (2005) | 27 | 7.4% (5.0–11.3%) | Three deaths owing to hypoglycemia | 70% | – |
| Müller et al. [12] (2007) | 67 | Malignant: 7.5%<br>Benign: 6.7% | No death related to diabetes; 8.3% readmission for diabetes control | 41% | Diarrhea 41%<br>Abdominal pain 15% |
| Casadei et al. [18] (2010) | 13 | 8% (5.2–10.3%) | No death related to diabetes; 23% readmission for glycemic control | 85% | – |
| Crippa et al. [15] (2011) | 45 | 7–9% in 56% of patients, >9% in 11% of patients | No death related to diabetes | 45% | Abdominal pain 22%<br>Diarrhea 13%<br>Steatorrhea 27% |
| Barbier et al. [19] (2013) | 25 | 7.8% (6.3–10.3%) | One death owing to hypoglycemia; one death owing to ketoacidosis | 60% | 28% with night stools |

$HbA_{1c}$, hemoglobin $A_{1c}$.

Recently, new levels of diabetes management using well-established long-acting insulin formulations [10] and specialist nurse-led diabetic care have dramatically improved diabetic outcomes following TP [20,24]. Several reports have shown that hemoglobin $A_{1c}$ ($HbA_{1c}$), as a long-term marker of blood glucose concentrations, can be kept within a tolerable range (median $HbA_{1c}$, ranging from 6.5% to 8.0%, Table 106.2) [10,12,15,18–20]. However, the potential morbidity associated with endocrine deficiency must not be underestimated, because there have been several reports of deaths due to hypoglycemia and hyperglycemia after TP [10,19]. Preoperative referral to a department of endocrinology and advice on postoperative management and use of insulin formulations as well as postoperative education by specialists on the treatment of diabetes mellitus are therefore essential for patients undergoing TP.

## Exocrine Insufficiency After Total Pancreatectomy

Exocrine insufficiency is an important late complication after TP [9]. It can cause diarrhea, steatorrhea, weight loss, osteopathy and osteoporosis, and hepatic steatosis (Table 106.2). Diarrhea and/or steatorrhea contribute to the loss of fat-soluble vitamins, especially vitamin D, magnesium, and trace elements, leading to malnutrition-related complications such as osteopathy and osteoporosis, as well as to hepatic steatosis [28]. Increasing attention has been given to the development of hepatic steatosis after pancreatectomy, because postoperative hepatic steatosis may be progressive and lead to life-threatening hepatic decompensation [29–31]. However, the etiology and pathogenesis remain largely unknown. Malnutrition resulting from a lack of pancreatic enzyme formulations is one hypothesis [30,31], and female sex and early postoperative nutritional status have been reported to be independent risk factors for hepatic steatosis after TP [29].

Pancreatic exocrine enzymes break down ingested food into micronutrients for absorption [28,32]. Disruption of this process leads to severe diarrhea and steatorrhea with subsequent nutritional deficiencies [28]. Nutritional interventions, such as low-fat diets and pancreatic enzyme replacement therapy, are used to improve clinical symptoms. Pancreatic enzyme replacement therapy, including ingestion of 40,000–50,000 units of lipase per day, is standard therapy for pancreatic exocrine insufficiency, because it significantly improves absorption of fat and nitrogen [29,33,34]. Special attention should therefore be given to patient education with regard to exocrine insufficiency and available treatment after TP.

## Anastomotic Ulcer After Total Pancreatectomy

An anastomotic ulcer at gastrojejunostomy can occur both in the early postoperative course and in the long term after TP [19,35]. This complication can be severe, resulting in reoperation or even death. An anastomotic ulcer may be observed after TP with or without preservation of the pylorus ring of the stomach, indicating that this complication cannot be prevented technically [19]. However, it has been reported that routine administration of a proton pump inhibitor (PPI) may prevent this complication [19]. Life-long treatment with a PPI may therefore be necessary for patients who have undergone TP.

## Long-Term QOL After Total Pancreatectomy

There have been several reports evaluating long-term QOL following TP [10,12,20,27]. Overall QOL was considered to be acceptable; however, patient reports varied with regard to the scale of symptoms, with a decrease in

QOL focusing mainly on fatigue and diarrhea, and healthcare satisfaction scores were poor [10,12,20,27]. It is therefore important to provide sufficient information to patients before and after TP to help improve postoperative QOL.

## Indications for Total Pancreatectomy

TP is a reasonable procedure for some cases of pancreatic disease, because perioperative mortality is low and the long-term consequences are now better managed, with an acceptable morbidity rate and postoperative QOL [10–13,15,16,18–20]. Therefore, TP should no longer be generally avoided for patients in whom complete removal of the pancreas is required for oncologic prophylactic reasons. Furthermore, with the extension of resection criteria in pancreatic malignant or premalignant disease, and more advanced knowledge of specific disease entities of the pancreas that can affect the whole pancreas and require TP, the number of cases requiring the procedure have been increasing. Diseases that might require TP include extensive pancreatic head or body cancers, recurrence or new tumors developing in the remnant pancreas after previous partial pancreatic resection, diffuse or multifocal intraductal papillary mucinous neoplasms (IPMN), renal cell metastases, multifocal neuroendocrine tumors and inherited neoplastic disease, including multiple endocrine neoplasia 1 (MEN1) syndrome, history of familial pancreatic cancer, and hereditary chronic pancreatitis. In addition, TP may also be performed to avoid pancreatic-enteric anastomotic-related complications or salvage complete pancreatectomy for severe complications after partial pancreatectomies [12,20], although these indications are controversial.

### Pancreatic Ductal Adenocarcinoma

The frequency of TP in patients with pancreatic ductal adenocarcinoma (PDAC) varies from 3–9%, according to previous reports [16,26,36,37]. Less than 1 year of median overall survival time was reported in the 1980s–1990s [6,37,38]; however, recent reports have described more than 1-year overall survival after TP, ranging from 12 months to 18 months [20,25,26,36], due to improvements in surgical techniques and postoperative management, and advanced adjuvant therapies. Hartwig et al. reported that poor tumor grading, higher stage cancers according to the American Joint Committee on Cancer tumor staging system, age >70 years, and an R1 resection were independent risk factors for poor survival of patients who had undergone TP [20]. Satoi et al. reported that the rate of completion of adjuvant therapy was lower and the frequency of postoperative liver metastasis was higher in PDAC patients undergoing TP, compared with patients who had a pancreaticoduodenectomy; however, overall survival was similar between the TP and pancreaticoduodenectomy matched-pairs groups [36]. Schmidt et al. reported that among PDAC patients with a positive pancreas margin pathologically, the surgical results were compared between patients undergoing subsequent TP after pancreaticoduodenectomy and R1 patients undergoing only pancreaticoduodenectomy. The authors showed that mortality and morbidity rates were similar between the two groups, although conversion of pancreaticoduodenectomy to TP was associated with survival benefits [25]. However, it was unclear whether radical oncologic surgery, including extended lympadenectomy and increased soft tissue clearance around the pancreatic gland by TP, improved survival, when compared with partial pancreatectomies [20,24,26,36]. Based on these results, TP seems to be a powerful strategy for patients who have a positive margin of transected pancreas after pancreaticoduodenectomy to achieve an R0 resection; completion of adjuvant therapies after TP is necessary to improve survival, as with other pancreatectomies. As discussed earlier, adequate control of endocrine and exocrine pancreatic insufficiency is essential to improve survival of PDAC patients who have undergone TP.

### Intraductal Papillary Mucinous Neoplasm

According to international consensus guidelines for the management of IPMN [39], main-duct IPMN is an indication for surgical resection, because of the risk of malignancy. Diffuse main-duct IPMN or multifocal branch-duct or mixed-type IPMN sometimes require TP, and long-term outcomes for these cases are favorable [20,22]. Therefore, these types of IPMN are a good indication for TP, although careful preoperative diagnosis of malignancy [16,40] and patient selection are necessary to obtain survival benefits.

### Inherited Diseases

Patients with a family history of hereditary pancreatic cancer and patients suffering from hereditary chronic pancreatitis are at increased risk of developing pancreatic cancer during their lifetime [22,41]. Therefore, TP is a prophylactic measure for patients at high risk of developing pancreatic cancer, although the timing and extent of surgery are still controversial.

### Tumor Recurrence or New Tumor Developing in the Remnant Pancreas After Previous Partial Pancreatic Resection

Tumor recurrence or new tumor, such as PDAC or IPMN, developing in the remnant pancreas without distant metastasis is sometimes found, and several reports have shown survival benefits of a two-stage completion pancreatectomy with low rates of mortality and morbidity [12,15,20,42]. A tumor developing in the remnant of the pancreas is therefore an indication for two-stage complete pancreatectomy.

### Conversion From Partial Pancreatectomy to Total Pancreatectomy Because of Avoidance of Pancreatic-Enteric Anastomosis-Related Complications

Pancreatic-enteric anastomotic leakage, called pancreatic fistula, after partial pancreatectomy can cause life-threatening complications, and conversion to TP from pancreaticoduodenectomy is sometimes performed intraoperatively. Hartwig et al. reported that in 20% of cases, intraoperative conversion to TP was performed because of the morphology of the remaining pancreas, including extremely soft or lipomatous pancreas that might be associated with high risk of postoperative pancreatic fistula, and combined arterial reconstruction during pancreatectomy [20]. However, the indication for conversion to TP from pancreaticoduodenectomy to avoid postoperative pancreatic fistula, but with resulting endocrine and exocrine insufficiency, remains controversial.

### Salvage Complete Pancreatectomy for Complications After Partial Pancreatectomies

As described earlier, the mortality and morbidity rates of salvage TP for severe complications after partial pancreatic resections are extremely high; therefore, this procedure should be avoided, if possible [12,16]. The significant decline in the use of salvage complete pancreatectomy relative to a pancreaticoduodenectomy reflects a shift in the management of pancreatic fistula and postoperative hemorrhage, with radiologic drainage and arterial embolization now readily available and preferred to re-laparotomy [23,43].

## Limitations of Total Pancreatectomy

Although mortality rates after TP have dramatically decreased, the perioperative morbidity rates remain high [10–13,15,16], particularly in the case of salvage completion pancreatectomy for severe complications after partial pancreatectomies [12,16]. This procedure should therefore be avoided, if possible. Furthermore, postoperative endocrine and exocrine insufficiency after TP can cause life-threatening complications [10,12,15,18–20]. Careful patient selection while considering the balance between clinical benefit and postoperative risk, and providing information about postoperative management before and after TP are necessary to improve survival and QOL in patients who undergo TP.

# Laparoscopic and Robotic Resection for Pancreatic Cancer

*Deepa Magge, Herbert J. Zeh, and Melissa E. Hogg*

*Department of Surgery, University of Pittsburgh Medical Center, Pittsburgh, PA, USA*

## Introduction

Minimally invasive techniques (MIS) have begun to revolutionize the surgical management of benign and malignant pancreatic disease. Both laparoscopic and robot-assisted approaches to pancreatic surgery have been shown to be safe and feasible in high-volume centers of excellence [1–3]. Additionally, the MIS approach demonstrates improvement in the traditionally high morbidity rates associated with these procedures [4].

The pancreaticoduodenectomy was described and popularized in 1935 by Allen O. Whipple as a two-stage procedure, which was refined into the single-stage procedure we recognize today [5,6]. Since its inception, pancreatic surgery has resulted in high morbidity and mortality, which prevented widespread implementation for many years.

Though the laparoscopic approach to the pancreaticoduodenectomy was initially met with skepticism because of the long operative times when first performed in 1994, it has now been established as safe and feasible when performed by select high-volume surgeons at experienced centers [7]. The robotic pancreaticoduodenectomy (RPD), first performed in 2007, is now being increasingly utilized for pancreatic malignancies due to perceived benefits of stereotactic vision, magnification, platform stability, and favorable ergonomics [8]. We present a review of the minimally invasive techniques for pancreaticoduodenectomy (PD) and distal pancreatectomy (DP), focusing on current data on metrics of technique, safety, morbidity, and oncologic outcomes.

## Patient Selection and Indications for the MIS Approach to Pancreaticoduodenectomy

Determining the resectability of pancreatic adenocarcinoma (PDA) of the head of the pancreas depends primarily on the involvement of the mesenteric vessels. Preoperative assessment of presence of metastatic disease and vascular involvement is critical in determining whether a patient is a candidate for an open versus MIS pancreaticoduodenectomy or whether they are a surgical candidate at all [9]. Given that minimally invasive approaches, including laparoscopic and robotic techniques, do not allow for palpation of the tumor intraoperatively, patients undergo triphasic CT scanning and EUS prior to any surgical planning since both modalities have been found to be useful in predicting which patients can undergo an R0 resection [10]. In our institution, resectable and borderline resectable tumors are offered RPD. The only strict exclusion criterion is the need for a long segment vein resection with conduit for reconstruction.

## Laparoscopic Pancreaticoduodenectomy

### Technique of LPD

Zureikat et al. previously described a total LPD (TLPD), which involves complete laparoscopic mobilization of the pancreas and duodenum [11]. After gaining access to the abdomen using an optical-separator device in the left

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

upper quadrant, seven ports are placed in a semilunar shape around the xiphoid process. A right lower quadrant utility incision is used for specimen extraction. The inferior border of the pancreas is dissected in order to identify the superior mesenteric vein prior to the Kocher maneuver. Once the hepatic flexure is mobilized and the duodenum is kocherized, the porta hepatis is dissected. The retropancreatic tunnel is then created between the pancreatic neck and the portal vein, and the pancreas is divided using bipolar electrocautery.

Reconstruction proceeds with an end-to-side duct to mucosa pancreaticojejunostomy using a two-layered closure technique with running absorbable monofilament. A running 4-0 absorbable monofilament suture is used for the hepaticojejunostomy. A stapled technique is utilized for the gastrojejunostomy, and drains are left around the pancreaticojejunostomy prior to closure [11].

### Outcomes of LPD

The initial report of 10 LPD in 1997 by Gagner and Pomp revealed a high conversion rate from the laparoscopic approach to open technique for the pancreaticoduodenectomy (OPD) without noting any significant benefits [12]. However, many reports have emerged subsequently describing the safety and oncologic efficacy of the LPD, and some have directly compared it to the OPD to determine benefits of the minimally invasive technique. Some of the key publications to summarize LPD outcomes are shown in Table 107.1 [12–21].

Palanivelu and colleagues described the largest series of laparoscopic pancreaticoduodenectomies to date, including 130 LPD performed for malignant indications [13]. This report demonstrated the advantages and feasibility of the MIS approach when performed by highly skilled surgeons. Mean operative time for the entire cohort was 310 ± 34 minutes, mean blood loss (EBL) was 110 ± 22 mL, with one conversion to open surgery, and an average hospital stay of 8 ± 2.6 days. The overall postoperative morbidity was 29.7%, with a pancreatic fistula (POPF) rate of 8.46%. Overall mortality rate was 1.53%. In regard to oncologic outcomes, resected margins were positive in 9.23% of cases, and mean number of retrieved lymph nodes was 18.15 ± 4.73. The overall 5-year actuarial survival was 29.42%, and the median overall survival was 33 months [13].

Numerous other case series are outlined in Table 107.1 delineating LPD outcomes, including Kim et al.'s series of laparoscopic pylorus-preserving PD with 100 cases, which held an overall morbidity rate of 25%, including postoperative hemorrhage in five patients, only one of whom required reoperation, and delayed gastric emptying (DGE) in two patients. Another series of 62 LPD (45 patients with malignant disease) by Kendrick and Cusati, had a mean hospital stay of 7 days and overall morbidity rate of 42%, including DGE in nine patients and PF in 18% of patients. Reoperation was required in three (5%) patients for POPF (1), control of hemorrhage following percutaneous drain placement (1), and revision of a biliary leak (1).

Several comparative effectiveness studies have also been performed, comparing laparoscopic pancreaticoduodenectomy to the open approach (Table 107.2) [11,22,23]. Croome and Kendrick et al. focused on the oncologic effectiveness of the minimally invasive distal pancreatectomy (MIDP) in another review, comparing 108 patients who underwent LPD to 214 patients who underwent OPD for PDA [22]. They found a significantly higher proportion of patients in the OPD group (12%) who had a delay of greater than 90 days or who did not receive adjuvant chemotherapy at all compared with the TLPD group (5%; $P = 0.04$). There was no significant difference in overall survival between the two groups, but a significantly longer progression-free survival was seen in the TLPD group ($P = 0.03$), revealing a possible oncologic advantage to the laparoscopic approach over the open technique [22]. Another comparative study by Asbun et al. included 215 and 53 patients who underwent OPD and LPD, respectively [23]. Significant differences favoring LPD were seen in intraoperative blood loss ($P < 0.001$), transfusions ($P < 0.001$), length of hospital stay ($P < 0.001$), and length of ICU stay ($P < 0.001$). Operative time was significantly longer for LPD ($P < 0.001$). There were no differences in overall complications, POPF, or DGE. Oncologic outcomes demonstrated no significant differences in resection margins, size of tumor, or T/N stages. There were significant differences in number of lymph nodes retrieved ($P = 0.007$) and lymph node ratio ($P < 0.001$) in favor of LPD [23].

## Robotic Pancreaticoduodenectomy

### Technique of RPD

As described by Zeh et al., the first step in the robot-assisted approach to the pancreaticoduodenectomy was previously achieved laparoscopically and included mobilization of the right colon and kocherization of the duodenum along with mobilization of its third and fourth portions [24]. Our institution now performs the entire procedure robotically, docking the robot immediately upon gaining access to the abdomen (Fig. 107.1). We start with a near total Cattell-Braasch maneuver followed by an extended Kocher maneuver where the ligament of Treitz is dissected and the jejunum is pulled into the right upper abdomen. The jejunum is transected about 10 cm distal to the uncinate using a linear stapler and then dissection of the posterior stomach from the

anterior surface of the pancreas is performed. The stomach is divided with a linear stapler.

The porta dissection begins with removal of the hepatic artery lymph node, facilitating delineation of the common hepatic artery, gastroduodenal artery (GDA), and portal vein (PV). After the borders of the common bile duct and PV are fully exposed, the GDA is transected and periportal lymphadenectomy is completed, taking care to identify an aberrant right hepatic artery. The SMV is dissected off the inferior border of the pancreas and a tunnel is created over the portal vein. After completion of the tunnel, the neck of the pancreas is divided with electrocautery, reserving sharp robotic scissor transection for the pancreatic duct. The first jejunal branch is identified and preserved where possible. The SMV-PV is reflected medially and the SMA is identified. Dissection proceeds along the SMA by clearing all the tissue around the anterior, right side, and posterior surface of the SMA [25].

Reconstruction is started with a two-layered end-to-side duct to mucosa pancreaticojejunostomy in a modified Blumgart fashion. The choledochojejunostomy is then performed in a running fashion. An anticolic hoffmeister end-to-side gastrojejunostomy had been sewn in two layers for the first 5 years, and most recently stapled with the common enterotomy sewn in two layers [24].

## Outcomes of RPD

To date, one of the largest series of open PD was reported by Winter et al. from Johns Hopkins in 2006 [25]. Their review of 1,432 cases for PDA, demonstrates a high-volume historic control for comparison when describing new technology. The authors reported a mean operative time of 380 minutes for the procedure, a mean blood loss of 800 mL, 58% R0 resection, and a mean length of stay of 9 days. They described a 5% POPF (pre-ISGPF criteria) and a 2% mortality rate.

Both LPD and RPD outcomes are similar, and are not inferior to OPD in large single institutional series (Table 107.2 and Table 107.3). One challenge of national administrative databases is that many of these report small-volume centers performing their first and possibly only case. They do not represent a mature series of surgeons who have surpassed their learning curve. Tseng et al. demonstrated that the OPD has an inherent learning curve. After 60 cases, surgeons achieved significantly decreased EBL, operative time, and hospital stay, and carried out more margin-negative resections. Improvement in measured outcomes continues during the operative career [26]. A recent publication showed that minimally invasive PD may be associated with a higher 30-day mortality using the National Cancer Database (NCDB) [27]. These reports need to be evaluated with some caution, as the same group published another report 6 months later also using NCDB data demonstrating no differences in 30-day mortality [28]. Surgeon volume and experience need to be taken into account and large national databases are not granular enough to do so. Outcomes for the RPD have been comparable, with certain parameters even showing superiority to historic series.

Our institution has performed over 365 RPD to date, 43.5% of which were completed for PDA. Our experience

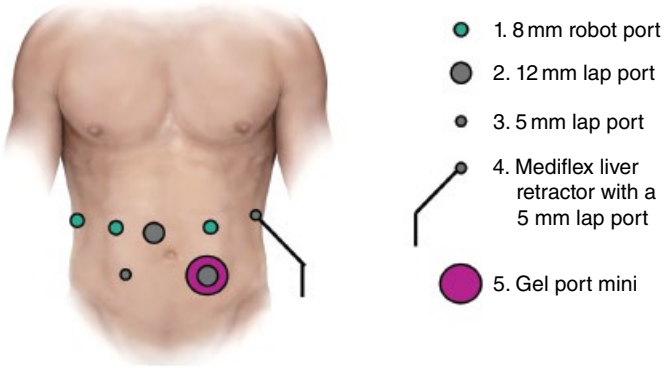

**Figure 107.1** Port configuration for robotic pancreaticoduodenectomy.

has shown that not only is RPD feasible, but that it can be performed safely with a 30- and 90-day mortality of 1.4% and 2.9%, respectively. Median EBL was 300 cc, with a conversion rate of only 5%, superior to most open series and laparoscopic series, respectively. Despite an overall median time in excess of 404 minutes, the first 80 within our learning curve had a median operative time of 569 minutes and were performed primarily by attendings. The last 80 cases have seen a reduction to a median time of 362 minutes even with the integration of the trainee into the operative team. The conversion rate and blood loss metrics have also improved with increased experience. Morbidity remains a considerable factor with any new technology, but showed comparable grade 3 and 4 complication rates of 10.6% and 12%, respectively to the open approach. With increased experience, POPF rate was 17.9% (grade C = 3%), comparing favorably with the most recent large analysis by Denbo et al. of over 2,700 OPD (18% POPF, grade C ≤ 5%) [29]. Several case-control studies and case series evaluating outcomes of RPD have been performed and have shown that EBL and length of stay is significantly better in the RPD with no increase in operative mortality compared to the open cohort (Table 107.1 and Table 107.3) [30–36]. None of the studies to date have demonstrated an improvement in overall morbidity, POPF rate, or operative time.

### Summary

Laparoscopic and robotic platforms seem to be advantageous to OPD with respect to blood loss, shorter hospital stay, and potentially complications. Our personal opinion is that the robotic approach will prove to be the more robust and durable MIS platform with the shortest learning curve for surgeons. Larger studies are still needed to confirm this hypothesis.

## Indications for the MIS Approach to the Distal Pancreatectomy

The minimally invasive approach to the distal pancreatectomy is now considered by many to be the preferred method of resection for malignant tumors of the distal pancreas. Several studies have been performed, collectively supporting that LDP and RDP can be performed with superior results to the open approach in patients with malignant disease [37,38]. Specifically, the minimally invasive approach results in shorter hospital stay, reduced EBL, and decreased complication rates [39]. Similar oncologic resections can be accomplished in terms of lymph node dissection and resection margins, although larger reports of long-term survival are still lacking.

## Laparoscopic Distal Pancreatectomy

### Technique of LDP

As previously described, the peritoneum is accessed via an optical separator technique inserted in the left subcostal area to induce pneumoperitoneum, which is followed by placement of four additional trocars. Dissection begins with division of the gastrocolic ligament in order to enter the lesser sac. The splenic flexure of the colon is then mobilized inferiorly, the inferior border of the pancreas is dissected, and the pancreas is mobilized out of the retroperitoneum at the site of transection by creating a subpancreatic tunnel. Early identification of the splenic vessels and dissection of the vein and artery off the superior-posterior aspect of the pancreas allows safer pancreatic transection. Once the vessels have been mobilized, the pancreatic parenchyma is divided using a linear stapler or harmonic scalpel, which is followed by division of the splenic

vessels using a stapling device or clips. The spleen is then mobilized by sectioning the suspending ligaments, and the specimen is then placed in a large bag and brought through an access incision [39].

### Outcomes of LDP

Since the first LDP was described by Cushieri for chronic pancreatitis disease in 1996, there have been a number of series reporting on LDP. In 2008, a large multi-institution study was performed by Kooby et al. evaluating laparoscopic distal pancreatectomy to the open approach in a 3:1 matched comparison (Table 107.4) [39–41]. They demonstrated that the laparoscopic approach was associated with a lower blood loss, shorter length of hospital stay, increased splenic preservation, less overall morbidity without an increase in POPF rates.

Two methodologic problems complicate prospective studies of surgical technique for distal PDA: (i) only 20.8% of PDA arise in the distal pancreas; and (ii) the 1,640 distal pancreatic resections performed annually in the United States are distributed among 1,743 hospitals according to 1998–2003 data in the Nationwide Inpatient Sample, an average annual case volume of one per hospital [42]. As a result, most comparative effectiveness research has been retrospective and confined to single institution data [43]. Several case series have demonstrated the advantages of the laparoscopic approach to the distal pancreatectomy (Table 107.4) [39–41].

Our institution performed a retrospective case series comparing clinicopathologic and long-term oncologic outcomes after MIS and ODP for PDA in 62 consecutive patients at a single institution [37]. Intention-to-treat analysis demonstrated no evidence for inferiority of MIDP compared with ODP in terms of postoperative outcomes or long-term survival.

## Robot-Assisted Distal Pancreatectomy

### Technique of RDP

After the peritoneum is accessed in a similar fashion to that obtained in the laparoscopic approach, additional trocars are placed, and the robot is docked (Fig. 107.2) [31]. The splenic artery is isolated at its take off from the celiac trunk, and divided with a vascular stapler. A lymphadenectomy is then carried out starting from the left side of the SMA laterally, taking the posterior pancreatic fascia en bloc, and a comprehensive celiac lymphadenectomy is completed. With large tumors, involving the fourth portion of the duodenum or colon, the robot allows meticulous en bloc resections with reconstructions performed in a similar fashion to the open technique [31].

### Outcomes of RDP

At the University of Pittsburgh, we compared outcomes of LDP and RDP in a retrospective matched comparison [38]. Patients undergoing RDP and LDP demonstrated equivalent age, gender, ethnicity, ASA score, and tumor size. They noted a statistically significant decrease in the conversion rate to open with RDP compared to LDP; 0% versus 16% [38]. A more recent updated series of 100 RDP demonstrated a persistently low conversion rate of 2% [31]. This may be secondary to the surgeon at the console's ability to control large vessels and manage unexpected bleeding via intracorporeal suturing more readily with the robot than using laparoscopy. The authors minimized patient selection bias in that the easier cases may have been chosen for the newer robotic technique by relegating the LDP control cohort to a period when robotic surgery was not available. In this comparison, a 35% margin-positive rate was observed in the LDP group compared to zero in the RDP group,

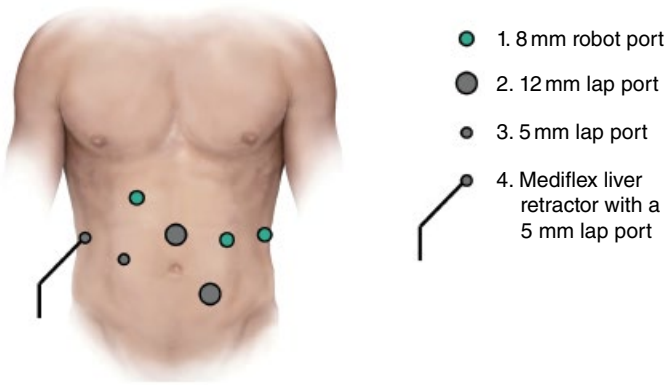

**Figure 107.2** Port configuration for robotic distal pancreatectomy.

which was statistically significant ($P < 0.05$), suggesting that the laparoscopic approach may be inferior to the robotic approach in this matched comparison. It has been shown that patients having undergone RDP as opposed to LDP or ODP have shorter hospital stays given decreased wound complications and increased rates of splenic preservation [44]. As further experience with the robot-assisted approach is gained, additional advantages may be realized. Several case series have been performed demonstrating the benefit of the robotic approach to the distal pancreatectomy (Table 107.4) [31,38,45]. Comparative studies of robotic and laparoscopic distal pancreatectomies have shown a decreased blood loss in the robot group as well as shorter hospital stays and decreased wound complications [46,47].

The oncologic outcomes between the MIS and open approaches for distal pancreatectomy have been shown to be equivalent. Our institutional experience demonstrated that despite a higher percentage of adenocarcinoma in the robotic group (43% vs. 15%, $P < 0.05$) and a similar median tumor size of approximately 3 cm, RDP was associated with improved R0 resection rates (100% vs. 64%, $P < 0.05$), and median lymph node count (19 vs. 9, $P < 0.01$) when compared to laparoscopy [38].

### Summary

The minimally invasive approach to the distal pancreatectomy has proven advantages over the open approach. The robotic approach does appear to offer benefits over the laparoscopic technique in regards to blood loss as well as splenic preservation.

## Adopting the MIS Pancreatectomy: The Learning Curve

A recent RPD analysis from the University of Pittsburgh confirmed that outcomes are optimized after an initial steep learning curve of approximately 80 cases. In-depth analysis of this learning curve revealed that blood loss and conversions were optimized after 20 cases (600 vs. 250, $P < 0.05$, and 35% vs. 3%, $P < 0.05$ respectively), incidence of POPF after 40 cases (27% vs. 14%, $P < 0.05$), and operative time after 80 cases (582 min vs. 417 min, $P < 0.05$) [48]. Complication rates, length of hospital stay and readmissions also improved but the sample size was underpowered to detect a significant difference. In the last 100 cases, we found a POPF rate of 6%, a 90-day mortality rate of 3%, and a median length of stay of 8 days. Importantly, a two attending approach was employed throughout the learning curve period to ensure patient safety and procedural efficacy [48]. Additionally, the laparoscopic platform for the PD has also been shown to have a learning curve. Speicher et al. demonstrated that the initial 10 cases represent the biggest hurdle with respect to operative times, but for an experienced teaching center using a staged and team-based approach, LPD appears to offer meaningful reductions in operative time and blood loss within the first 50 cases [49]. This data suggests that meaningful comparative effectiveness studies of minimally invasive and open PD should take into consideration the impact of the learning curve before any outcomes are assessed.

The learning curve for the distal pancreatectomy appears to be somewhat shorter. A study by Braga et al. described 30 patients who underwent LDP between 2009 and 2010. Overall conversion rate was 23.3%, but it dropped significantly after the first 10 patients ($P = 0.01$) [50]. Mean operative time progressively declined from 254 min in the first subgroup of 10 patients to 206 min in the second ($P = 0.09$ vs. first), and 183 min in the third subgroup ($P = 0.006$ vs. first). No significant difference was found for operative blood loss, postoperative morbidity rate, and length of hospital stay in the different subgroups. Both conversion rate and operative time dropped after the first 10 patients who underwent LDP. The robotic approach to distal pancreatectomy has also been demonstrated to have a learning curve of about 10 cases as well, as shown by Napoli et al. [51].

In today's age of increased outcome scrutiny, learning curves may not be feasible. Fong et al. wrote about this concern in a recent editorial, reflecting on the importance of performing these operations in high-volume centers in a somewhat centralized fashion [52]. We have developed a detailed curriculum for surgical oncology fellows that maximizes the mastery of basic and advanced robotic skills outside of the operating room. After adoption of this curriculum we have successfully integrated these trainees into the operative team with no increase in operative times.

## Conclusion

The safety and feasibility of MIS pancreatic resections have now been established by the early adopters. Preliminary comparative effectiveness studies of high-volume providers suggest some advantage. However, dissemination and decreasing the learning curve for new centers is critical for success and sustainability of MIS pancreatectomies.

# Extended Radical Surgery for Pancreatic Cancer

*Thilo Hackert, Alexis Ulrich, and Markus W. Büchler*

*Department of General, Visceral and Transplantation Surgery, University of Heidelberg, Heidelberg, Germany*

## Introduction

In only 15–20% of patients suffering from pancreatic ductal adenocarcinoma (PDAC), surgery is possible at time of diagnosis, which offers the chance of long-term survival in 20–25% when combined with adjuvant chemotherapy [1, 2]. With the ongoing development of specialization and centralization for pancreatic surgery since the late twentieth century, not only has postoperative mortality considerably decreased but also the borders of resectability have been extended [3–7]. This has led to the development of so-called "extended resections," which exceed the standard historic approaches of partial pancreatoduodenectomy and distal or total pancreatectomy. In particular, extended lymphadenectomy, resection of adjacent vessels (superior mesenteric and/or portal vein, celiac axis, superior mesenteric artery) and organs have been performed and were investigated in a large number of studies [8–18]. These developments raised the need for a definition and standardization of local resectability to better compare publications on this topic and to establish pathways for the diagnostic and therapeutic management of these patients. Today, the only situation that represents a clear contraindication for surgery is the finding of systemic spread, especially peritoneal carcinomatosis or diffuse liver metastases [19, 20]. Regarding limited metastatic PDAC (i.e., single liver metastasis), resections are technically possible and several small case series have been reported [21]. Despite some encouraging results in these studies, surgery in metastatic PDAC remains a highly individual concept and the oncologic outcome is unclear to date [21].

The definition of "extended resection" in PDAC is closely correlated with the definition of "resectability." The critical anatomic structures to evaluate local resectability in PDAC are the arterial and venous vessels located close to the pancreatic head and body, namely the superior mesenteric (SMV)/portal vein (PV) and the celiac axis (CA) as well as the superior mesenteric artery (SMA).

Resectability is defined as (i) primary resectable PDAC, (ii) borderline resectable (BR-PDAC), or (iii) irresectable PDAC according to the criteria published by the International Study Group of Pancreatic Surgery in 2014 [22], which are mainly based on the recommendations of the NCCN (National Comprehensive Cancer Network) [19]. Besides these two recently published definitions, two other classifications are in clinical use, namely the definition of the AHPBA/SSO/SSAT published in 2009 [23] and the MD Anderson criteria, which were published in 2006 [24].

All of these definitions are similar with regard to resectable PDAC. This implies that the tumor does not involve any vascular structures (no distortion of SMV or PV and clearly preserved fat planes towards CA and SMA).

BR-PDAC is characterized by a distortion/narrowing or occlusion of the respective veins but there is a technical possibility of reconstruction on the proximal and distal margin of the veins (Fig. 108.1). PV involvement according to the MD Anderson definition does not include contact or narrowing of the vein, but gives occlusion as the criterion for BR-PDAC. Regarding arterial structures, all definitions describe a semicircumferential abutment (<180°) of the SMA or an attachment at the hepatic artery without contact toward the CA as borderline resectable.

Unresectable PDAC is defined as a more extended involvement of the SMA, CA, aorta, or inferior vena cava as well as an SMV/PV venous involvement without a possibility for surgical reconstruction of the venous tract because of the lack of a suitable luminal diameter of the feeding and/or draining vein. This situation is most likely associated with tumor-related portal cavernous transformation.

Beyond the topic of vascular tumor involvement, the involvement of an adjacent organ, that is, mesocolon, colon, stomach, adrenal gland, or kidney may require extended radical resection approaches. There is international consensus that these extended approaches are feasible in terms of surgical and oncologic outcome and organ involvement should not be considered an obstacle for resection as long as a radical tumor removal is possible [22].

## Surgical Procedures and Outcomes

### Lymphadenectomy

Lymph node spread is one of the most important prognostic factors for long-term outcome after PDAC resection. The extent of lymphadenectomy during PDAC surgery is well defined and included in national guidelines and international consensus statements [25]. In partial pancreatoduodenectomy, the lymph nodes of the hepatoduodenal ligament, those along the common hepatic artery, portal vein, and the cranial portion of SMV as well as right-sided lymph nodes of the celiac trunk and along the SMA [25]. In distal pancreatectomy for tumors of the body and the tail of the gland, tumor spread involvement is mainly observed in the lymph nodes attached to the pancreas [26]. Further frequent metastatic sites are the nodes along the splenic artery, the para-aortic area, and along the inferior margin of the pancreas as well as along the SMA. These lymph nodes should be routinely removed [27, 28]. Lymphadenectomy during total pancreatectomy can be regarded as a combination of the approaches of lymph node dissection in partial pancreatoduodenectomy and distal resection. It includes the dissection of the hepatoduodenal ligament, the lymph nodes along the hepatic artery, both sides of the celiac trunk, the splenic artery as well as the inferior pancreatic margin. This procedure will usually result in approximately 30–50 lymph nodes included in the resected specimen. The most commonly reported extended approach in lymphadenectomy is the dissection of inter-aortocaval and para-aortic lymph nodes, especially when these are macroscopically suspicious during exploration [14–18]. Although there are differences between the studies with regard to the total number of harvested lymph nodes and outcome of certain subgroup analyses, there is no evidence that extended lymphadenectomy results in a better oncologic outcome or survival. This is confirmed by a recent meta-analysis including 13 studies and demonstrating that positive para-aortic lymph nodes are associated with significantly worse survival [29]. Furthermore, extended lymphadenectomy is associated with a significantly increased surgical morbidity (i.e., chyle leakage and fluid collections) and decreased quality of life (QOL) (i.e., diarrhea and intestinal discomfort) in the postoperative follow-up [18]. Consequently, the concept of extended lymphadenectomy during PDAC resection is not recommended as an uncertain oncologic value is achieved at the price of a high postoperative morbidity.

### Vascular Resections

Historically, major vessel involvement has been a contraindication for PDAC resection. In 1973, Fortner described a surgical approach of regional pancreatectomy with en bloc resection of peripancreatic soft tissue, regional lymph nodes, and PV resection (type I), or resection and reconstruction of a major artery (type II) [30]. These initial extended resections, which were associated with a high morbidity (67%) and mortality (23%) as well as low survival rates (3-year survival rate 3%), discouraged generalized adoption of major vessel resection and reconstruction [30]. However, major advances in radiologic and surgical techniques improved preoperative staging and reduced surgical morbidity and mortality [2, 3, 31].

### Venous Resections

Resection of the PV and/or SMV during PDAC surgery can be performed without an increased perioperative morbidity or mortality and with good oncologic outcome compared to standard resections [6–9, 11, 12, 31]. This has been demonstrated in a large number of studies and meta-analyses and has consequently been implemented in national guidelines and consensus recommendations [19, 20, 32].

Venous resection can be done either by a tangential or a segmental resection [6–9]. A small defect can be closed by direct suture if the vein is not relevantly narrowed as this may cause thrombosis in the postoperative course. If a tangential resection defect needs to be augmented, this is possible by an autologous peritoneal patch [33]. In case of segmental resection, the reconstruction requires an end-to-end anastomosis (Fig. 108.2). Depending on the length of the resection, either a direct suture is possible or an autologous venous/prosthetic graft must be inserted. For this purpose, autologous grafting (e.g., renal vein, saphenous vein, internal jugular vein) is possible but requires a venous harvesting before clamping and resection [34, 35]. Alternatively, a synthetic graft, that is, a 10–12 mm ringed GORE-TEX® prosthesis, can be chosen to bridge the resected vein segment [36]. When a resection of the venous confluens is required during partial PD, the splenic vein should be reinserted by an end-to-side anastomosis as long as this does not create any lateral tension on the anastomosis. This avoids left-sided portal hypertension and restores free drainage of the stomach. In case of total pancreatectomy with splenectomy, stomach drainage is an important topic as well. In this situation, the gastric coronary vein may be preserved or reinserted, if necessary [37]. Another important aspect during PV/SMV resection is the diameter of the distal venous vessel especially in tumors located in the uncinate process. The presence of a SMV branch of a sufficient diameter has to be confirmed before resection as otherwise it may be impossible to restore small bowel drainage afterwards, which may be a technical limit for resectability. Furthermore, for all attempts of venous resection, the mesenteric root should be mobilized completely by resolving the attachment of the right hemicolon to the retroperitoneal adhesions (Cattell-Braasch maneuvre [38]). This enables long distances to be bridged after resection of the vein, and graft interposition can often be avoided by this approach. When other surgical outcome parameters are considered, it has been demonstrated that both—resection with a direct anastomosis or the interposition of a graft—can be performed safely. Numerous authors have reported a mortality rate below 5% in patients undergoing venous resection with PD, similar to that of standard PD [6–9, 34–36]. A systematic review [8] of outcome of synchronous PV/SMV resection during pancreatectomy included 52 studies encompassing 1,646 patients undergoing venous resection mainly together with partial PD (71%) or total PD (24%). The median morbidity rate for patients undergoing PD with venous resection was 42 %, and the mortality rate was 6% with a median survival of 13 months and 1-, 3-, and 5-year overall survival rates of 50%, 18%, and 8%, respectively. Another more recent meta-analysis [9] included 19 studies and compared 661 patients with and 2,247 patients without venous resections. Both groups showed similar surgical outcomes without any difference in overall survival. Furthermore, in terms of oncologic results, no difference in overall survival between both patient collectives was found, resulting in a 5-year survival rate of 12.3%, certainly superior to palliative treatment. This demonstrates that resection of the PV or SMV is potentially curative and the involvement of the SMV or PV seems to be rather a consequence of the tumor located close to these structures than a reflection of an uncommonly aggressive tumor biology.

**Figure 108.2** Intraoperative situs after PV confluens resection. End-to-end anastomosis (white arrow) between SMV and PV. Splenic artery (broken white arrow); splenic vein (black star) has been reinserted under preservation of the gastric coronary vein.

## Arterial Resections

Arterial resection during PDAC surgery has remained an area of controversy since Fortner first introduced the concept as part of regional pancreatectomy. Many authors regard the invasion of hepatic artery and celiac axis of the SMA as a contraindication for surgery because of the high morbidity and mortality rates associated with arterial resection and reconstruction as well as assuming a rather poor oncologic outcome [11–13, 39]. Recently, with the introduction of effective neoadjuvant and adjuvant therapies, attention is being refocused on the

potential benefit of removing the primary tumor, even in the setting of complex arterial abutment or encasement, when this is the only site of disease [40–46]. Although in some patients arterial invasion is considered as borderline resectable according to the ISGPS consensus statement, an upfront resection is rarely recommendable, even if it can technically be performed [32]. Furthermore, arterial invasion usually predicts extensive involvement of the mesenteric neural plexus with an inability to achieve a negative resection margin even with radical extended surgery. However, there is growing evidence that patients after neoadjuvant therapy should be subjected to surgical exploration as long as no signs of systemic tumor spread are present. Using this approach, in 33–50% of all primarily unresectable patients, a radical resection might be possible and R0 resection rates comparable to standard resections can be achieved [40–45]. With the use of FOLFIRINOX as the most effective neoadjuvant chemotherapy regimen, this rate can even be increased to more than 60% of all patients who undergo a successful resection after being initially staged as locally advanced and unresectable [46].

An artery-first approach with evaluation of the SMA and celiac axis should be routinely used early during surgical resection in order to explore arterial as well as retroperitoneal tumor invasion [47–50]. Various artery-first approaches during PD can be carried out, either through a right-sided route after Kocher maneuver or through a left-sided route after lowering the duodenojejunal flexure or by an infracolic route [47]. These techniques offer several oncologic benefits, such as facilitating interaortocaval lymphadenectomy at the origin of the SMA and checking resectability at the retroperitoneal margin. The most comprehensive meta-analysis on arterial resections included 26 studies with 366 patients undergoing arterial resection and 2,243 patients without arterial resection [39]. Then analysis showed a median perioperative morbidity of 54% and mortality of 12%, respectively. Survival analysis did not show a benefit compared with patients who underwent only venous resection. However, compared with patients who underwent only palliative treatment, the 1-year survival was favorable being threefold greater for patients with arterial resection.

Regarding SMA resection, only a few studies are available, including a total number of less than 50 patients. All studies show that the resection is technically possible and grafting with the saphenous vein is the most commonly used method for reconstruction. However, morbidity of this approach remains high and the oncologic outcome is not convincing from the limited evidence to date. Celiac axis or hepatic artery resection is performed more often. Current literature includes approximately 200 patients on this topic [39]. Surgical morbidity is up to 40% and mortality in PD with arterial resection ranges from 0–35%, showing the inconsistent data basis of this approach. Overall outcomes following PD with arterial resection seem to justify the approach especially in DP and were comparable to previous reports of major cancer operations commonly performed regarding long-term survival and oncologic results. From the technical point of view, after celiac axis or hepatic artery resection reconstruction can be carried out either by direct anastomosis, by interposition of a venous graft (i.e., reversed saphenous or internal jugular vein) or with a prosthesis. The celiac axis might be resected down to its aortal orifice in PD as well as in DP or total pancreatectomy. As long as the proper hepatic artery can be preserved, a reconstruction is possible. An arterial graft (i.e., splenic artery) can also be used [51].

Regarding DP, celiac axis resection without revascularization (modified Appleby procedure) is an option for tumor removal as long as the proper hepatic artery is preserved and a sufficient arterial inflow via the gastroduodenal artery is present (Fig. 108.3). Numerous case series have described this procedure with reasonable results in terms of surgical and oncologic outcome, which seem to be nearly equal to the standard approaches [52–59]. According to the larger series in the literature, including more than 10 patients, these procedures can be carried out with mortality rates of 0–7% and an average overall morbidity of ~50%. Median survival in these reports ranges between 10 and 25 months, in the majority of publications ~20 months can be achieved. According to these retrospective studies, the modified Appleby procedure seems to be a considerable option in terms of postoperative and long-term outcome; however, no high-level evidence is available to support these findings.

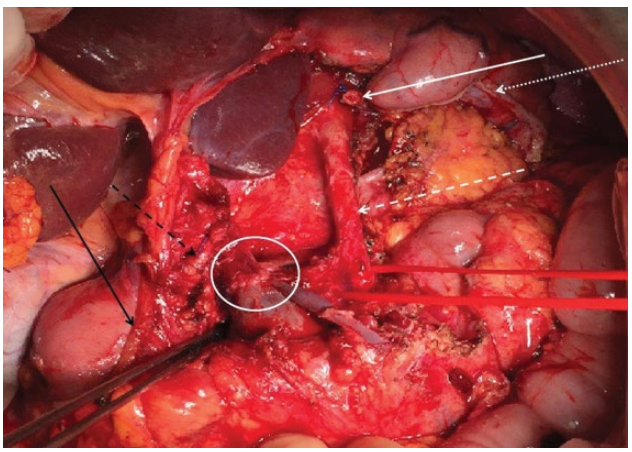

**Figure 108.3** Intraoperative situs after modified Appleby resection for PDAC of the pancreatic body combined with PV resection (white circle). Cut CA basis (white arrow), dissected SMA (broken white arrow), subcardial cut margin of the stomach (dotted white arrow), cut margin of the duodenum (black arrow), preserved gastroduodenal artery for hepatic perfusion (broken black arrow).

### Combined Vascular Resections

Data on combined vascular procedures (venous and arterial resection) are scarce. There is only very limited literature published on this topic, no conclusive evidence with regard to perioperative morbidity and oncologic outcome is available. The approach is technically feasible, but is not recommended as a standard procedure and must be based on individual decisions.

### Multivisceral Resections

If adjacent organs are affected by locally advanced PDAC (i.e., colon, stomach, left adrenal gland, small bowel, or left kidney), complete tumor removal requires partial or total resection of these organs, which also fulfils the criteria of "extended resections" defined by the ISGPS in 2014 [32]. A neoadjuvant treatment is not indicated if technically a complete resection can be achieved based on the preoperative cross-sectional imaging. In larger series, between 20 and more than 270 patients are included and the most commonly resected organs are the colon and stomach [5, 10, 60–62]. In many patients also PV/SMV resections are often performed synchronously reflecting the local extension of the tumor and the close anatomic relationship of these venous structures. Multivisceral resections have been investigated in large patient collectives and are associated with an increased postoperative morbidity predicted by a long operation time and a resection of two or more additional organs [10, 60–62]. Postoperative mortality is not increased unless patients show a relevant preoperative comorbidity. Regarding oncologic outcome, survival is similar to standard resections and in ~10–15% of these patients 5-year survival can be achieved, which is clearly superior to any palliative treatment option. These results underline that extended surgery is a feasible approach if patients are accurately selected for these procedures as certain subgroups seem to have a much greater benefit from surgery than others. For this purpose, common cross-sectional imaging is not sufficient and other markers need to be defined in the future. Tumor markers, especially CA 19-9, are used in the clinical practice. A cutoff value of 400 U/mL has been identified as the threshold for a poor oncologic outcome and may help to stratify patients preoperatively [63].

### Metastases Resection

According to international guidelines and clinical practice, Stage IV PDAC patients are generally referred to palliative treatment by chemotherapy [2, 19, 20]. With the administration of modern chemotherapy regimens, a median survival of 11 months can be achieved in a palliative setting [64]. However, these regimens are often associated with severe side effects that can impair patients' QOL and no long-term survivors have been reported. Although it remains unquestionable that PDAC with diffuse tumor spread to the liver, peritoneum, or the lung is a situation in which surgery is not indicated, the approach of a surgical resection or liver-directed therapies in oligometastatic situations has been performed in a limited number of studies in the past with partly conflicting results [65–69]. An older meta-analysis published in 2007 [21] showed no clear benefit for resection of metastases; however, the study was based on a small case series and, therefore, the evidence was highly limited. A recent study showed more encouraging results with a median survival of 12 months [70], which is clearly superior to recently reported survival times of 6–7 months following palliative standard chemotherapy (i.e., gemcitabine). Although this survival time may be expanded by modern chemotherapy regimens (i.e., FOLFIRINOX), this is achieved at the price of high toxicities with a considerable impairment of quality-adjusted life-time. An additional resection of liver metastases may not have an influence on postoperative morbidity resulting in reduced QOL. In addition and most importantly, in contrast to the palliative setting, the combination of surgery and adjuvant chemotherapy can give the perspective of a long-term survival with 5-year survival rates of 10%, which is impossible without surgery in Stage IV PDAC. This underlines the importance of a comprehensive multimodal approach and a proper patient selection of surgical candidates with Stage IV PDAC. Besides synchronous resection in an oligo-metastatic situation, also metachronous approaches to liver metastases have been reported [66–68, 70]. In this context, the interval between the initial and the consecutive operation or liver-directed therapy may be useful as an additional criterion for patient selection, and probably best reflects the tumor biology and potential prognosis of the individual patient. In general, from the clinical experience a time interval of 12 months can probably be regarded as a reference, although not based on high-level evidence. As this observation period cannot be used for synchronous resection of liver metastases, the decision for surgery in this situation remains even more challenging and additional studies and markers are warranted for prognostic patient stratification and evaluating these approaches in the future.

## Postoperative Outcome of Extended Surgical Approaches

The outcome after extended resections has to be differentiated between short-term postoperative morbidity and mortality and the long-term consequences for the respective patients in terms of metabolism, nutritional status, and QOL.

As mentioned earlier, extended lymphadenectomy procedures are associated with a considerable rate of postoperative complications, although in-hospital mortality is not increased [14–18]. A major—and often long-lasting—problem is the occurrence of chyle leaks, which are observed after 1.3–10.0% of all pancreatic resections [71–73]. In extended approaches, especially when dissection of para-aortic lymph nodes has been performed, this rate may increase and require total parenteral nutrition, percutaneous interventions or even surgical leak closure [74]. As also severe diarrhea can impair patients' QOL and no survival benefit has been shown for extended lymphadenectomy, this approach is not recommended and has mostly been abandoned [14–17, 75].

Postoperative morbidity after extended PDAC surgery including vascular and multivisceral resection is increased compared to standard approaches. In large series, the most important complications comprise bleeding with the need for transfusion, POPF, and DGE [10, 60–62, 76, 77]. Moreover, the rate of re-laparotomy, the length of ICU stay and—in some studies—also in-hospital mortality (up to 9%) is increased [60, 76]. With regard to the oncologic benefit of these procedures compared to palliative treatment, however, these approaches are recommendable and established in high-volume centers around the world.

Long-term QOL after extended pancreatectomies is dependent on the performed resection. The most invasive resection is total pancreatectomy, which inevitably leads to a complete endocrine and exocrine failure with the need for insulin and high-dosage enzyme replacement. Especially within the first 12 months postoperatively, these changes occur with a body weight loss of ~10% [78–80]. Even under good glycemic control, which can be achieved in most patients with $HbA_{1c}$ levels between 6.4–7.0%, the occurrence of fatty liver disease is observed within this time period in up to 75% of patients [80]. Despite these problems, it has to be emphasized that in most patients undergoing total pancreatectomy for PDAC, in the long term QOL is not determined by postoperative changes but by the underlying disease itself, as within 2–3 years local recurrence or metastatic disease are frequently observed. Therefore, chemotherapy and tumor progression may impair QOL to a much greater extent than pathophysiology of glycemic and nutritional status. Furthermore, in case of actual long-term survival, it has been shown that QOL continuously improves up to 4 years postoperatively and patients can reach a functional scale level of up to 90% compared to healthy controls with regard to physical, social, emotional, and role functioning [78]. For PD or DP combined with extended procedures, QOL impairment is generally less pronounced than after total pancreatectomy. In a 105 patient cohort of patients after PD, a similar overall QOL was observed when standard and extended PD was evaluated [81]. In all subscale scores (physical, social, emotional, and functional well-being) results between both groups were comparable after a median follow-up of 2.2 years. These results imply that no negative long-term QOL outcomes are associated when extended resections instead of standard procedures are required during PDAC surgery. Yet, it seems reasonable to subject patients to a structured follow-up postoperatively to recognize potential metabolic and nutritional problems early and initiate or optimize the required therapeutic measures [82].

# Palliative Pancreatoduodenectomy: Benefits and Limitations

*Christoph W. Michalski[1], Max Heckler[1], Mert Erkan[2], and Markus W. Büchler[1]*

[1] *Department of Surgery, University of Heidelberg, Heidelberg, Germany*
[2] *Department of Surgery, Koc University, Istanbul, Turkey*

## Introduction

While surgical removal of the tumor remains the only curative treatment option for patients suffering from pancreatic ductal adenocarcinoma (PDAC), only a minority of diagnosed cases receive surgery. This is due to frequent diagnosis of PDAC in locally advanced stages, distant metastatic disease [1], and sometimes delayed referral to a pancreas center [2]. When possible, resection of the primary pancreatic tumor is the treatment of choice and is considered potentially curative. However, rates of margin-positive resection (R1) are exceptionally high (>70%), according to recent data using a revised pathology classification [3,4]. Thus, the term "palliative resection" should be used with caution and be reserved for obvious R2 situations. This is particularly true, because in both the margin-negative (R0) and -positive (R1) groups of patients, long-term survivors are found [5]. However, planned "palliative resections," for example debulking procedures, have been shown to have no effect on survival and should thus generally not be attempted [6–9]. For palliation of symptomatic advanced PDAC, interventional bile duct stenting and/or bypass surgery without tumor removal are the treatment of choice [10,11].

## Definition of Palliative Resection

One of the greatest clinical challenges in making treatment decisions for patients with PDAC is the pretreatment stratification of tumors deemed to be either locally confined or locally advanced. Metastatic disease is usually found before treatment is initiated. Because of the lack of biomarkers to stratify the heterogeneous group of PDAC preoperatively, the treating physician's most important tool of diagnosis is cross-sectional imaging. The diagnostic accuracy of computed tomography (CT) and magnetic resonance imaging (MRI) has considerably improved over the last decades. However, the exact dimensions of the tumor and its relationship to surrounding structures and organs are frequently difficult to determine. While putative invasion of the superior mesenteric/portal vein axis can be managed surgically to achieve margin-negativity (at least at the vein margin), tumor extension towards the superior mesenteric artery is at times hard to determine in preoperative scanning and may even intraoperatively be only detected in the final pathology specimen. Similarly, the medial margin (the so-called "mesopancreas"), is frequently at risk but can mostly only be judged on when the resection has been performed. Thus, exploratory laparotomy followed by dissection of the superior mesenteric artery axis (and/or the celiac axis) is sometimes necessary to determine exactly local resectability.

## Review of the Literature

The advent of higher resolution in cross-sectional imaging and the advance in surgical techniques have led to the expansion of the spectrum of patients receiving surgery. A cohort study including over 16,000 patients receiving pancreatic resection identified an in-hospital mortality of 5% [12] illustrating both the risk of pancreatic surgery and the rising standard of intraoperative and postoperative treatment. However, it is important to notice that pancreatic surgery is a field where great expertise of the surgeon and the whole team is required to reduce patient risk to a minimum. This is especially true for initial assessment of operability, which paves the way for the further course.

## Imaging and Staging

Contrast-enhanced helical computed computer tomography (tri-phasic pancreatic-protocol CT) and/or magnetic resonance imaging of the abdomen and pelvis represent the essential cornerstones of preoperative tumor staging and assessment of resectability [13,14]. Involvement and invasion of major abdominal vessels including the superior mesenteric artery (SMA), superior mesenteric vein (SMV), portal vein, and celiac axis are crucial determinants of local operability and the possible extension of surgery beyond classical procedures such as the Whipple's operation. While venous and/or portal vein involvement are no strict contraindication for a potentially curative approach [15], tumors with advanced arterial involvement are regarded as locally incurable [16]. It is generally accepted that in these cases R0 resection is practically impossible to achieve, and extension of surgery, that is, major arterial resection, may increase morbidity and mortality without a proven benefit for survival and therefore should only be performed in selected cases within clinical studies. As described later, recent multimodality treatment strategies using polychemotherapy as a neoadjuvant therapy are valid options in such a setting.

In recent years special attention has been drawn to the SMA, as the adherent posterior resection margin is the most common location of microscopic tumor remains (R1 situation) [4]. While neither of the cross-sectional imaging modalities provide high accuracy in predicting SMA involvement, surgical exploration remains the only reliable diagnostic means. During a classical pancreatoduodenectomy the medial and posterior resection margins can only be reliably assessed after transection of the pancreas has been performed. These findings have led to the so-called posterior artery-first approach for locally advanced tumors [17], which allows for precise intraoperative assessment of the SMA before transection of the pancreas.

In addition to palpation and visual control, intraoperative ultrasonography (IOUS) has further increased the accuracy of resectability assessment [18,19]. This illustration of the diagnostic process, which in many cases only begins at the time of laparotomy, suggests that only specialized surgeons in high-volume centers should perform operations on malignomas of the head of the pancreas labeled as borderline resectable.

## Perioperative Multimodal Therapy

Due to highly invasive growth and the tendency to metastasize in early tumor stages, PDAC can be considered a systemic disease. While surgery is the only curative option in early tumor stages, the systemic nature of advanced disease PDAC justifies the need for a multimodal therapeutic approach.

If local unresectability is confirmed intraoperatively, surgery is terminated and chemotherapy or chemoradiation may be initiated. Because FOLFIRINOX-based chemotherapy regimens have recently been shown to be effective with considerable response rates (at least when compared with classical chemoradiation) [20–23], we advocate administrating four to six cycles of FOLFIRINOX before restaging, followed by pancreas CT-staging. If there is no local growth, no distant metastasis, preferably a decrease in CA 19-9, and if the patient's general health status allows, re-exploratory laparotomy is performed and resectability judged again. This approach has shown considerable local response to chemotherapy with margin negativity. However, intraoperative judgment is complex because of the remaining local fibrotic response, which cannot be differentiated from the presence of remaining cancer cells, resulting in a longer, more demanding operation compared to surgery without neoadjuvant treatment [24]. A recent publication by Katz et al. [25] even suggests surgery in the setting of local tumor growth during restaging, as long as distant metastases are excluded, due to the lack of adequate predictive value of imaging in this setting. If the tumor had primarily been unresectable, resection rates after neoadjuvant therapy can be up to 40–50% [26,27]. Several studies demonstrated that the rate of margin-negative resections in this setting is comparable to the rate in initially resectable patients [26,27]. Intraoperative frozen tissue sampling may be helpful in distinguishing the fibrotic tissue from viable tumor.

Intraoperative radiotherapy (IORT) is a treatment option when an intraoperatively obtained frozen tissue section shows margin positivity. A recent systematic review on the topic suggests possible survival benefits for selected patients, without reaching statistical significance [28].

## Novel Classification of Margin Status

Recently, Verbeke et al. demonstrated that after application of a novel, standardized pathology protocol, a significantly higher amount of patients (85%) had a positive margin [3]. Esposito et al. presented similar data and showed that most pancreatoduodenectomy specimens (operated on with curative intent) in their series of 111 patients had a locally incomplete resection (76% R1 resections) [4]. This led the authors to the assumption that a standardized protocol on tissue workup rather than the extent of surgery predominantly determines the

R1 status. An intriguing but difficult-to-prove hypothesis is that R1 status in resected PDAC may be linked to the underlying biologic phenotype. A more aggressive biologic tumor phenotype in R1 resected tumors with an elevated lymph node ratio and more microvascular invasion compared with R0 resected tumors was identified in a recent study by Kimbrough et al. [29]. This underlines the urgent need for a diagnostic approach reaching beyond macroscopic and microscopic description of the cancer towards a biologic model allowing for individualized, tumor-adapted treatment.

### Palliative Surgery

In patients with jaundice and/or gastric outlet obstruction who suffer from a tumor labeled as unresectable, bypass surgery is a viable option (see Chapter 110) to ensure symptomatic relief. Because debulking is sometimes inevitable, there are a few studies evaluating outcomes after debulking procedures.

A recent systematic review performed by Gillen et al. [7] includes four patient cohorts with a total of 399 patients. Of these patients, 138 received pancreatic resection (R2 status), whereas the others underwent surgical bypass (biliary and/or enteral). Operation time, morbidity and mortality were significantly increased in the resection group, whereas overall survival was only minimally extended. Similar results were obtained by Tachezy et al. who included 22 patients in their study and also reported significantly higher rates of complications in the resection group [6]. Both authors conclude that in the context of locally advanced carcinoma intentional incomplete pancreatoduodenectomy is not justified [30].

## Management of Preoperatively Under-Staged Patients

Because of the limitations of contemporary diagnostic methods and the resulting vagueness in preoperative imaging, some patients are also discovered to have locally advanced tumors during operation in our institute. Nevertheless, routine staging laparoscopy is not employed because of the reported limited detection rate and the likely absence of a large gain after switching from surgical to endoscopic palliation [31].

In patients without any evidence of distant metastasis and when the tumor is clearly locally unresectable, the operation is terminated and neoadjuvant therapy is planned [20–23]. Palliative bypass (biliary and gastric) operations in such patients depend on the tumor extent and on the patient's symptoms. For example, in patients with functional biliary stents, bypass operations are not undertaken. However, if the patient has biliary obstruction, biliary and gastric bypass operations are performed. After completion of neoadjuvant therapy, patients are reevaluated. All patients without clear evidence of distant metastasis are offered surgical exploration. The exploration is terminated if metastatic disease is detected during laparotomy. All patients without metastasis may receive—if available in the institution—another boost of IORT (15 Gy) regardless of resection status, and all tumors deemed resectable after neoadjuvant treatment are removed.

In patients without any evidence of distant metastasis, when the tumor appears to be locally resectable, a resection is carried out. When a resection is only achieved with a likelihood of a tumor-positive margin, the patients may receive intraoperative radiation to the resection bed, if available.

In any event, when a positive SMA and/or celiac trunk margin is verified by frozen section after resection of the pancreas is performed, a careful and meticulous surgical attempt is made to convert an R2 resection into an R1/R0 resection (it can also be argued that once tumor integrity is disturbed, it is no longer possible to achieve an R0 resection). However, it should be emphasized that such an attempt could create a domino effect that may ultimately necessitate the ligation of major vessels or re-arterialization of the liver or the bowels. Therefore, it should be kept in mind that such procedures can potentially increase the morbidity and mortality rates, and should not be attempted outside of referral centers.

## Conclusions

True palliative pancreatoduodenectomy in PDAC (e.g., with macroscopically positive margins) is generally regarded as obsolete and should not be performed electively. Nevertheless, with the currently limited diagnostic modalities, it is unavoidable in approximately 10% of patients. Under such circumstances, most R2 resections can be converted to R1 resections with meticulous surgery. It should be emphasized that such an attempt is not based on evidence and should only be performed as part of a scientific study in tertiary referral centers. Aggressive surgical approaches are justified, since resection provides the only chance of cure for some, and the best palliation for most, of the patients. Further research to preoperatively stratify the patient cohorts is necessary to delineate groups that benefit from extended resections from those who do not.

# Bypass Surgery for Advanced Pancreatic Cancer

*Jürgen Weitz[1], Thomas Pausch[2], Christoph W. Michalski[2], and Thilo Hackert[2]*

[1] *Department of Surgery, Dresden University Hospital, Dresden, Germany*
[2] *Department of Surgery, University of Heidelberg, Heidelberg, Germany*

## Introduction

Complete surgical removal is the only curative therapy for pancreatic cancer [1]; however, fewer than 20% of patients present with resectable disease at the time of diagnosis. Among them, fewer than 10% receive a margin-negative resection (according to the latest pathology standards) and overall 5-year survival rates remain at less than 5% [2]. Palliative therapy to reduce or to prevent symptoms is needed in many patients not eligible for resectional surgery [3]. Different from the situation with a potentially resectable tumor, histologic confirmation should be obtained in potentially palliative cases in order to guide further management. Palliative therapy primarily aims to reduce pain, obstructive jaundice, and duodenal obstruction. The latter two are most frequently palliated using endoscopic/interventional methods, but can also be treated with bypass surgery. However, the potential benefit of a surgical procedure must be weighed carefully against perioperative morbidity and length of hospital stay. This holds particularly true for patients with a presumed very limited overall survival. The decision to perform a surgical bypass procedure is made either in patients in whom the tumor was initially deemed resectable, in those where endoscopic/interventional bypass is impossible, or in select cases with a potentially relatively good prognosis (e.g., over 1 year of expected survival). This chapter focuses on the indications for endoscopic/interventional versus surgical bypass procedures and the respective operative techniques and approaches.

## Background

Before the mid-1980s, palliation of biliary and/or duodenal obstruction was provided primarily through surgical bypass [4]. In some series, up to 57% of the patients with unresectable pancreatic cancer underwent surgical bypass [5]. Palliative surgical bypass of the gastrointestinal and biliary tracts has been the standard course of therapy in many of these cases [6]. Due to great improvements in interventional and endoscopic therapies, palliation of jaundice and/or gastric outlet obstruction is nowadays mostly performed nonsurgically.

## Symptoms

Biliary obstruction with jaundice most frequently emerges as a result of carcinomas of the pancreatic head and is the most frequent presenting symptom [7]; it occurs in about 80% of patient with tumors of the pancreatic head. In patients with a carcinoma of the body or tail of the pancreas, it occurs in late course of the disease and thus only rarely requires palliative bypass procedures. Because obstructive jaundice causes malaise, malabsorption and anorexia, severe and resistant pruritus, and impaired liver function leading to liver failure, its palliation is clinically important. Mechanical gastric outlet obstruction, however, occurs in less than 5% of all patients with pancreatic carcinoma at time of presentation and in only approximately 10–30% in cases of advanced disease [7]. Importantly, nausea and vomiting

occur in the majority of pancreatic cancer patients without suffering from duodenal obstruction. This is attributed to retroperitoneal infiltration of autonomic nerve plexus leading to gastric dysfunction and cannot be palliated by a bypass procedure [8].

## Endoscopic or Interventional Biliary Decompression

Endoscopic stenting through endoscopic retrograde cholangiopancreatography (ERCP) is widely accepted as the standard palliative treatment for patients with malignant biliary obstruction (current studies comparing covered and uncovered stents are summarized in Table 110.1). Through a minimally invasive procedure, endoscopic stenting relieves biliary obstruction within a short period of hospitalization. Compared to surgical methods, it is associated with a lower short-term complication rate (also see later). However, it frequently necessitates redo procedures, mainly because of stent occlusion or stent migration. Alternatives to endoscopic stenting are the percutaneous transhepatic cholangio-drainage (PTCD) or the surgical bypass.

Palliative endoscopic transpapillary drainage was first described in 1980 [9] and today endoscopic decompression has a 90% success rate and low morbidity and mortality [10]. Endoscopic endoprostheses need to be changed approximately every 4–6 months, while self-expanding metal stents (SEMS) have longer patency rates [11]. SEMS have been enhanced with different kinds of walls promising better patency and stent migration rates but definitive data favoring one special type of stent over another are missing [12–14]. However, a recent publication demonstrated that covered SEMS were not inferior to multiple plastic stents [15], with the restriction that this study was carried out on patients with a benign biliary stricture.

Although endoscopic stenting is the preferable method for treating bile duct obstruction, it is technically unfeasible in some patients; particularly, when there is an occlusion that cannot be bridged endoscopically (e.g., complete obstruction) [16]. In such cases, PTCD—which was initially described in 1974 [17]—is a valid option, despite the higher risk of major complications (i.e., bleeding, biliary fistula, liver abscess) and its conflicting therapeutic success rate [18,19].

## Surgical Bypass: Techniques

Despite the success of endoscopic treatment of biliary obstruction, surgery continues to be an important alternative option for select patients. Surgery was historically the first option as a bypass procedure and the initial techniques have been described as cholecystojejunostomy by Monastyrski in 1887, as choledochoduodenostomy by Sprengel in 1891, and as hepaticojejunostomy by Dahl in 1909 [20]. Cholecystojejunostomy is a relatively simple procedure but has low long-term patency rates with 8–11% of recurrent jaundice compared to 0–3% after choledochojejunostomy [5]. In a large cohort study of 1,919 patients, cholecystoenterostomy was significantly inferior to other bypass procedures [21]. Occlusion of the cystic duct might explain the lack of long-term patency since the hepatocystic junction was located most frequently within 1 cm distance from the biliary obstruction. Because of this anatomic situation, cholecystojejunostomy was thus found to be frequently inadequate for the permanent relief of recurrent obstruction [22]. We believe that this procedure is only an option in cases where dissection of the porta hepatis is technically challenging, for example because of local variceal conversion due to portal hypertension/portal vein thrombosis. Recently, hepaticocholecystojejunostomy has emerged as a potentially viable alternative to hepaticojejunostomy. Here, similar functional results have been shown, whereas the construction of the bypass was technically less demanding than a hepaticojejunostomy [23,24]. While laparoscopic biliary decompression would be feasible in principle, laparoscopy does not commonly allow for judging resectability at the same extent as open surgery. It is thus infrequently used [25,26].

## Endoscopic Versus Surgical Bypass

In general, surgical bypass has been linked with a higher risk of morbidity and mortality [27]. In 2007, Moss et al. published a meta-analysis comparing surgery with plastic stent deployment [27]. However, no differences in technical success, therapeutic success, quality of life, or length of survival were found. Similar results were obtained by two previous meta-analyses using the same data and methods [28,29]. Maosheng and co-workers reported a retrospective study comparing biliary bypass with SEMS in treating biliary obstruction caused by unresectable pancreatic cancer [30]. Here, there was no significant difference in procedure success rate, early complication, and survival between the surgical and stenting groups, though patients receiving surgery had a lower prevalence of late complications (mainly due to recurrent biliary obstruction). In line with these data, the incidence of recurrent jaundice in surgical patients is consistently lower than that in stented patients despite the fact that surgery itself tends to be associated with a higher early complication rate [31–33]. Apart from the biliary bypass, two randomized controlled trials

**Table 110.1** Selected studies on endoscopic biliary stenting.

| | Year | Type of stent | Patient number | Mean stent patency | Mean patient survival | Cumulative stent patency rate at 6 months | Cumulative stent patency rate at 12 months | Complications rate (early, late) | Stent occlusion (%) |
|---|---|---|---|---|---|---|---|---|---|
| Lee | 2014 | SEMS | 20 | 413 | 359 | 74% | 63% | (0%, 20%) | 20% |
| Lee | 2014 | CSEMS | 20 | 207 | 350 | 49% | 25% | (5%, 50%) | 50% |
| Ung | 2014 | SEMS | 34 | 127 | 157 | – | – | (0%, 17%) | 17% |
| Ung | 2014 | CSEMS | 34 | 153 | 154 | – | – | (6%, 13%) | 13% |
| Kitano | 2013 | SEMS | 60 | 132 | 222 | 60% | 43% | (3%, 37%) | 37% |
| Kitano | 2013 | CSEMS | 60 | 187 | 285 | 82% | 63% | (3%, 23%) | 23% |
| Krokidis | 2011 | SEMS | 40 | 166 | 203 | 70% | 70% | (10%, 30%) | 30% |
| Krokidis | 2011 | CSEMS | 40 | 234 | 247 | 92% | 87% | (12.5%, 10%) | 10% |
| Kullman | 2010 | SEMS | 191 | – | 174 | 78% | 56% | (10%, 23%) | 23% |
| Kullman | 2010 | CSEMS | 188 | – | 116 | 74% | 50% | (7%, 24%) | 24% |
| Telford | 2010 | SEMS | 61 | 711 | 239 | 90% | 55% | (26%, 18%) | 18% |
| Telford | 2010 | CSEMS | 68 | 357 | 227 | 87% | 47% | (33%, 29%) | 29% |

demonstrated that an additional prophylactic gastrojejunostomy (e.g., double bypass) is effective in preventing the development of potential gastroduodenal obstruction without increasing surgery-related morbidity and mortality [6,34]. However, surgery itself is more extensive and may significantly affect the quality of life of patients with a short life expectancy. Advantages of surgical bypass increase with longer survival of the patient, avoiding frequent readmissions and recouping initial higher costs with less future management costs than in nonsurgical patients [35]. Thus, surgical bypass is a good option for those patients in whom unresectable cancer during surgery for planned tumor resection is found, and also occasionally for patients who have a relatively long life expectancy [6,36]. Several factors were found to predict early mortality following palliative bypass: presence of distant metastatic disease, poor tumor differentiation, severe preoperative nausea and vomiting, and lack of previous placement of a biliary stent [37]. These factors may be helpful in selecting appropriate interventions for this group of patients undergoing a palliative bypass procedure. Nevertheless individual clinical judgment is still important when discussing the options with the patient. Importantly, the recent increases in survival even in Stage IV disease using polychemotherapy [38] may render surgical bypass a more frequently used procedure in the (near) future.

## Gastric Decompression

Placement of a nasogastric tube or percutaneous gastrostomy are options for palliative gastrostomy that reduce quality of life substantially and do not give nutritional support for the patient. The endoscopic method to bridge malignant stenosis with a metal stent has been proven to be an alternative to surgical bypass in retrospective studies and small randomized control trials with a technical success rate of over 90%, a stent-obstruction rate of about 10% within 15 weeks, and a stent migration rate of less than 3%; however, data on long-term outcomes are scarce [39]. Thus, in cases with true gastric outlet obstruction, surgical gastrojejunostomy remains the standard of care [40].

## Surgical Technique

Surgical gastric bypass was initially described by Wölfler and Wosler in 1881 in an antecolic way. Retrocolic gastrojejunostomy was performed first by Courvoisier in 1883 with the patient not surviving the operation while von Hacker performed it successfully in 1885. After years of debate about the value of gastrojejunostomy due to high morbidity and mortality, the results of gastroenterostomy have improved significantly [40]. Today's standard side-to-side gastrojejunostomy can be performed in antecolic or retrocolic fashion, but delayed gastric emptying is still a relevant clinical issue after this procedure [34]. Laparoscopic gastric bypass procedures are a viable option and recently gained more attention [25,41].

## Comparison of Surgical Gastric Decompression with Nonsurgical Management

Prophylactic retrocolic gastrojejunostomy at diagnosis of unresectable disease during explorative laparotomy was studied by Lillemoe et al. [6] and showed an increase in operation length, no differences in blood loss or transfusion, or in postoperative morbidity and mortality including delayed gastric emptying rate, length of hospital stay, and mean survival (8.3 months) compared with no gastric bypass. About 80% of the patients received additional hepaticojejunostomy. Late gastric outlet obstruction appeared more frequently in the control group (19% vs. 0%, $P = 0.01$) after a median of 2 months. Therefore the authors concluded that prophylactic gastrojejunostomy should be performed routinely in patients with unforeseen unresectable periampullary cancer. This was confirmed in a recent meta-analysis and systematic review [40]. Van Heek et al. [34] compared double bypass (hepaticojejunostomy and retrocolic gastrojejunostomy) to single bypass finding no significant differences in terms of postoperative morbidity including delayed gastric emptying, length of hospital stay, survival, and quality of life. Gastric outlet obstruction occurred significantly more often in the single bypass group, leading to an increased rate of repeat gastrojejunostomy. A longitudinal analysis of quality of life after double bypass by the same authors showed that quality of life can be preserved for a considerable time [42]. Fig. 110.1 shows a CT scan of a pancreatic cancer with distal infiltration of the duodenum and the mesenteric root with consequent local unresectability. A surgical biliary and duodenal bypass procedure was performed after multiple, unsuccessful attempts at endoscopic/interventional bypass.

## Our Approach

Given these data, we perform prophylactic gastrojejunostomy and hepaticojejunostomy as our standard approach in patients with unforeseen unresectable pancreatic

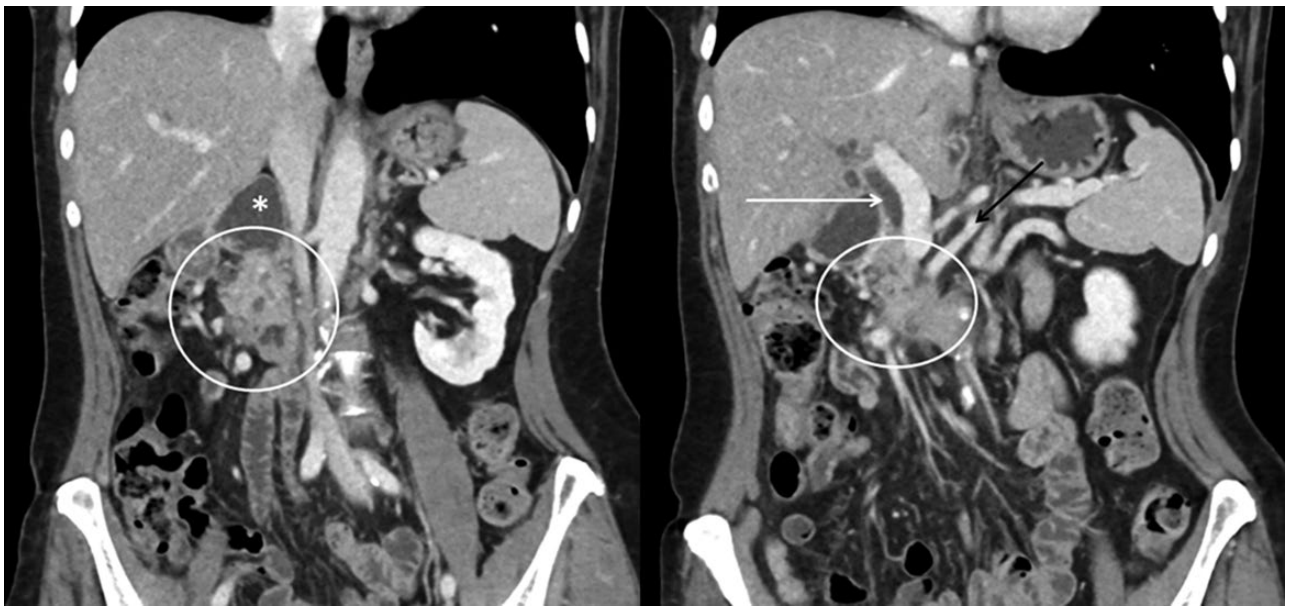

**Figure 110.1** Locally advanced pancreatic cancer with invasion of the duodenum and obstruction of the bile duct. Left side: tumor (white circle) with complete duodenal obstruction (white star). Right side: infiltration of the superior mesenteric artery (black arrow) by the tumor (white circle) and obstruction of the bile duct (white arrow).

cancer to reach palliation of symptoms in one definite procedure [43]. Patients with primarily unresectable disease but a presumed favorable survival time may receive surgical bypass in select cases. Laparotomy includes cholecystectomy and obtainment of histopathologic diagnosis. After double fenestration of the transverse mesocolon and isolation and division of the bile duct followed by running suture closure of the distal bile duct stump, division of the jejunum with a linear intestinal stapler is conducted 60–80 cm distal to the ligament of Treitz. Retrocolic end-to-side hepaticojejunostomy is conducted with the distal jejunal part before an isoperistaltic side-to-side gastrojejunostomy of about 6 cm length to the first jejunal loop and an end-to-side jejunojejunostomy at least 40 cm distal to the hepaticojejunostomy is performed. Routine nasogastric tube is only used in cases of gastric dilatation. Oral feeding is started and removal of the intra-abdominal drains is performed on the first postoperative day. This standardized approach is associated with minimal morbidity and mortality. However, constant improvement in preoperative staging in the last years has led to a significant reduction in the number of such bypass procedures. As described earlier, recent progress in multimodality treatment may considerably increase survival time for many more patients, which in turn may again increase the number of surgical bypass procedures.

# Nonsurgical Palliation of Pancreatic Cancer

## 111

## Endoscopic and Interventional Palliation of Pancreatic Cancer

*Takao Itoi*

*Department of Gastroenterology and Hepatology, Tokyo Medical University, Tokyo, Japan*

## Introduction

The number of cases of pancreatic cancer has been increasing worldwide. The latest data show that the number of cases of pancreatic cancer has increased to more than 50,000 in the United States [1]. Most pancreatic cancers are in their advanced stage when they are detected with more than 80% of patients not surgically resectable [2]. Most patients with advanced pancreatic cancer show resistance to adjuvant therapies such as chemotherapy, resulting in a mortality of more than 40,000 in the United States [1]. Unresectable pancreatic cancers cause various complications, such as obstructive jaundice, gastric outlet obstruction, abdominal pain, main pancreatic duct obstruction, and pancreatitis, which will delay the start of palliative chemotherapy. Surgical intervention such as hepatojejunostomy and gastrojejunostomy are invasive procedures and delay recovery compared with nonsurgical intervention by interventional endoscopy (IVE) and interventional radiology (IVR). Intervention by endoscopic ultrasonography (EUS) supplements therapeutic endoscopic retrograde cholangiopancreatography (ERCP).

## Biliary Obstruction

Malignant biliary obstruction, particularly in the extrahepatic bile duct, is one of the most common symptoms in patients with advanced pancreatic cancer. The progression of biliary obstruction causes cholestasis and jaundice, and sometimes acute cholangitis, leading to fat malabsorption, malnutrition, and cachexia. Absence of therapy for obstructive jaundice leads to exacerbation of liver dysfunction and eventually liver failure. Thus, biliary drainage has been traditionally performed to improve the quality of life of patients. For resectable pancreatic cancer with jaundice, preoperative biliary drainage (PBD) has been preferred to improve the postoperative morbidity and mortality rates. However, recent high-quality studies [3,4] have suggested that PBD should not be performed routinely. There are a number of drainage methods including percutaneous transhepatic biliary drainage (PTBD), endoscopic drainage by ERCP, and combined procedures, and various types of endoscopic stents including small and large bore plastic stents. PBD using a large-bore metal stent is now the preferred technique as a bridge to surgery with a low adverse event rate [5–7].

Traditionally, biliary decompression in patients with unresectable pancreatic cancer has been conducted by ERCP and PTBD as nonsurgical and palliative interventions. The choice of the drainage method depends on the preference of the physician and the presence of skilled ERCP endoscopists and interventional radiologists in each institution. Endoscopic ultrasonography-guided biliary drainage (EUS-BD) has emerged as a salvage therapy in cases of failed ERCP [8].

### Palliation of Obstructive Jaundice by ERCP (Table 111.1)

#### Conventional ERCP

Endoscopic plastic stent placement by ERCP is the most common procedure for biliary decompression since the first report by Soehendra and Reynders-Frederix in 1980 [9]. Early randomized controlled trials (RCT) have revealed that endoscopic plastic stent placement in the palliation of biliary obstruction has a similar outcome in terms of technical success, morbidity, and mortality to surgical intervention [10,11], and is the preferred option

to reduce morbidity and mortality [12]. Plastic stents are usually used at the initial biliary drainage because they are less expensive and can be removed easily while the pancreatic lesion is evaluated. Self-expandable metal stents (SEMS) with a larger bore stent (8–10 mm) allow a longer stent patency, reducing the number of reinterventions compared with small-bore plastic stents (7-Fr to 10-Fr) [13,14]. Plastic stent occlusion occurs within 4 months compared to about 9–12 months with SEMS. A Cochrane review concluded that SEMS were preferable to plastic stents with an additional patency period of more than 4 months, a lower stent failure rate, a lower risk of acute cholangitis, a decreased total hospitalization period, and overall lower costs [15]. Davids et al. [16] showed that the initial use of SEMS results in a 28% decrease in the interventions compared with the initial use of plastic stents. SEMS also appear preferable in patients with borderline resectable pancreatic cancer undergoing neoadjuvant therapy, with fewer preoperative complications [3,17]. Endoscopic metal stent placement has a similar outcome for biliary obstruction compared with surgical bypass [18].

Two meta-analyses have shown equivocal advantages of covered compared to uncovered SEMS [19,20] but a more recent RCT demonstrated a superiority for covered SEMS [21]. Evaluation between stent types is challenging because of the clinical setting and disease heterogeneity and differences in stent engineering such as stainless versus nitinol metals, braded or laser cut, fully or partially covered, and with or without an antimigration system.

One of the most critical issues of endoscopic stenting is reintervention owing to stent blockage. Although a plastic stent can be exchanged with a new stent, removal of a SEMS, particularly an uncovered SEMS, is much more difficult. A stent-in-stent technique inserting a new stent within the existing occluded metal stent can be performed using a plastic stent or an uncovered/covered SEMS. Plastic stent placement may be as effective as a second SEMS placement [22]. Removal of an occluded covered SEMS seems to be an even better option [23–25].

#### Balloon Enteroscopy-Assisted ERCP

ERCP in patients with a Roux-en-Y (RY) reconstruction including a RY gastrectomy and a RY gastric bypass is always a challenging procedure. Conventional endoscopy has a success rate of less than 50%. Single-balloon (SBE) and double-balloon enteroscopy (DBE) have improved success rates in RY reconstructions [26–29]. In patients following a Whipple resection, malignant or benign stenosis of the hepaticojejunostomy can be treated by balloon dilation and/or stent placement using BE-assisted ERCP [30].

### Palliation of Obstructive Jaundice by EUS

Selective biliary cannulation by ERCP for biliary decompression is not always successful because of intradiverticular papillae, surgically altered anatomy, or gastroduodenal obstruction. In the case of failed ERCP but EUS-BD using transmural approaches such as the EUS-rendezvous technique (EUS-RV), EUS-guided choledochoduodenostomy (EUS-CDS), EUS-guided hepaticogastrostomy (EUS-HGS) (Fig. 111.1), and EUS-guided antegrade stenting (EUS-AS) are options [31]. Technical and clinical success rates are around 80–90% with moderate adverse event rates of 10–30% such as bile leakage, bleeding, and stent migration although the severity of most adverse events are mild or moderate [32]. Covered SEMS reduce unexpected adverse events such as bile leakage for biliary decompression, although there is no difference between plastic stents and covered SEMS in the EUS-HGS procedure [33]. Of the EUS-BD procedures, EUS-RV appears to achieve minimum invasive drainage because ERCP and BE-assisted ERCP can be performed. EUS-CDS can be an effective and safe alternative to PTBD with a similar success rate, complication rate, cost, and patient quality of life [34].

### Palliation of Obstructive Jaundice by IVR

PTBD can be achieved by external drainage, internal–external drainage, and internal drainage. A 7-Fr to 8-Fr percutaneous tube is used, which allows sufficient drainage for the therapy of obstructive jaundice. Internal drainage appears to be the most efficacious. Percutaneous SEMS placement using a small-caliber (approximately 6-Fr to 7-Fr) delivery system allows good efficacy, with few complications and reduced pain [35]. Percutaneous covered SEMS placement provides long stent patency compared with percutaneous uncovered SEMS [36]. Endoscopic stenting, however, has a significantly higher

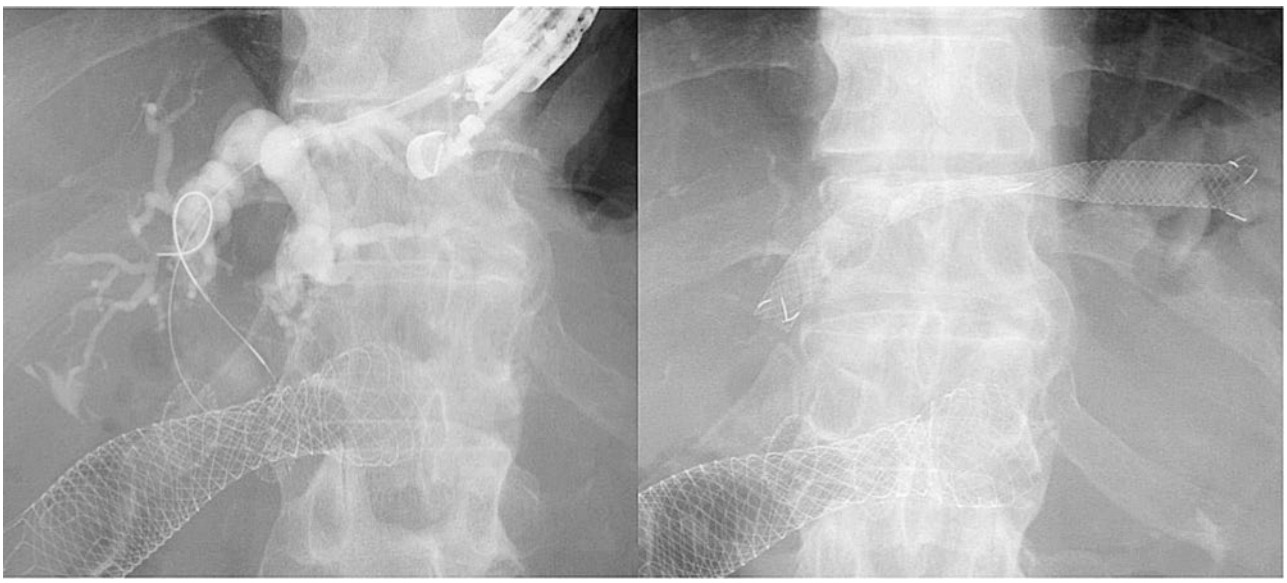

**Figure 111.1** EUS-guided hepaticogastrostomy. Metal stent delivery system was inserted in the intrahepatic bile duct (left). Hepaticogastrostomy was completed using a metal stent.

success rate than percutaneous stenting in relieving jaundice with a lower 30-day mortality from complications associated with liver puncture [37,38]. The success rate of needle puncture in a nondilated bile duct is lower than that in a dilated bile duct (63% vs. 86%) [39]. PTBD remains a salvage therapy [40,41].

## Malignant Gastric Outlet Obstruction

Surgical gastrojejunostomy (GJ) by laparotomy or laparoscopy, provides good palliative treatment for malignant gastric outlet obstruction MGOO, but has a relatively high morbidity and mortality [42,43].

### Duodenal Metal Stent Placement

Duodenal stent placement is undertaken using a 20–22 mm diameter SEMS under fluoroscopic guidance, or endoscopically using a thinner 10-Fr delivery system as an alternative to surgical GJ because the stent can be inserted through the accessory channel with a high technical success rate and less invasiveness [42–47]. A systematic review [42] has revealed that the initial clinical success rate was higher after stent placement than after surgical GJ (89% vs. 72%, respectively) with fewer minor complications (9% vs. 33%, respectively). However, recurrent obstructive symptoms were more frequent after stent placement (18% vs. 1%, respectively) owing to tumor ingrowth, preventing the patient from being able to eat soft solid food or a full diet. Endoscopic stenting might be preferable in patients with a relatively short life expectancy, whereas surgical GJ might be preferable in patients with a longer expected survival (>2 months) [42,43]. Endoscopic stent occlusion often occurs during longer follow-up periods owing to tumor ingrowth. In this cohort, an additional stent is often placed within the original stent, which can lead to early stent occlusion or stent-related adverse events such as perforation. One study has demonstrated that EUS-guided GJ using a dedicated double balloon and a fully covered lumen-apposing SEMS (15 mm in diameter) had a high technical and clinical success without causing serious adverse events (Fig. 111.2) [48].

### Duodenal and Biliary Stent Placement: Double Stenting

In patients with unresectable pancreatic cancer, progression of the cancer is accompanied not only by MGOO but also by biliary obstruction, which is usually a late manifestation. In such patients, both biliary stent placement and duodenal stent placement, so called "double stenting" is often required. The methods and ease of the procedure vary according to the site and timing of the duodenal obstruction. In particular, the duodenal obstruction site appears to be more important in terms of planning the biliary stenting strategy. The duodenal obstruction site is classified in relation to the position of the major papilla, namely, Type I where the obstruction site is at the entrance from the principal papilla, Type II where the obstruction site is somewhat convoluted with the papilla present in the second portion, and Type III where the obstruction site is

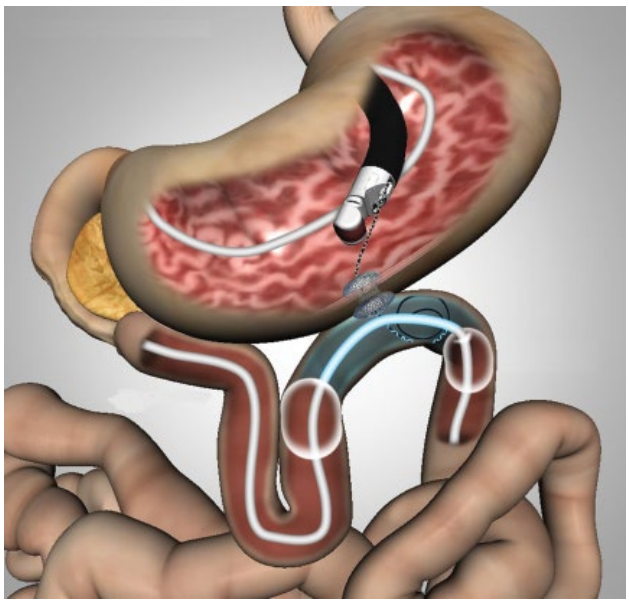

**Figure 111.2** EUS-guided gastrojejunostomy. Lumen-apposing metal stent was placed over the wire using a dedicated double-balloon tube.

closer to the anal side than to the major papilla [49]. In double stenting, biliary drainage with or without the rendezvous technique is performed using three kinds of approaches: the percutaneous transhepatic approach, an ERCP approach, and the EUS approach. In double stenting by ERCP, if the duodenal obstruction site is convoluted around the major papilla (Type II), the treatment is most complicated. Even if the balloon is stretched or the duodenal stent is placed first, cancer invasion makes it difficult to identify the major papilla and confirm the distance from the scope. In addition, it is very difficult to pass the biliary stent through the mesh gap of the duodenal stent. Thus, in case of Type II, the traditional percutaneous transhepatic approach including biliary drainage and rendezvous appears more preferable for double stenting than the ERCP approach. The EUS approach has allowed biliary drainage including EUS-HGS, EUS-CDS, EUS-AS, and EUS-RV even in Type I and Type II MGOO. In Type I and Type II MGOO, EUS-HGS and EUS-AS appear to be suitable drainage techniques for the treatment of obstructive jaundice and can replace the percutaneous transhepatic approach because of the minimum invasive procedures involved [50].

## Pain Management Derived from Cancer

Pain due to cancer invasion of the celiac plexus is a major manifestation of pancreatic cancer occurring in approximately 70% of patients with unresectable pancreatic cancer [51]. At present, pain is comparatively well controlled by opioid analgesics, IVE, and/or IVR. Celiac plexus neurolysis (CPN) is most often performed by injecting a local anesthetic followed by absolute alcohol into the celiac plexus neural network of ganglia with the intention to ablate the tissue transmitting pain from the pancreas and adjacent visceral organs. Currently, there are two CPN approaches, namely, EUS-CPN and percutaneous CPN.

### Endoscopic Ultrasonography-Celiac Plexus Neurolysis (EUS-CPN)

Standard EUS-CPN is performed using a 19-gauge to 25-gauge EUS-guided fine-needle aspiration (EUS-FNA) needle [52]. A needle is advanced anterior to the lateral aspect of the aorta at depiction of the celiac trunk. Then, after confirming the absence of backflow of blood, absolute alcohol is injected following local anesthetic injection. A meta-analysis has demonstrated that pain was reduced in 80% of the patients following EUS-CPN for pancreatic cancer [53]. Although most adverse events of EUS-CPN are mild and include transient hypotension, diarrhea, constipation, and pain exacerbation, serious and fatal adverse events can occur [53]. Unilateral neurolysis is conducted by a single injection into the base of the celiac artery takeoff. In contrast, bilateral neurolysis is performed by injecting into both sides of the celiac plexus. Bilateral injection is superior to central injection for pain reduction (86% vs. 46%, respectively) [53]. An RCT comparing the two approaches in pancreatic cancer among 50 patients showed no significant difference in terms of pain control or adverse events [54]. An RCT comparing EUS-guided celiac ganglia neurolysis (EUS-CGN) in which alcohol is injected directly into the celiac ganglia (detection rates of 80–90%) by EUS showed greater pain relief than in the EUS-CPN group (73.5% vs. 45.5%, respectively) with similar adverse events [55].

### Percutaneous CPN

Percutaneous CPN, which is performed using a 22-gauge needle mostly by anesthesiologists and radiologists under transabdominal ultrasound (US), fluoroscopy, or computed tomography (CT), is also an option [52]. A meta-analysis has shown that percutaneous CPN improves pain in patients with upper abdominal cancer, with a decrease in opioid consumption and side effects although it is unclear whether there is any change in the quality of life [56]. US-guided CPN (US-CPN), using a unilateral paramedian needle-insertion technique is comparable with a bilateral paramedian needle-insertion technique with regard to pain relief and side effects [57]. Another open randomized comparison of clinical effectiveness of

protocol-driven opioid analgesia, celiac plexus block, or thoracoscopic splanchnicectomy for pain management in patients with pancreatic and other abdominal malignancies showed no significant difference [58].

## Anticancer Therapy

Although EUS-guided or percutaneously guided intratumoral TNFerade biologic with 5-fluorouracil and radiotherapy as first-line treatment for locally advanced pancreatic cancer is feasible, it is not effective [59]. EUS-guided interstitial implantation of $^{125}I$ seeds might improve pain, but without any survival benefit [60]. EUS-guided radiofrequency ablation of unresectable pancreatic cancer is also technically feasible and safe but without any proven therapeutic efficacy demonstrated [61]. EUS-guided cryothermal ablation therapy [62] and EUS-guided dendritic cell injection therapy [63,64] are also being evaluated.

## Miscellaneous

ERCP stent placement has been used to relieve pain thought to be due to pancreatic duct (PD) obstruction and then EUS-guided PD stent placement if this fails. EUS-guided PD stent placement can also be used for symptomatic anastomotic stricture (pain or intermittent acute pancreatitis) of the pancreatojejunostomy after pancreatoduodenectomy. Acute pancreatitis due to pancreatic cancer is rare but is observed in some patients. Pancreatic fluid collections including walled-off necrosis and pseudocyst, require EUS and/or percutaneous drainage. Furthermore, endoscopic necrosectomy may be required to remove the infected necrotic tissue.

## Neoadjuvant Treatment of Pancreatic Cancer: Downstaging Results

*Robert A. Wolff and Gauri Varadhachary*

*Department of GI Medical Oncology, The University of Texas MD Anderson Cancer Center, Houston, TX, USA*

### Introduction

In order to appreciate the evolution of therapy for localized pancreatic cancer, a brief overview of clinical results in resectable pancreatic cancer is required. For years, the standard approach to resectable pancreatic cancer has been upfront surgical resection followed by adjuvant therapy [1,2]. Over time, it has been established that the completeness of surgical resection has prognostic implications. Better survival has generally been observed for patients undergoing complete resection with microscopically negative surgical margins compared with patients left with gross or microscopic residual disease at the completion of surgery [2–5]. It is now broadly accepted that all pancreatic resections should be classified according to residual disease status, termed "R" factor: R0, no gross or microscopic residual disease; R1, microscopic residual disease (microscopically positive surgical margins with no gross residual disease); and R2, grossly evident residual disease. This designation was previously used to describe the completeness of resection in rectal cancer in which margins of resection also have prognostic implications [6]. The United States definition defines an R1 margin as one or more cancer cells at any surface margin but this differs from that used in Europe, which shares this part of the definition with the US but also states that one or more cancer cells up to 1 mm from any surface also counts as an R1. If one or more cancer cells is not at any surface margin but is less than 1 mm from any surface the US definition would refer to this as an R0, not an R1 as in Europe [7].

Reports from single institutions and from large multicenter adjuvant trials have shown that R1 resections occur quite frequently in pancreatic adenocarcinoma and are generally associated with worse survival [2,8–11]. While high-quality cross-sectional imaging has been quite reliable in predicting the surgeon's ability to remove all gross tumor [12], the diffusely infiltrating nature of pancreatic adenocarcinoma and the very narrow space from the tumor to the mesenteric vessels, portal vein, and celiac trunk make achievement of an R0 resection a therapeutic challenge [13]. Thus, some centers have focused on preoperative or neoadjuvant therapy as a means to sterilize the tumor's periphery, which is very close to vasculature that cannot be sacrificed.

### Neoadjuvant Therapy for Resectable Pancreatic Cancer

The rationale for delivering preoperative treatment to patients with potentially resectable tumors is based on: (i) the early treatment of micrometastatic disease, which is present in the majority of patients; (ii) providing a sufficient time interval to assess the underlying tumor biology thereby selecting patients for surgery who have the highest likelihood to benefit from it; (iii) delivering "adjuvant" therapy in a "neoadjuvant" setting, when it is expected to be better tolerated since surgical recovery will not complicate the timely delivery of treatment; and (iv) the potential to sterilize the periphery of the tumor, thereby improving the chances of an R0 resection. In several trials of preoperative therapy utilizing chemoradiation, high R0 resection rates have been reported with antitumor treatment effect demonstrated in resected specimens ranging from minimal killing to occasional complete pathologic responses [14–17].

### Early Results in Downstaging Pancreatic Tumors

As neoadjuvant therapy for resectable pancreatic cancer was being studied, publications from the 1990s to 2000s reported on the potential to downstage initially unresectable pancreatic cancer with neoadjuvant therapy. One of the earliest trials reported modest success using infusional 5-fluoruracil (5FU) with external beam radiation (EBRT) in 16 patients with locally advanced disease [18]. While only two (12.5%) were able to undergo surgery with curative intent, the survival of these two patients was comparable to patients with resectable pancreatic cancer treated with upfront surgery and adjuvant therapy. In a larger trial, the group at Duke University reported on 111 patients treated with preoperative chemoradiation from 1995 to 2000 and included patients with resectable ($n$ = 53) or locally advanced disease ($n$ = 58) [17]. The overall resection rate was superior for patients defined as having resectable disease (53%) compared with the rate for patients with locally advanced disease (19%) with an overall R0 resection rate of 70%.

Importantly, during this time frame an appreciation for the distinction between tumors that would now be considered borderline or marginally resectable was emerging [19]. For example, one of the earliest reports utilizing preoperative therapy to downstage what is now known as borderline resectable disease was conducted at Stanford University and reported by Mehta et al. [20]. The investigators reported on 15 patients they described as having "marginally resectable adenocarcinoma of the pancreas" defined as tumors having "PV, SMV, or artery involvement." These patients were treated with infusional 5-FU and EBRT to doses ranging from 50.4–56 Gy. Nine patients (60%) underwent surgical resection with negative surgical margins and 2 of 9 (22%) had a complete pathologic response to preoperative treatment. Furthermore, there was a striking difference in overall survival between those patients who did undergo surgical resection and those who did not (30 vs. 8 months, respectively).

These and other reports have suggested that for a subset of patients with pancreatic cancer not initially considered resectable, neoadjuvant therapy could provide sufficient tumor destruction or "downstaging," to proceed with surgical resection. However, the resection rates reported after neoadjuvant therapy have varied widely from as low as 1% to 60%, with most studies reporting resection rates ranging between 20–40% [21–24]. Patients reported in these studies likely represented a heterogeneous population comprised of some having tumor with complete vascular encasement and others having some degree of tumor-vessel contact without encasement.

## Emerging Recognition of Borderline Resectable Pancreatic Cancer

Broadly defined, borderline resectable tumors represent a subset of localized pancreatic cancers that have a high risk of R1 resection with upfront surgical intervention based on a tumor's intimate proximity to surrounding vascular structures [25]. A number of factors have led to the recognition of the entity now known as borderline resectable pancreatic cancer. First, it has been increasingly appreciated that high-quality cross-sectional imaging is now capable of characterizing the tumor/vessel interfaces as having clearly interposed fat planes (potentially resectable), having tumor abutment (<180°) without encasement of a vessel or vessels (borderline resectable), or having tumor encasement of critical vascular structures (locally advanced). Second, most experts agree that an R1 resection puts the patient at risk for poor survival. Third, as discussed earlier, neoadjuvant therapy is capable of producing some local tumor destruction and appears to increase the chances of achieving an R0 resection for patients with resectable disease. While this should not be considered downstaging per se, microscopic downstaging is likely occurring as a result of neoadjuvant therapy in this setting. Fourth, studies from a number of institutions suggests that a subset of patients who are defined as having borderline resectable disease may ultimately undergo surgical resection with curative intent after a period of neoadjuvant therapy [26]. For these patients, median overall survival has been encouraging.

Recognition of borderline resectable disease is increasingly appreciated and provides a framework for better defined, more homogeneous, and reproducible subsets of patients for entry onto clinical trials investigating neoadjuvant therapy as a downstaging strategy. This allows for three separate categories of localized pancreatic cancer: potentially resectable, borderline resectable, and locally advanced, and reports are now emerging on the role of neoadjuvant therapy for these three distinct subsets.

## Downstaging Borderline Resectable Disease with Neoadjuvant Therapy

In addition to the report by Mehta et al., other centers have reported on results with neoadjuvant therapy for borderline resectable disease. For example, we performed a retrospective analysis and classified 160 patients as having borderline resectable disease (based on our previously published definition) [22]. Among those patients, all of whom were treated with neoadjuvant therapy, approximately 40% had some combination of clinical, laboratory (i.e., drop in tumor marker), or radiographic

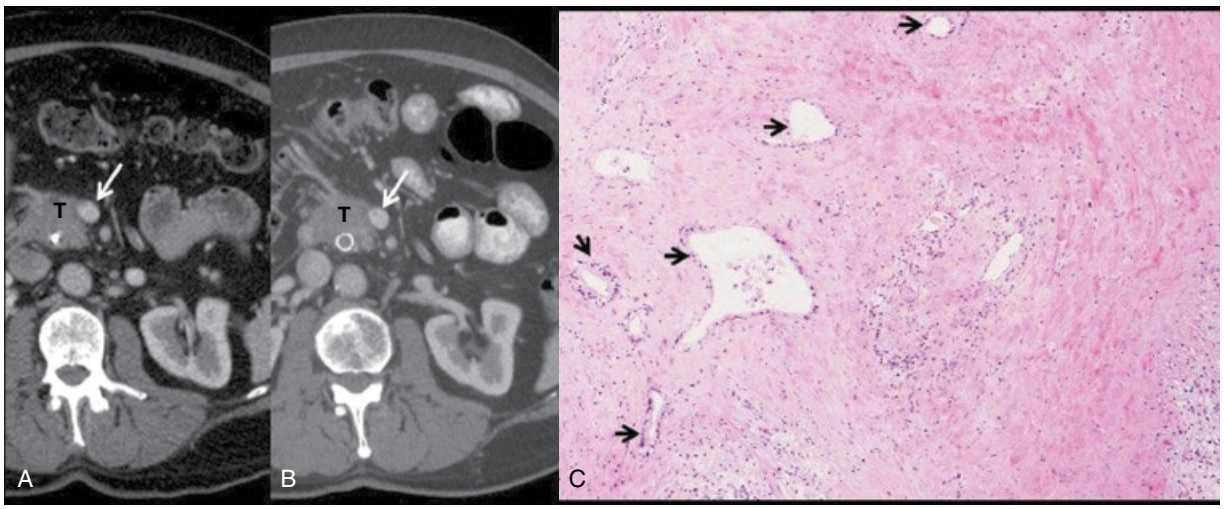

**Figure 112.1** A. Pre-treatment CT image of a borderline resectable pancreatic cancer. B. Post-treatment CT image of tumor after induction FOLFIRINOX followed by gemcitabine-based chemoradiation. T depicts tumor mass; white arrow depicts SMV. Note no overall change in tumor. C. Photomicrograph of resected specimen. Black arrows show small residual nests of viable tumor glands with large areas of fibrosis and necrosis. Tumor estimated to be 85% nonviable.

response to therapy to justify surgery. For the patients that ultimately underwent resection, the R0 resection rate was 94% with a median overall survival of 40 months. Of note, the survival of patients who did not undergo surgery was consistent with patients having locally advanced disease and managed with nonoperative therapy (13 months). A number of other institutions are beginning to publish their resection rates after neoadjuvant therapy for borderline resectable tumors with several reporting resection rates between 40–60% and some having rates around 80% [26]. Recently, Katz et al. have reported on results of a multi-institutional trial of 5FU, folinic acid, irinotecan, and oxaliplatin (FOLFIRINOX) followed by capecitabine-based chemoradiation, for patients with borderline resectable disease. Among the 23 patients enrolled, 68% underwent surgery with curative intent; the R0 resection rate was 93% [27]. Taken together, these reports have led some groups to recommend against upfront surgical resection in the setting of borderline resectable disease, while others do not [28–31]. Currently, a randomized trial of surgery versus preoperative chemoradiation followed by surgery, is being conducted among patients with resectable and borderline resectable disease [31].

## Challenges of Neoadjuvant Therapy in Borderline Resectable and Locally Advanced Pancreatic Cancer

Despite keen interest, questions remain about tumor downstaging using a neoadjuvant approach. First, what is the optimal duration of therapy prior to considering surgery resection? Second, what is the relative contribution of systemic therapy and radiotherapy to tumor downstaging? Third, and perhaps the most difficult question is what response criteria can identify patients most likely to benefit from surgical resection after neoadjuvant therapy? Recent publications describe the inability of repeat cross-sectional imaging to reliably identify tumor downstaging [32,33]. It is widely known that the tumor microenvironment of pancreatic cancer can have a dense desmoplastic and fibrotic component which prevents overall tumor shrinkage to be demonstrated despite significant tumor cell destruction (Fig. 112.1). In general, radiographic evidence of a stable or shrinking tumor mass, with evidence of clinical improvement, decrease in tumor marker levels, and no interval development of metastatic disease are indications for surgery. Furthermore, normalization of CA 19-9 in response to neoadjuvant therapy is associated with long-term survival in resected patients [34].

## Future Directions

The complex biology of the microenvironment of pancreatic adenocarcinoma, with stromal elements that may act to both sequester malignant cells and protect them from cytotoxic therapy or immunologic attack, is steadily being elucidated. Future interventions that lead to stromal changes with agents such as hyaluronidase, vitamin D analogs, or other immunomodulating agents are certain to be investigated as strategies to enhance downstaging in localized pancreatic cancer [35–37]. Further,

other locally destructive techniques are being explored for their potential to enhance local tumor killing while sparing normal surrounding structures. Investigations of irreversible electroporation are being conducted as a way to improve treatment of locally advanced pancreatic cancer and to enhance complete tumor destruction at the margin of resection in borderline resectable disease [38]. Stereotactic body radiation and proton beam therapy are also being evaluated as alternatives to conventional EBRT [39,40].

Lastly, based on some improvements in systemic therapy now available, more attention to local control strategies to include aggressive surgical intervention is certain to develop. At present, venotomy with primary repair, or en bloc venous resection with reconstruction are commonly performed in pancreatic cancer centers of excellence with some renewed interest in arterial resections and reconstruction [41]. Thus, more aggressive surgical approaches coupled with active neoadjuvant therapy may allow for even greater numbers of patients to undergo surgery with curative intent.

## Summary

Neoadjuvant therapy is a rational approach to therapy for nonmetastatic pancreatic cancer. Tumor downstaging is not required in the setting of resectable pancreatic cancer, but it may lead to microscopic downstaging and improve the likelihood of an R0 resection. In borderline resectable disease, which by definition places the patient at high risk for an R1 resection, treatment with neoadjuvant therapy is sufficiently active in 40–60% of patients to ultimately allow for surgical resection. For those with locally advanced pancreatic cancer, although the chances of subsequently undergoing surgery with curative intent are only 20%, newer drug therapies and locally destructive techniques may expand the proportion of these patients who can undergo surgery. Lastly, the recognition of and formalized definitions for borderline resectable disease that is intermediate in the spectrum of resectable and locally advanced/unresectable pancreatic cancer will allow for more reliable comparison of results in clinical trials of various neoadjuvant regimens.

## Introduction

Pancreatic ductal adenocarcinoma remains the most common malignancy of the pancreas, and is the fourth highest cause of cancer death in the developed world. An estimated 367,000 new cases were diagnosed worldwide in 2015, and it is likely to become the second leading cause of cancer mortality within the next decade [1].

The majority of patients with pancreatic cancer present with advanced disease. Surgery remains the only potentially curative option, but even in specialized centers just 10–15% of patients are suitable for resection [2]. The mortality associated with major pancreatic surgery has reduced considerably in recent years, and is now routinely reported as less than 5% [3]. Following surgery alone, prognosis remains dismal with a median survival of around 13 months and only 10% surviving for 5 years [4]. Increasingly radical resections that include extended lymphadenectomy or total pancreatectomy have been employed in an attempt to improve long-term outlook, but prospective trials comparing these more radical resections with classical surgical techniques have failed to demonstrate any survival benefit, with significant disadvantage in terms of postoperative quality of life [5].

Around 70% of patients undergoing curative intent surgery succumb to distant metastases rather than local recurrence [6] and so attention has turned to additional therapies that may delay or prevent the development of recurrence in an effort to improve long-term outcome. Adjuvant therapy is used with the aim of reducing these occult micrometastases and the results from contemporary randomized studies provide the most compelling evidence so far to support its use after surgery for pancreatic cancer. This chapter aims to provide a summary outline of key trials in adjuvant therapy, as well as to highlight potential future avenues to improve outcomes in this deadly disease.

## Rationale for Adjuvant Therapy

The first randomized assessing the role of adjuvant treatment for pancreatic cancer was the small 1985 Gastrointestinal Tumour Study Group (GITSG) study, where 43 resected patients were randomized to receive either 5-FU concurrent with radiation (50 Gy) followed by maintenance 5-FU, or observation alone. Such was the nihilistic approach to pancreatic cancer at that time, the trial closed prematurely because of failure to recruit. Despite these problems, median survival was considerably longer for the adjuvant therapy arm (20 months vs. 11 months, $P = 0.04$) (see Table 113.1) [7]. However, it was impossible to tell whether it was systemic chemotherapy or radiotherapy that led to this improvement.

Subsequent to this, a larger European study (EORTC 40891) assessed concurrent 5-FU and radiation (40 Gy) versus observation alone for 120 patients with resected pancreatic head cancer and periampullary tumors but demonstrated no difference in median [8] or long-term [9] survival, even when the pancreatic head group was evaluated independently.

The European Study Group of Pancreatic Cancer (ESPAC)-1 trial [10,11] provided a further challenge to the value of chemoradiation and suggested that chemotherapy alone provided the primary survival benefit seen in GITSG. The study used a $2 \times 2$ factorial design to stratify patients undergoing curative intent surgery for pancreatic adenocarcinoma by center, type of tumor, and resection margin status. Patients were then randomized to one of four arms: (i) chemoradiation (50 Gy split

course), (ii) 6 months of systemic chemotherapy (bolus 5-FU), (iii) combination chemotherapy and chemoradiotherapy, or (iv) observation. A total of 289 patients from across Europe were randomized. At a median follow-up of 47 months, 5-year survival was significantly higher for those receiving chemotherapy versus those who did not (21% vs. 8%, $P = 0.009$). Median survival for those treated with chemotherapy was 20.1 months compared to 15.5 months for those without ($P = 0.009$). Median survival was also significantly longer in the group who did not receive chemoradiotherapy (17.9 vs. 15.9 months, $P = 0.05$), which translated to an estimated 5-year survival rate of 10% for those treated with chemoradiation compared to 20% for those who did not ($P = 0.05$) (see Fig. 113.1). The survival rates for patients treated with chemoradiation in ESPAC-1 were broadly in keeping with those from other series, and the superior outcomes seen after systemic chemotherapy led to a move away from adjuvant radiotherapy in favor of systemic chemotherapy across Europe.

The promising results of ESPAC-1 led other researchers to question whether the use of more active systemic chemotherapies would translate to improved long-term outcome. The Charité Onkologie (CONKO)-001 trial compared six cycles of systemic gemcitabine with observation alone in 368 patients who had undergone resection, and found a significant improvement in median disease-free survival (13.4 vs. 6.7 months, $P < 0.001$) [12], which also translated into improved 5-year survival (20.7% vs. 10.4%, $P = 0.01$) [13]. This benefit was consistent irrespective of tumor stage, nodal status, and margin status although patients with a postoperative CA 19-9 level >92.5 KU/L were excluded from trial entry and so the patient population included a prognostically more favorable group.

Both ESPAC-1 and CONKO-001 therefore confirmed the role of adjuvant therapy as standard of care after curative resection, and led to an almost doubling in the 5-year survival after surgery.

ESPAC-3 built on these findings by randomizing 1,088 patients to observation, bolus 5-FU/leucovorin, or bolus gemcitabine for 6 months after surgery [14]. The observation arm was closed when the final results of ESPAC-1 were published. Final analysis at a median follow-up of 34.2 months demonstrated equivalence in median survival (23.0 months for 5-FU/leucovorin vs. 23.6 months for gemcitabine, $P = 0.39$) (see Fig. 113.2) but significantly lower grade 3/4 toxicity in the gemcitabine arm (7.5% vs. 14%, $P < 0.001$). These results defined gemcitabine as the optimal adjuvant monotherapy for patients who had undergone curative resection.

The Japan Adjuvant Study Group of Pancreatic Cancer (JASPAC)-01 trial assessed S-1 (a 5-FU analog with marked efficacy in the Japanese population) versus

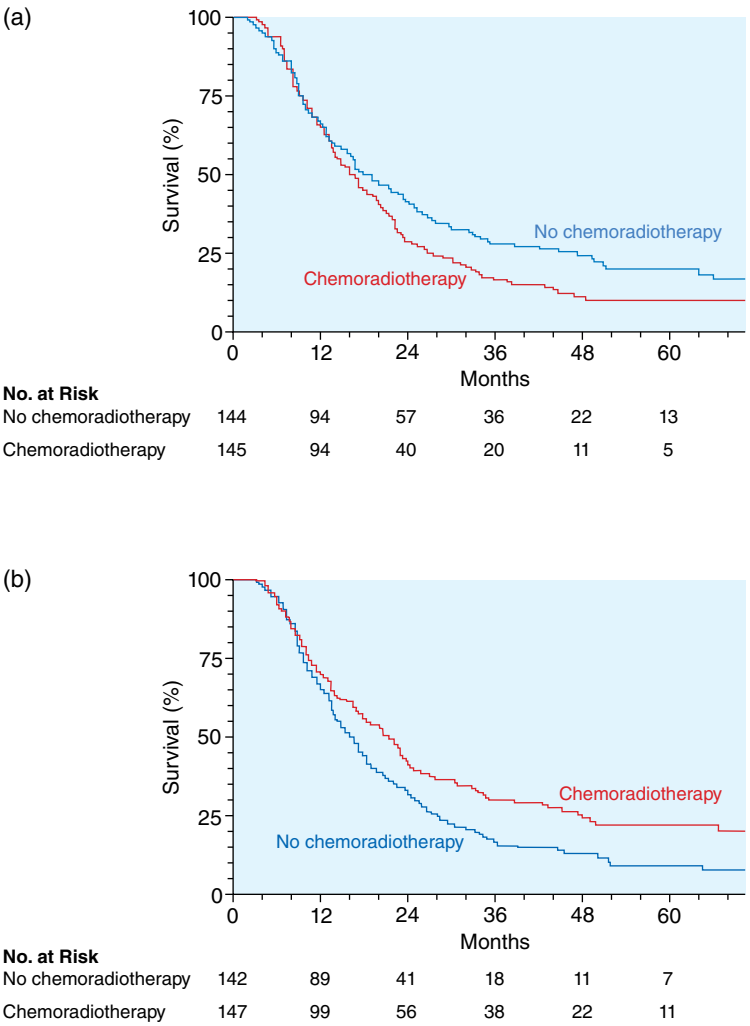

**Figure 113.1** Overall survival from the ESPAC-1 trial [11]. *Source:* New England Journal of Medicine, Neoptolemus JP et al., A randomized trial of chemoradiotherapy and chemotherapy after resection of pancreatic cancer, Vol. 350. gemcitabine in the adjuvant setting. This noninferiority study randomized 385 Japanese patients, and found overall survival at 2 years of 70% for the S-1 group compared with 53% for the gemcitabine group, with a 5-year overall survival of 24.4% in the gemcitabine group and 44.1% in the S-1 group ($P < 0.0001$ for noninferiority, $P < 0.0001$ for superiority) [15]. While these results are impressive, it remains unclear whether they are applicable to a non-Japanese population with different S-1 metabolism where efficacy is lower and toxicity higher. In addition, randomized patients were a prognostically favorable group with only 13% having an R1 resection and only 21% having a raised CA 19-9. As such, the results may have limited applicability in a real-world Western population.

Combination therapy with gemcitabine and capecitabine has become increasingly common in the palliative treatment of metastatic pancreatic cancer, with good response rates and acceptable toxicity [16,17]. The ESPAC-4 study therefore assessed whether these improved response rates translated to improved overall survival in the adjuvant setting. A total of 732 patients were randomized to six cycles of intravenous gemcitabine with or without oral capecitabine. Median survival was slightly longer in the combination therapy arm (25.5 vs. 28.0 months, $P = 0.03$). However, the 5-year survival rates were considerably higher for patients receiving dual therapy rather than gemcitabine alone (28.8% vs. 16.3%) (see Fig. 113.3) [18]. Severe toxicities were similar, and both regimens were well tolerated. It is also important to note that ESPAC-4 recruited a wider variety of patients than other studies (see Table 113.2). For example, patients with raised postoperative CA 19-9 and without immediate preadjuvant imaging were eligible for inclusion. These findings suggest that combination therapy with gemcitabine/capecitabine should now be considered standard of care after curative resection, with a proven benefit in real-world patient population.

The overwhelming evidence supporting adjuvant therapy is reflected in the recent 2016 American Society of

Clinical Oncology (ASCO) Clinical Practice Guidelines for Potentially Curable Pancreatic Cancer [19], which recommend that all patients with resected pancreatic cancer should have 6 months of adjuvant chemotherapy with gemcitabine and capecitabine and either gemcitabine or fluorouracil plus folinic acid if patients are only suitable for mono-chemotherapy.

## Adjuvant Chemoradiotherapy

The data presented from the CONKO-001, JASPAC-1, and ESPAC-1, -3, and -4 trials provide compelling evidence to support systemic chemotherapy for 6 months after surgical resection as standard of care. The role of additional adjuvant chemoradiotherapy remains less clear, with no randomized trial providing clear benefit in terms of overall survival.

Although the previously described GITSG and EORTC 40891 trials provide some evidence, these trials do not allow direct comparison of chemotherapy versus chemoradiotherapy. Concerns about the long-term survival benefit of additional adjuvant radiotherapy are supported by retrospective reviews and meta-analyses. Merchant et al. [20] performed a pooled analysis of 646 patients from seven high-volume centers, 299 of whom were treated with surgery followed by chemoradiation and 347 with surgery alone. Median overall survival was 20 months for the adjuvant chemoradiation arm, versus 14.5 months for surgery alone ($P = 0.001$). The investigators found a significant survival advantage only in patients with lymph node-positive disease. Somewhat surprisingly, the authors also identified reduced disease-free survival in patients with lymph node-negative disease who received adjuvant chemoradiotherapy (14.5 months vs. 18.6 months, $P = 0.034$). These findings were further supported by another large retrospective series that compared 1,130 patients treated with surgery, with or without adjuvant chemotherapy or chemoradiotherapy at eight major US centers over 10 years. They identified reduced local recurrence after chemoradiation, but no impact on distant recurrences (in contrast to systemic chemotherapy) and therefore no impact on overall survival [21].

The first attempt to directly compare systemic chemotherapy with systemic chemotherapy and additional radiotherapy was the 2010 EORTC 40013 study, which randomized 90 patients to four cycles of gemcitabine versus gemcitabine with concurrent chemoradiation (50.4 Gy). Median overall survival was the same for both arms at 24 months, with comparable toxicity profiles. Eighty-seven percent of patients treated with gemcitabine alone completed all planned treatments, compared to 73% undergoing combination therapy [22]. Supporting previous retrospective series, local recurrence as site of first progression was 24% for the chemotherapy arm compared with 11% in the chemoradiotherapy arm. However, this did not translate into a long-term survival benefit.

In 2005, Stocken et al. [23] performed a meta-analysis assessing the impact of adjuvant chemoradiation and chemotherapy on survival and included patient level data from five randomized trials of adjuvant therapy. Individual patient data was available in four out of the five studies (94% of patients). Analysis demonstrated a 25% reduction in the risk of death (HR 0.75; 95% CI: 0.64–0.90, $P = 0.001$) with chemotherapy compared to no chemotherapy but no significant difference between chemoradiation and no chemoradiation (HR 1.09; 95% CI: 0.89–1.32, $P = 0.43$). On subgroup analysis, chemoradiation was more effective and chemotherapy less effective in patients with positive resection margin.

In 2013, Liao et al. [24] performed an updated meta-analysis of adjuvant 5-FU versus gemcitabine versus

chemoradiation with 5-FU or gemcitabine, and showed that chemotherapy alone with either 5-FU (HR 0.65; 95% CI: 0.49–0.89) or gemcitabine (HR 0.59; 95% CI: 0.41–0.83) was associated with significant overall survival benefit. By contrast, adjuvant chemoradiation was associated with worse overall survival when compared with 5-FU (HR 1.69; 95% CI: 1.12–2.54) and gemcitabine (HR 1.86; 95% CI: 10.4–3.23) as monotherapy with significant additional toxicity.

The role of adjuvant chemoradiotherapy therefore remains unclear, with benefit seeming to be limited to patients with margin positive disease where it may have a role in reducing local recurrence.

## Future Directions in Adjuvant Therapy

Increasingly, biologically active palliative regimens are now being considered as adjuvant therapies. FOLFIRINOX (5-FU, leucovorin, irinotecan, oxaliplatin) demonstrated an increase in overall survival compared to single agent gemcitabine (6.8 months to 11.1 months) in the metastatic setting [25]. The same group has now developed the PRODIGE 24/ACCORD 24 trial comparing gemcitabine monotherapy with modified FOLFIRINOX (without infusional 5-FU) following resection of pancreatic adenocarcinoma. This regimen has been associated with significant toxicities, and so trial entry is only open to patients with good performance status who have fully recovered from surgery. With a target recruitment of 490 patients, the trial is due to mature in 2020.

Nab-paclitaxel (albumin-bound paclitaxel) has demonstrated synergistic clinical activity when delivered alongside gemcitabine [26], and so the 2013 MPACT trial compared nab-paclitaxel/gemcitabine with gemcitabine alone in the palliative setting with an improvement in median survival from 6.7 months in the gemcitabine monotherapy group to 8.5 months in the nab-paclitaxel/gemcitabine group (HR 0.72; 95% CI: 0.62–0.83, $P < 0.001$) [27]. The US-led ABI-007-PANC-003 trial aims to compare the same regimen in the adjuvant setting, with a trial reporting date somewhere in 2020.

As well as attempting to use increasingly active regimens, targeted adjuvant therapies offer great appeal. Whole genome sequencing of large numbers of tumors has led to the identification of frequently mutated genes in pancreatic cancer [28], as well as identifying distinct molecular subtypes [29]. Unfortunately, the four most commonly mutated genes (*KRAS*, *CDKN3A*, *TP53*, and *SMAD4*) are not currently actionable, with druggable mutations occurring with much lower frequencies. Although the reducing cost of whole-genome sequencing means that precision therapy based on identifiable and actionable mutations on a case-by-case basis is a possibility, its mainstream use remains some way in the future.

To overcome some of these limitations, targeted agents with wider mechanisms of action have been investigated. Erlotinib is an oral tyrosine kinase inhibitor that has demonstrated improvements in overall survival when added to gemcitabine in the palliative setting [30]. CONKO-005 therefore randomized 436 resected patients to receive gemcitabine or gemcitabine/erlotinib. However, there was no difference in disease-free survival (11.6 months for both) or overall survival (24.6 months for combination therapy vs. 26.5 months for gemcitabine alone) [31].

Immunotherapy has shown great promise in other cancer types. Around 90% of pancreatic cancers contain an activating mutation in *KRAS*. A small phase II trial therefore assessed the use of a novel *KRAS* vaccine in the adjuvant treatment of 23 patients with resected pancreatic cancer. The researchers found an immune response in 85% of patients, with a median survival of 28 months [32]. However, these results have not been replicated by other groups [33].

During repeated rounds of DNA replication, the telomeric ends of DNA become progressively shortened leading to eventual cell death. Reactivation of telomerase, the telomere-repair enzyme, is a crucial event in oncogenic transformation and occurs in nearly all pancreatic cancers. The TELOVAC trial therefore compared gemcitabine/capecitabine with or without a novel telomerase peptide vaccine (GV1001) in the palliative setting, but demonstrated no significant survival benefit, suggesting further ways to enhance the immune response are required for clinical efficacy [34].

As well as trialing novel agents, there are increasing efforts to improve the patient stratification for existing treatments. Penetration of gemcitabine into dense pancreatic stroma appears to be highly variable. Koay et al. [35] demonstrated widely variable incorporation of gemcitabine into tumor DNA despite consistent serum pharmacokinetics. They also identified and validated a series of novel radiomic markers that would allow preoperative assessment of gemcitabine efficacy. However, this issue was further confused by the demonstration of widely varying incorporation of gemcitabine even within individual tumors [36], suggesting intratumoral heterogeneity may pose a problem not only for novel targeted agents but also for existing cytotoxic regimens.

Biomarkers to predict response to treatment also offer significant potential to improve the stratification of treatment. Human equilibrative nucleoside transporter 1 (hENT1) is a cell surface protein that bidirectionally transports gemcitabine across pancreatic cell membranes.

Greenhalf et al. [37] assessed hENT1 expression in 434 patients from the ESPAC-3 trial, of whom 176 received gemcitabine. Median survival for patients treated with gemcitabine was 17.1 months for those with low hENT1 expression compared to 26.2 months for those with high hENT1 expression ($P = 0.002$), suggesting hENT1 may predict response to gemcitabine chemotherapy. However, this finding was not confirmed in the prospective LEAP (Low hENT1 Adenocarcinoma of the Pancreas) trial in patients with metastatic disease [38] where there was no difference in overall survival following treatment with gemcitabine in the hENT1 high and low groups. However, hENT1 status was determined from metastatic tissue and so inherent differences between the patient population in this trial and the adjuvant cohort cannot be excluded.

The GATA6 transcription factor has also been proposed as a predictive biomarker of response to adjuvant therapy. Martinelli et al. [39] assessed the expression of GATA6 in 313 patients treated with adjuvant 5-FU/leucovorin or gemcitabine, and found that in the 5-FU group patients with high GATA6 expression survived significantly longer than those with low expression. This finding did not hold true in the gemcitabine arm, suggesting GATA6 may be a predictive biomarker for response to adjuvant 5-FU.

## Timing and Duration of Adjuvant Therapy

The optimal timing of adjuvant therapy after surgery remains unclear. Patients need sufficient time to recover from the physiologic insult, whilst treatment needs to commence soon enough to prevent the establishment of micrometastatic deposits. Valle et al. [40] assessed the optimal timing to start of therapy in the ESPAC-3 trial. A total of 985 patients were included, of whom 486 received gemcitabine, 675 (68.5%) received all six planned cycles of adjuvant therapy, and 457 (46.4%) started treatment within 8 weeks of surgery. Overall survival was much better in those who received the full six cycles of treatment (28 months vs. 14.6 months) (HR 0.516; 95% CI: 0.443–0.601, $P < 0.001$) whilst time to start of treatment did not predict overall survival (HR 0.985; 95% CI: 0.956–1.015, $P = 0.99$). However, for the subgroup of patients who did not complete all six cycles of treatment the time to initiation of therapy was important, with overall survival better in those who waited more than 8 weeks (HR 0.92; 95% CI: 0.86–0.97, $P = 0.004$). These findings suggest that completion of a full course of treatment is more important than early initiation, and suggest that allowing patients to fully recover from surgery may lead to better tolerability of therapy and an increased likelihood of completing treatment.

## Conclusions

The last 20 years have seen a paradigm shift in the management of pancreatic cancer. The routine use of adjuvant treatment has led to significant increases in median and 5-year overall survival. The recently reported results of ESPAC-4 are likely to define 6 months of treatment with combination gemcitabine/capecitabine as standard of care, with growing recognition of the importance of patients receiving the full planned treatment course (see Fig. 113.4).

**Figure 113.4** Kaplan-Meier plots for overall survival in the ESPAC-1 (E1), ESPAC-3 (E3), and ESPAC-4 (E4) trials.

Future directions for adjuvant therapy include the use of more active regimens, as well as better stratification of patients to existing therapies. Novel agents have shown some promise in the palliative setting, but this has not translated to improved outcomes after resection. Immunotherapy and targeted therapies offer great promise, but many technical challenges remain before these approaches enter routine clinical practice.

## Introduction

Pancreatic ductal adenocarcinoma (PDAC) comprises only 3% of all cancers diagnosed in the United States, yet it is the third leading cause of cancer-related deaths in men and women [1]. The only current chance of cure remains surgical resection but <30% of patients who present with PDAC are candidates for curative resection. The majority of those who undergo surgical resection will ultimately relapse and die from their disease [1]. While cytotoxic chemotherapy has been shown to improve survival in those with metastatic disease [2,3], the 5-year survival rate for these patients remains dismally poor. PDAC is notoriously resistant to chemotherapy and radiation therapy but there have been positive advances made by harnessing the immune system to help combat this disease.

## Immunology of Pancreatic Cancer

The tumor microenvironment (TME) of pancreatic tumors is renowned for its stromal density and heterogeneity, containing numerous cellular components including fibroblasts, pancreatic stellate cells, blood vessels, and immune cells [4].

The immune system is classically activated in response to foreign antigens, whereas cancer cells can express tumor-associated antigens as well as neoantigens that occur in response to the tumor's continuously changing molecular composition. In both cases, the immune system can be activated to recognize these tumor antigens. However, tumor cells are more likely to interact with the immune system and lose antigen recognition through the process of immunoediting [5]. This dynamic process consists of three phases: elimination, where the immune system successfully destroys the tumor cell; equilibrium, where the system controls tumor growth but does not destroy the tumor cell; and escape, where the tumor cell overcomes the immune system and progresses to a clinically detectable disease state.

The innate immune system consists of immune cells (e.g., macrophages, granulocytes, dendritic cells) that serve as "first responders" of the immune response and are attracted to regions of inflammation or infection within minutes or hours. The adaptive immune system comprises B- and T-cell lymphocytes which respond to foreign invasion of cells typically by infectious agents. Professional antigen presenting cells (APC, e.g. dendritic cells and macrophages) are alerted and take up foreign proteins for processing and triggering B- and T-cell responses. B lymphocytes are responsible for mounting a long-term response to a foreign antigen by producing an antibody-secreting effector cell. T lymphocytes, categorized according to cell surface markers, and the cytokines/chemokines they produce, have many distinct effector functions. CTL (cytotoxic T lymphocytes) express CD8 and kill cells by secreting molecules that induce apoptosis. When an APC expresses an antigen on major histocompatibility class II (MHCII), a $CD4^+$ T cell (helper T cell, Th) becomes activated and differentiates into distinct effector subtypes mediating the immune response through the secretion of specific cytokines (Fig. 114.1). A specific subtype of $CD4^+$ T cells, Treg, suppress T-cell activation thereby protecting the body from autoimmune reactions. $CD4^+$ T cells comprise the majority of T cells in PDAC and are associated with metastasis and negatively associated with survival [6,7].

The protective role of the immune system in cancer is demonstrated by the observation that increased amounts

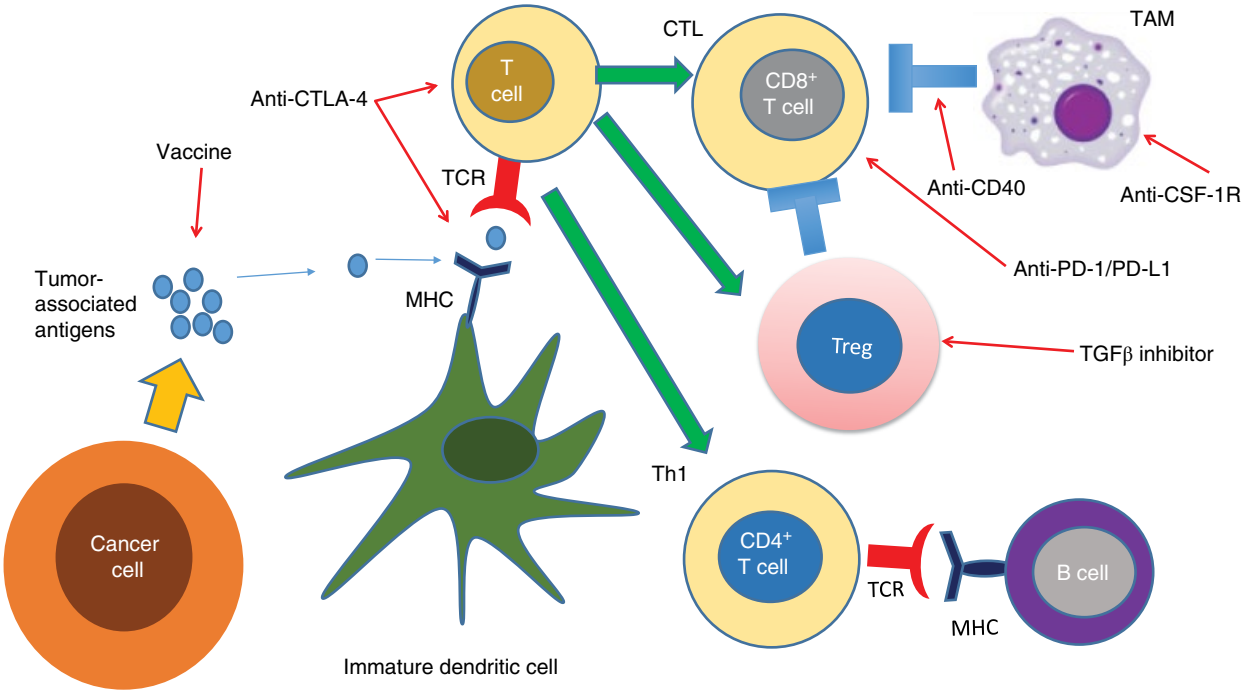

**Figure 114.1** Components of immunotherapy in pancreatic cancer. Tumor cells express specific antigens which can activate antigen-presenting cells by binding to MHC molecules on their cell surface which in turn bind to T-cell receptors (TCR) on T cells. Anti-CTLA-4 therapy directly targets this interaction. This results in T-cell activation and differentiation into various T-cell subtypes including CD8+ cytotoxic T lymphocytes (CTL), regulatory T cells (Treg), and Th1 (T helper cells). CTL activity can be eliminated by tumor-associated macrophages (TAM) resulting in tumor progression. Pharmacologic inhibition of CSF-1R (colony-stimulating factor-1 receptor) and CD40 can reduce this effect. Treg can also suppress CTL, an effect which can be negated by targeting TGFβ (transforming growth factor β). Th1 cells induce B-cell activation, which results in antibody production and activation of humoral immunity.

of tumor-infiltrating lymphocytes (TIL) correlate favorably with survival in many tumor types including melanoma and PDAC [8,9]. The complexity of the immune system results in certain immune components promoting immune suppression such as myeloid-derived suppressor cells (MDSC) and tumor-derived macrophages (TAM) [10,11]. Preclinical models, which faithfully recapitulate the progression of precursor pancreatic lesions in their development from preinvasive PanIN (pancreatic intraepithelial neoplasia) to invasive PDAC, show that immunosuppressive cells dominate the TME, even during the early stages of tumor development [12]. These cells, which include MDSC, Treg, and TAM, result in reduced T-cell development and infiltration (specifically effector T cells), which indirectly drives tumor promotion. This has led to efforts to directly target these immunosuppressive cells, for example targeting colony-stimulating factor 1 (CSF-1R), which regulates the differentiation and survival of TAM [13].

The procarcinogenic inflammatory response found in most tumors is highly regulated by the progressive genetic alterations that occur with cancer development and progression. For example, the *KRAS* proto-oncogene is mutationally activated in 90% of PDAC and results in constitutive activation of *KRAS* and its downstream signaling pathways. *KRAS* activation results in driving cancer cell migration and metastasis [14]. Preclinical models have shown that *KRAS* inactivation results in the high expression of granulocyte-macrophage colony-stimulating factor (GM-CSF) [15,16]. GM-CSF has been shown to result in the accumulation of Gr-1$^+$ CD11b$^+$ cells (MDSC) by inducing the proliferation and differentiation of precursor c-kit$^+$ stem cells, which leads to the suppression of CD8$^+$ T-cell-mediated antitumor immune responses thereby permitting tumor growth.

T cells express a number of stimulatory and inhibitory signals depending on the type of inflammation they encounter. Whether a T cell becomes activated or deactivated depends on the sum of the signals that are engaged. Two T-cell inhibitory signals have already been shown to have clinical relevance in cancer. CTLA-4 (cytotoxic T-lymphocyte-associated protein 4) acts as an immune checkpoint striving to maintain immune homeostasis by downregulating T-cell function once CD28 binds to its ligand B7, therefore inducing T-cell cycle arrest (Fig. 114.2) [17]. Due to its role as a negative

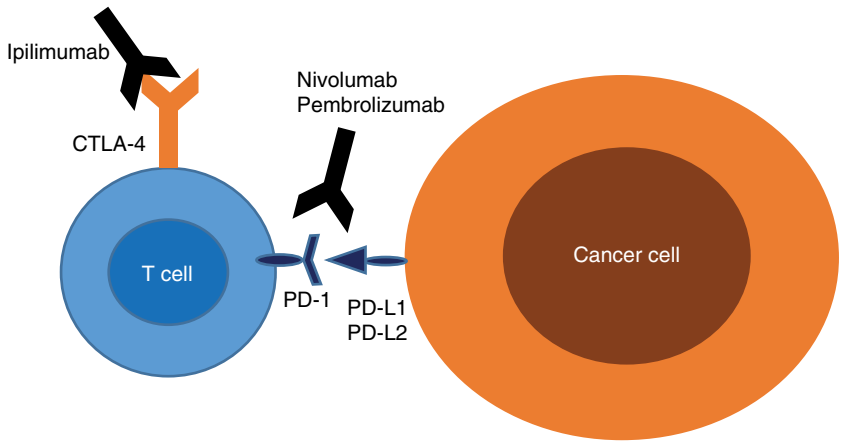

**Figure 114.2** Checkpoint inhibitors in pancreatic cancer. T cells express CTLA-4 (cytotoxic T lymphocyte associated-4) antigens on their cell surfaces which downregulate T-cell function. Anti-CTLA-4 antibodies (e.g., ipilimumab) can bind to CTLA-4 receptors on T cells and reverse immunosuppressive T-cell functions. PD-1 (programmed death-1) receptors on T cells bind to PD-L1 and PD-L2 ligands on cancer cell surfaces. Anti-PD-1 antibodies bind to PD-1 receptors preventing interactions with its ligands.

regulator of immunity, it was the first checkpoint to be targeted after preclinical models showed that antibody blockade of CTLA-4 leads to antitumor immunity [18,19]. PD-1 (programmed death-1) is also an immune checkpoint which negatively regulates T-cell activity when it interacts with its ligands, PD-L1 and PD-L2 [20]. PD-1 is expressed on many immune cells and inhibits effector T-cell function [21]. Antagonist antibodies that inhibit these molecules have recently become standard of care for cancers that naturally attract effector T cells into their tumor. However, PDAC patients have failed to respond to these single agent immune modulators. However, combinatorial immune-based approaches are currently under development to target multiple immune suppressive pathways and are showing promise in PDAC patients.

## Therapeutic Vaccines

Cancer vaccines are used to generate a humoral/cellular immune response to stimulate the immune system as a defense mechanism against tumor cells. Therapeutic vaccines deliver specific pancreatic tumor antigens systemically with the aim of stimulating the patient's immune system to recognize minor differences in the antigen that exists between normal and tumor cells. These vaccines are generally well tolerated because of their antigen specificity. Therapeutic vaccines can be broadly categorized into whole-cell vaccines and antigen-specific vaccines.

### Whole-Cell Vaccines

Polyvalent vaccines are derived from whole cells or cell lysates and have the capacity to allow the targeting of multiple antigens.

The allogeneic whole cell pancreatic tumor vaccine GVAX developed by Jaffee et al. [22] was derived from two human pancreatic cancer cell lines stably transfected to produce the human cytokine GM-CSF. GM-CSF has the capacity to overcome tumor-induced suppression and promote the recruitment and maturation of APC resulting in upregulation of MHC class II co-stimulatory molecules and cytokine production. GMC-CSF-producing tumor cells are subsequently irradiated and administered to patients intradermally. The phase I study comprised 14 patients with Stages I–III pancreatic cancer who received multiple administrations of vaccine with concentrations ranging from $1–50 \times 10^7$ cells after surgical resection and standard adjuvant therapy. This study found that three patients who received $\geq 10 \times 10^7$ vaccine cells developed increased delayed-type hypersensitivity (DTH) responses and that these patients remained disease free for over 10 years [22]. GVAX was well tolerated without any local or systemic dose-limiting toxicities observed. The most common adverse effects were self-limiting skin reactions (erythema, induration, pain) at the sites of immunization.

The phase II study involved administering $5 \times 10^8$ GM-CSF-secreting cells to 60 patients with resected PDAC [23]. Patients received five doses of vaccine in addition to 5-FU-based chemotherapy. The median disease-free survival was 17.3 months (95% CI: 14.6–22.8) and the median survival was 24.8 months (95% CI: 21.1–31.6). The addition of immunotherapy to chemotherapy did not result in additional toxicities and the development of mesothelin-specific $CD8^+$ T cells in HLA-$A1^+$ and HLA-$A2^+$ patients was correlated with improved disease-free survival.

Based on preclinical data that giving cyclophosphamide (Cy) prior to immunotherapy could enhance the intended immune responses by inhibiting $CD4^+/CD25^+$ Treg cells [24–27], Laheru et al. designed a clinical study comparing the effects of administering Cy prior to GVAX vaccine in patients with advanced PDAC [28]. Fifty patients received Cy one day prior to the vaccine or the vaccine alone and minimal toxicities were observed in

both arms. Survival data from this nonrandomized study suggested that adding Cy prolonged median survival (130 vs. 69 days). This study also found that mesothelin-specific immune responses were detected in this cohort of patients with advanced disease.

PDAC has traditionally been regarded as a nonimmunogenic cancer compared with melanoma and lung cancer. A neoadjuvant and adjuvant clinical trial was designed to test whether GVAX ± Cy could convert the relatively nonimmunogenic TME of PDAC into an immunogenic tumor with infiltrating effector lymphocytes [29]. Two weeks prior to surgical resection, 39 patients were randomized to receive either GVAX alone, GVAX preceded by a single intravenous Cy dose, or GVAX with daily Cy on alternate weeks. Examination of the resected PDA showed that vaccines induced intratumoral tertiary lymphoid aggregates in 85% of patients. Further analysis of these aggregates showed that they consisted of organized T- and B-cell zones with predominance of $CD68^+$ and $CD163^+$ cells indicating that they represented adaptive immunity. Specific gene expression signatures were found in these intratumoral aggregates including those showing a suppressed Treg pathway and enhanced Th17 pathway, which were associated with improved survival. Consistent with prior studies, there was an association between those who developed an immune response/lymphoid aggregates and improved survival. This study also showed that the expression of immune checkpoint signaling, such as PD-1 and PD-L1, was induced by vaccination, suggesting that GVAX therapy could play a role in priming patients to combat the lack of response to anti-PD-1 therapies seen in PDAC. Current studies are testing the combination of vaccine to induce PDAC-specific immunity together with immune checkpoint antibodies that unleash the full potential of the vaccine-induced immune response.

Algenpantucel-L is the other whole-cell vaccine that has had promising clinical data in PDAC. It consists of two live, irradiated human PDAC cell lines that express murine α-1, 3-galactosyltransferase, an enzyme responsible for the synthesis of α-galactosylated (α-gal) epitopes on cell surface proteins. Binding of anti-α-gal antibodies to α-gal activates the classic complement pathway, and noncomplement fixing antibodies also induce cell-mediated cytotoxicity to generate hyperacute rejection of allografts in humans. Hardacre et al. conducted a phase II study of the algenpantucel-L vaccine in addition to chemoradiation therapy in 70 patients in the adjuvant setting after resected PDAC [30]. The 12-month disease-free survival rate and 12-month overall survival rate were 62% and 86%, respectively. Toxicities were limited to injection site reactions and fatigue. These results have led to a phase III clinical trial for borderline resectable or locally advanced unresectable PDAC, which has completed accrual (NCT01836432).

## Antigen-Specific Vaccines

Antigen-specific vaccines take advantage of inherent defects in the genetics of PDA and translate these into functional targets of immunotherapy. As *KRAS* mutations are universal in PDAC and are known for their role in driving the PDAC development [31,32], they are an obvious target for immunotherapy. Early studies involving administering synthetic KRAS peptides to patients with unresectable PDAC showed that it was safe and induced an immune response in two out of five patients [33]. Another phase I/II trial coadministered mutant KRAS peptides with GM-CSF in a study involving 48 patients with PDAC [34]. Immune responses were elicited in 58% of patients and in those with advanced disease, a peptide-specific immune response was associated with improved survival. A further study evaluated the administration of patient-specific *KRAS* mutations (codon 12) with a 21-mer epitope containing the patient's mutation and GM-CSF in patients with resected PDAC [32]. They demonstrated median recurrence-free survival and overall survival of 8.6 months and 20.3 months, respectively. However, there were low rates of immunogenicity with a single patient developing a detectable mutation-specific immune response and 13% of patients developing a nonspecific DTH.

Interest first arose in mesothelin, a tumor-associated antigen overexpressed in most PDAC, as a target for immunotherapy in PDAC based on the observation that mesothelin-specific responses were associated with improved disease-free survival after GVAX therapy [28]. This led to the development of CRS-207, a recombinant live-attenuated, double-deleted strain of *Listeria monocytogenes* (LADD-Lm), which was engineered to secrete mesothelin into the cytosol of infected APC, which ultimately are processed and presented as major histocompatibility complex molecules. The phase I study involving CRS-207 demonstrated that multiple administrations were well tolerated and sufficient to induce mesothelin-specific T-cell responses [35]. Preclinical data suggested that a heterologous prime/boost strategy combining GVAX and LADD Lm-expressing mesothelin induced a synergistic T-cell induction and antitumor effect. A phase II study randomized patients with previously treated metastatic PDAC to receive Cy/GVAX followed by CRS-207 versus Cy/GVAX alone [36]. Overall survival for all patients was higher in the Cy/GVAX + CRS-207 group (6.1 vs. 3.9 months). For those patients who received at least three doses, overall survival for the Cy/GVAX + CRS-207 group was 9.7 months compared with 4.6 months for the Cy/GVAX-alone group. Enhanced mesothelin-specific $CD8^+$ T-cell responses were associated with longer survival in both treatment groups. Multicenter follow-up studies are ongoing to determine the survival benefit from vaccine alone and from vaccine given with the immune modulating agent nivolumab.

Patients with PDAC receiving GVAX who developed antibody responses to AnnexinA2, a novel pancreatic cancer antigen that may play a role in early metastasis, were observed to have prolonged disease-free survival [37–39]. A listeria-based vaccine targeting AnnexinA2 is currently in development.

### Neoantigen-Based Vaccines

Somatic gene mutations occurring in individual tumors can generate novel epitopes or "neoepitopes" that serve as targets for immune responses [40]. The technology to recognize individual neoepitopes now exists, which can scan the entire cancer exome (coding regions), but for neoepitopes to be functional, their mutant peptides must be processed by MHC molecules and T cells must recognize this peptide-MHC complex. An added complexity lies in the fact that these epitopes must have been tolerated by the immune system to permit the tumor to grow. This tolerance appears to be mediated by immune checkpoints, for example PD-L1 [41]. It is unsurprising that these tumor types are typically sensitive to immune checkpoint inhibition since they induce effector T-cell infiltration that resembles untreated melanomas [42].

Unlike tumors typically associated with high rates of mutations, for example melanoma, PDAC characteristically harbors fewer mutations although neoepitopes do exist [43]. Notwithstanding the challenges of identifying tumor neoantigens suitable for immunization, determining the number of neoantigens required for targeting and the challenges of producing personalized vaccines, future efforts should concentrate on developing neoantigen-based vaccines [44].

## Non-Vaccine Immunomodulators Used in Pancreatic Cancer

### CTLA-4

Ipilimumab is a fully human IgG1κ antibody that recognizes CTLA-4 and blocks its interaction with B7-1 and B7-2 on APC. This results in prolonged T-cell activation and amplification of T-cell-mediated immunity [45]. Ipilimumab has received FDA approval for use in Stages III–IV melanoma due to improved recurrence-free survival (adjuvant setting) [46] and overall survival (metastatic setting) [47].

A phase II study evaluated single-agent ipilimumab for patients with locally advanced or metastatic PDAC [48]. Twenty-seven patients received ipilimumab 3 mg/kg every 3 weeks for a maximum of eight doses. There were no responders by RECIST (response evaluation criteria in solid tumors criteria) although one subject experienced a delayed response after initially being diagnosed with progressive disease. The concept of pseudoprogression is a recognized phenomenon in immunotherapy whereby tumors may initially increase in size during treatment with immune checkpoint inhibitors only to produce delayed clinical responses which may be durable [49]. This phenomenon has prompted the inclusion of immune-related response criteria as a means of objectively assessing tumor response to immunotherapy [50].

### PD-1

A number of FDA-approved antibodies disrupting the PD-1 axis have been developed including pembrolizumab and nivolumab. These drugs target PD-1 and block its interaction with PD-L1 and PD-L2. They demonstrated durable response rates in phase I studies including patients with melanoma, lung cancer, and renal cell cancer [51,52]. The phase I study of pembrolizumab included a single patient with PDAC and involved a dose escalation study up to 10 mg/kg every 2 weeks [53]. Pembrolizumab was well tolerated with no dose-limiting toxicities observed. Two patients experienced complete responses (melanoma, merkel cell carcinoma) with the majority of patients experiencing disease stability. However, in contrast to other tumors, PDAC is not associated with high density of tumor-infiltrating lymphocytes, the principal targets of PD-1 therapy [54]. Although immune checkpoint inhibition is associated with impressive durable response rates in other tumor types, there is no current method to reliably predict response. PD-L1 expression measured by immunohistochemistry has been postulated as a potential predictive biomarker but this is limited by the lack of standardized assessment of PD-L1 expression by immunohistochemistry [55,56].

Another pharmacologic approach to targeting the PD-1 axis involves targeting either of the ligands, PD-L1 and PD-L2. PD-L1 is expressed on the cell surface of many tumor cells and is likely to be involved in tumor cell immune evasion [21]. There are several commercially available monoclonal antibodies targeting PD-L1 which have entered clinical trials. Brahmer et al. evaluated BMS-986559 in a phase I study involving patients with advanced cancer and found that it induced durable tumor regression (objective response rate 6–17%) and prolonged disease stabilization (12–41% at 24 weeks) [57]. MEDI4736 (AstraZeneca) has been tested in a phase I study (NCT01693562) where it has been reported to be safe and has preliminary evidence of clinical activity. Another antibody, MPDL3280A has shown response rates of 36% with patients with melanomas having the highest response rates [58].

## Targeting Tumor-Associated Macrophages

Tumor-associated macrophages (TAM) alter their functional subtypes based on signals in the TME in an attempt to maintain immune homeostasis [59]. Higher density of TAM in pancreatic tumors is associated with worse survival due to their tumor-promoting effects [60]. The cell surface molecule CD40 is expressed on numerous immune cells, for example, B cells and dendritic cells, and its signaling results in activation of antigen-presenting cells and T cells [61]. CD40 activation using agonist antibodies can reverse immune suppression and induce tumoricidal CD40-activated TAM [62]. Antibody blockade of CSF-1 (colony-stimulating factor-1) and its receptor CSF-1R expressed on macrophages, has the capacity to improve antitumor T-cell responses and improve responses to checkpoint inhibitor therapy [63,64].

## Combination Immunotherapy

Current efforts focus on trying to overcome the inherent resistance to checkpoint inhibition in PDAC by combining immunotherapeutic strategies. Due to the relative absence of TIL, strategies that can induce further infiltration of effector T cells have the potential to prime the pancreatic TME to become more sensitive to immune checkpoint inhibition.

GVAX is known to have the capacity to induce the development of tertiary lymphoid structures in PDAC alongside the upregulation of the PD-1 pathway [29]. In addition, Soares et al. demonstrated that relatively nonimmunogenic tumors, such as PDAC, can be sensitized to PD-1 blockade with the aid of cancer vaccines [65]. Pancreatic tumors demonstrate weak membranous PD-L1 staining but treatment with GVAX significantly upregulates PD-L1 expression. They subsequently demonstrated that combination treatment with GVAX and PD-1 or PD-L1 blockade improved survival in a preclinical PDAC model with an increase in IFNγ-producing $CD8^+$ tumor-specific TIL indicating the recruitment of cytotoxic T cells to the TME.

These studies provided the rationale for combinatorial immunotherapy in PDAC. Le et al. reported the results of administering ipilimumab 10 mg/kg (anti-CTLA-4) with or without GVAX in patients with advanced PDAC [66]. During this phase II study, patients received induction doses every 3 weeks for a total of four doses followed by maintenance dosing every 12 weeks. Median overall survival was longer in those who received ipilimumab/GVAX compared with ipilimumab alone (5.7 vs. 3.6 months, $P = 0.072$). However, the rate of adverse events was high in both arms of this study (73% for ipilimumab, 80% for combination therapy) leading investigators to consider using alternate forms of immunotherapy.

A currently recruiting phase II trial (NCT02243371) is enrolling patients with previously treated metastatic PDAC to receive Cy/GVAX followed by nivolumab/CRS-207 versus vaccine alone. Combination immunotherapy is also being used outside of the metastatic setting in a study that involves Cy/GVAX with or without nivolumab in the neoadjuvant and adjuvant settings (NCT02451982).

## Conclusion

Pancreatic cancer has notoriously poor survival rates that are not dramatically improved with the use of traditional cytotoxic chemotherapy. Immunotherapy has the potential to produce durable remissions, which has been demonstrated in other tumor types. Cancer vaccines have shown the ability to reverse the relatively nonimmunogenic phenotype associated with PDAC and induce subsets of immune cells which can, in turn, be sensitized to immune checkpoint inhibition [29,65]. The future success of treating PDAC with immunotherapy likely lies in the use of combinatorial regimens. There is also potential for optimizing these regimens with alternative strategies including epigenetic modulation, radiation therapy, and T-cell transfer therapies, which have the added advantage of targeting other cell types in the TME. Given the marked heterogeneity in tumor genetics, there is also a need to discover biomarkers that can reliably predict which subsets of patients are likely to respond to immunotherapy.

## Introduction

Despite a continuously evolving understanding of the tumorigenesis and biology of pancreatic ductal adenocarcinoma (PDAC), current therapeutic strategies have only achieved modest improvements in patient outcomes. With FOLFIRINOX and gemcitabine-based therapies being the main arbiters in our armamentarium, intrinsic and acquired chemoresistance has prevailed as the rule rather than the exception in this disease. However, novel therapeutic options have begun to gain traction through the development and understanding of new targeted therapies and modulation of the tumor microenvironment through immunotherapies. Recent large-scale efforts in next generation sequencing (NGS) technologies have allowed us to interrogate the genomic landscape of PDAC and with it, the ability to tailor therapeutic options while exploiting molecular abnormalities. In this chapter, we describe how these efforts have given us insight into how we may be able to begin applying these therapies with the hope of curtailing this aggressive disease.

## Genomic Landscape of PDAC

Significant efforts through the International Cancer Genome Consortium (ICGC) and The Cancer Genome Atlas (TCGA) have allowed us to make meaningful progress in deciphering the genomic landscape of PDAC. Among the earliest events in PDAC pathogenesis is the activating point mutation in the *KRAS* oncogene, which is present in more than 90% of these tumors. Progression of this disease then follows a sequential model of loss of function mutations in *TP53*, *SMAD4*, and *CDKN2A*. Aside from these four key oncogenic drivers, it is important to note several low-frequency mutations that have been identified that converge on core signaling tumorigenic pathways including regulation of apoptosis, DNA damage, cell cycle, *KRAS* signaling, invasion, and transforming growth factor-B signaling [1–4] (Fig. 115.1). By identifying and understanding how these altered genes and pathways can affect tumorigenesis, we begin to interrogate how targeting these key nodes can be exploited for therapeutic stratification.

## Molecular Subtypes Reveal Therapeutic Vulnerabilities

In 2015, Waddell and colleagues reported whole genome sequencing and copy number variation analysis of 100 PDAC which revealed the presence of chromosomal rearrangements leading to genetic aberrations [4]. By classifying these structural variation profiles, four subtypes were identified and termed as: stable, scattered, unstable, and locally rearranged. Those classified as unstable were found to have widespread structural rearrangements and were characterized as having high levels of genomic instability secondary to defective DNA repair pathways (e.g., due to *BRCA1*, *BRCA2*, *PALB2*, and possibly, *ATM* aberrations). Described as having a "BRCA mutation signature," these tumors are more likely to have high sensitivity to DNA damaging agents such as

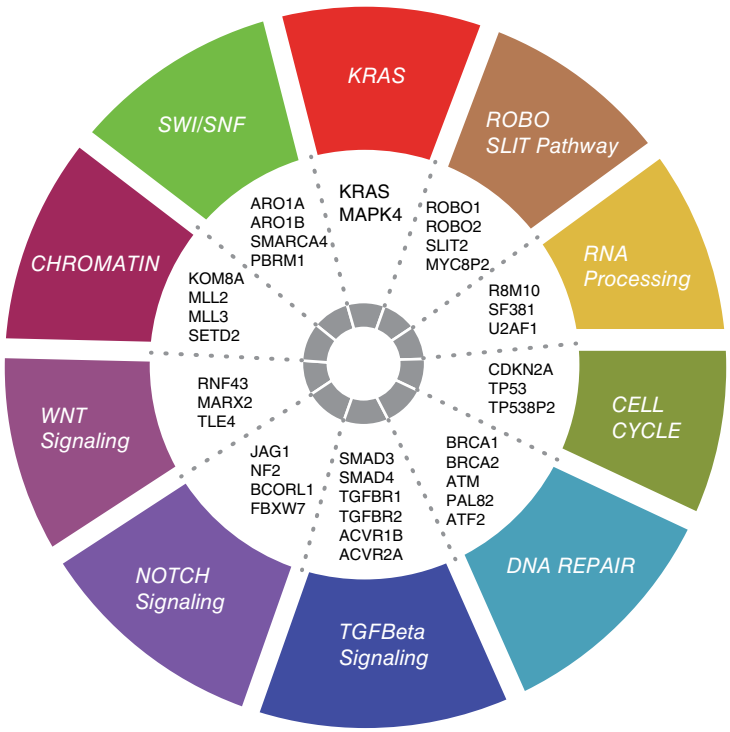

**Figure 115.1** Core signaling tumorigenic pathways in pancreatic cancer. Aberrant signaling pathways with associated genes enriched in pancreatic cancers based on NGS. Targeting these key nodes rather than specific gene mutations provides novel therapeutic strategies in treating pancreatic cancer. *Source:* Bailey et al. 2016 [2]. Reproduced with permission of Nature Publishing.

platinum-based therapies, mitomycin C, and PARP-1 (poly [ADP-ribose] polymerase 1) inhibitors. Another structural variant of interest is described as the locally rearranged subtype, which has the presence of intrachromosomal rearrangements leading to chromothripsis or breakage-fusion-bridge cycles, but more importantly contains regions of gains/amplifications in known oncogenes with therapeutic targets including *ERBB2*, *MET*, *CDK6*, *PIK3CA*, and *PIK3R3*.

In 2016, Bailey and colleagues performed the most comprehensive genomic analysis to date in PDAC involving 456 tumors, combining whole genome and exome sequencing, copy number analysis, and RNA expression profiles [2]. This identified four subtypes of PDAC based on differential gene expression signatures described as: squamous, pancreatic progenitor, immunogenic, and aberrantly differentiated endocrine exocrine (ADEX). Each subtype is associated with distinct histopathologic characteristics, with molecular features that infer different mechanisms of evolution. Among these, it is important to note the striking molecular similarities between subtypes across cancers rather than to subtypes within a single cancer. The implications of this now allow us to broaden our therapeutic options based on what has been effective in similar subtypes within other cancer types. For example, the squamous subtype of PDAC is more closely related to other so-called "basal" cancers seen in head and neck, bladder, lung, and triple negative breast cancers rather than the other three PDAC subtypes described; thus allowing us to expand clinical actionability based on these other tumor types.

Other identified actionable mutations include those in genes related to RNA splicing such as *SF3B1*, which is also found in myelodysplastic syndrome, breast and lung cancer, and infers potential targetability with the SF3b complex inhibitor spliceostatin A [5]. Aberrations in the oncogene *CCNE1*, involved in cell cycle regulation, were also found. *CCNE1* mutations in ovarian, breast, and lung cancers have dictated poor survival with resistance to platinum-based therapies, but may represent a therapeutic vulnerability to CDK inhibitors [6].

Another subset of sequencing efforts was performed by Witkiewicz et al., where they attempted to increase the purity of the tumor being profiled and thus mutation calling by using 109 micro-dissected PDAC [7]. Several frequently mutated pathways were identified and stratified based on genetic actionability, including:

1) Cell cycle progression (*RB*, *CDKN2A*, *CDKN2B*, or *CDK4*): CDK4/6 inhibitors (PD-0332991).
2) Beta-catenin (*RNF43*, *AXIN1/2*, or *APC*): porcupine and tankyrase inhibitors (LGK974 and XAV939).
3) NOTCH pathways: gamma-secretase inhibitors (MK0752).
4) MYC amplifications: CDK9 inhibitors or BET-bromodomain inhibitor (PHA767491 and JQ1) [7].

Identification of biomarkers with direct implications for the molecular biology of PDAC such as those

presented has the potential to influence treatment approaches with improvement in clinical outcomes for a subset of these patients.

## Targeting RAS

*KRAS* is among the most common oncogenic drivers in human cancers, making it the most obvious choice for targeted therapies. Activation of the RAS protein is the result of growth factor receptor signaling, which induces cycling of a GTP-bound (ON) and a GDP-bound (OFF) state that regulates downstream effectors. Within the protein lies an intrinsic GTPase, which allows RAS proteins to hydrolyze GTP to GDP and inactivate itself. Point mutations in *KRAS* effectively inhibit this interaction of RAS with GTPase-activating proteins resulting in the inability to hydrolyze GTP to GDP allowing for a constitutively active protein. Unfortunately, RAS has received notoriety as an "undruggable" target due to its high affinity to GTP and the smooth surface of the protein, prohibiting binding of therapeutic molecules [8]. Efforts at drugging RAS have involved direct inhibition, impairing localization, inhibiting downstream effectors, and exploiting synthetic lethality strategies.

Several direct *KRAS* inhibitors have been synthesized, but have yet to be clinically effective [9–11]. Among the most promising involves the development of a covalent inhibitor that targets the mutant form G12C, found mostly in lung and colorectal cancers but not typically observed in PDAC. This compound effectively increases the affinity of *KRAS* G12C for GDP over GTP leading to the accumulation of the GDP bound state, but suitable pharmacokinetics and pharmacodynamics remain to be optimized before use in the clinic.

Targeting intracellular trafficking of RAS has been a conceptually interesting alternative. Some of the earliest efforts at Ras targeting had focused on blocking its ability to attach to the plasma membrane for signal transduction using farnesyltransferase inhibitors, but these failed in phase II and III clinical trials [12–14].

Another strategy involves exploiting oncogene addiction wherein the cancer cells are dependent on Ras for survival and propagation. This is done through an approach known as synthetic lethality where defects in two genes leads to cell death, whereas a defect in one gene alone allows the cell to remain viable. By targeting genes activated by *KRAS* for tumor maintenance, several candidate synthetic lethal interactions have been identified.

Corcoran et al. performed a genome-wide screen using RNAi where they identified genes that cooperate with MEK inhibition leading to the identification of *BCL-XL*, an antiapoptotic gene [15]. When the MEK inhibitor, selumetinib, and the Bcl family inhibitor navitoclax were combined, researchers saw an induction of apoptosis in *KRAS* mutant cells. This combination therapy is currently in clinical trials for *KRAS* mutant cancers (NCT02079740). Another candidate target was found when researchers discovered that *KRAS*-mutant NSCLC requires CDK4 for survival and proliferation. Treatment with CDK4 inhibitors induced senescence and decreased tumor growth rates in mouse models, leading to a currently established clinical trial (NCT02022982) [16–18]. Although a clear effective drug for *KRAS* remains to be discovered, the novel strategies used by these described studies to identify viable candidates hold promise as we move forward.

While *KRAS* mutations are nearly ubiquitous in PDAC, it is important to note the oncogenic nature of wild-type *KRAS* PDAC. Recent studies have shown that these tumors still exhibit aberrations in RAS effector pathways, including mutations in *BRAF* and *PIK3CA* [7]. Particularly, *BRAF* mutations were found to be mutually exclusive of *KRAS* mutations and these cases might be sensitive to the FDA-approved BRAF inhibitor vemurafenib. This small subset of cases thus presents an opportunity for targeted therapies using BRAF and PI3K inhibitors.

## MEK/ERK Inhibition

A potential strategy to circumvent the "undruggability" of *KRAS* is to target its downstream effectors, which include the RAF/MEK/Erk and PIK3/AKT pathways. MEK and PI3K inhibitors, as well as combined inhibition of MEK and AKT pathways have shown promising effectiveness in the preclinical setting [19,20]. A phase I clinical trial on the safety and efficacy of the dual targeting strategy of the PI3K/AKT and RAF/MEK/ERK pathways showed the potential for favorable efficacy, but with associated increase in toxicity [21]. In phase II clinical trials, MEK inhibition in combination with gemcitabine did not demonstrate improved response rate or overall survival when compared to gemcitabine alone [22]. However, a noteworthy insight that came from this study was the prospect of increased effectiveness, although not statistically significant, in those patients with wild-type *KRAS* tumors. This demonstrates how molecular information may play a critical role in patient stratification for clinical trials.

## Epidermal Growth Factor Receptor Inhibition

Ligand binding to epidermal growth factor receptor (EGFR) with subsequent activation of downstream effector pathways (RAS/RAF/MEK, PIK3/AKT, and JAK/

STAT) involved in cell survival and proliferation is another potential target in PDAC [23]. Preclinical models have demonstrated the need for EGFR signaling in *KRAS* mutated pancreatic cancer initiation and progression [24,25]. Although initial phase III clinical trials demonstrated only modest improvement in overall survival for a subset of patients (<10%) using the tyrosine kinase inhibitor (TKI) erlotinib, other studies are under way testing additional anti-EGFR monoclonal antibodies and dual EGFR/HER2 targeting strategies (NCT00871169, NCT01204372, NCT01728818) [26]. Of particular interest are those patients with wild-type *KRAS* tumors who may find therapeutic potential with these TKI [27,28].

## Insulin Growth Factor-1 Receptor

Synonymous to EGFR signaling, insulin growth factor-1 receptor (IGFR) activation leads to effector pathways involved in survival and proliferation. Of note, clinical trials, including the phase III GAMMA trial, involving the monoclonal antibody against IGFR, AMG-479 (ganitumab), did not demonstrate any statistically significant improvement in overall survival, underscoring the complexity of signaling pathways in this disease.

## Pancreatic Stroma

PDAC is well known to be associated with a profuse desmoplastic stroma composed of fibroblasts, immune cells, endothelial cells, pericytes, and a complex extracellular matrix (ECM). Initial studies have demonstrated how various stromal elements can promote cancer cell proliferation, invasion, and immune suppression while decreasing drug perfusion, leading to the paradigm that the stroma acts as a tumor promoter [29–31]. However, recent work has challenged this model. Rhim et al. have shown that inhibiting the sonic hedgehog (SHH) pathway, which promotes the desmoplastic reaction, results in poorly differentiated tumors with increased vascularity and mortality in mouse models [32]. Ozdemir et al. demonstrated similar results, where depletion of aSMA+ pancreatic myofibroblasts and type 1 collagen led to cancer cells acquiring an EMT state, stem cell-like phenotype, and poor survival in genetically engineered mouse models [33]. This evolution in understanding the functional role of tumor stroma has led to several approaches in therapeutic targeting.

By following the route of the tumor stroma as a barrier to chemotherapy delivery, a SHH inhibitor, IPI-926, was used to decrease myofibroblastic proliferation and tumor collagen deposition. Although preclinical studies showed promise with this strategy, clinical trials with IPI-926 + gemcitabine in advanced PDAC failed to demonstrate survival benefit when compared to gemcitabine alone [34].

Hyaluronic acid is an ECM protein that induces a high interstitial pressure and vascular collapse within the PDAC stroma resulting in impaired perfusion. A strategy to overcome this barrier to perfusion involves the use of hyaluronidase, an enzyme that degrades hyaluron, and thus permits delivery of gemcitabine by lowering the stromal interstitial pressure. Clinical trials using gemcitabine and nab-paclitaxel ± PEGylated hyaluronidase have demonstrated significantly improved progression-free survival in advanced PDAC patients with high hyaluronic acid (HA) expression in preliminary results [35], and a phase III trial of front-line therapy with PEG-PH20 is being planned.

Another study has emphasized the role of "stromal reprogramming" in order to restore the normal function and homeostasis of the tumor stroma. Pancreatic stellate cells (PSC) are a stromal component of the pancreas, which when activated by cytokines, growth factors, oxidative or metabolic stress, transdifferentiate to myofibroblast-like cells that synthesize ECM proteins, contributing to fibrosis and tumor progression [36]. By activating the vitamin D receptor (VDR) present on these cells with an analog ligand, researchers were able to revert these activated PSC to a quiescent state where tissue homeostasis is restored, leading to increased drug delivery, reduced tumor volumes, and increased overall survival in preclinical models [37]. Synthetic Vitamin D priming as an adjuvant to chemotherapy is the subject of ongoing clinical trials in advanced pancreatic cancer patients.

Effective approaches to the tumor stroma remain to be fully elucidated considering the potential dual role that it can play in tumor progression or suppression. Still, it is important to note the heterogeneity of populations that exist within this microenvironment and how their divergent roles are likely a function of a dynamic process that is constantly changing and adapting to the conditions within the tumor.

## Enabling Targeted Therapies in Pancreatic Cancer

As detailed earlier, targeted therapies in the era of precision medicine are an exciting field considering the significant efforts made through the ICGC and TCGA. But an important caveat revolves around the fact that without having the ability to find the target, precision medicine becomes a futile endeavor. This is especially true for

patients with *de novo* or recurrent metastatic PDAC, where tumor tissue is rarely sampled apart from a fine-needle aspiration or a core-needle biopsy performed for diagnosis. Aside from only perfunctory molecular assays, such as immunohistochemistry and limited sequencing, the ability to discover actionable mutations remains a limitation to currently employed techniques [38]. Liquid biopsies involving three compartments: circulating tumor DNA (ctDNA), circulating tumor cells (CTC), and microvesicles referred to as exosomes have thus been used as an alternative for tumor profiling. These compartments represent tumor material that is released by primary and metastatic sites and can theoretically capture a full representation of tumor heterogeneity [39].

Sausen et al. have demonstrated the ability to detect somatic mutations in ctDNA of PDAC patients during subclinical, residual, and recurrent disease [40]. San Lucas et al. profiled tumor DNA contained within exosomes, identifying multiple actionable mutations including alterations in *NOTCH1* and *ERBB2* [41]. Of particular significance was the identification of a *BRCA2* mutation in a patient with exceptional response to a platinum-containing adjuvant regimen, underscoring the clinical applicability of the information stored within these exosomes. Genomic characterization of CTC has also demonstrated promise in guiding therapy options by predicting chemotherapy response and resistance [42]. Although preliminary, the collection of this data supports the utility of liquid biopsies in the context of targeted therapies by noninvasively monitoring tumor evolution and identifying emerging actionable mutations in real time.

## Summary

Much has been learned in the past three decades about the molecular mechanisms driving pancreatic carcinogenesis; allowing for therapeutic options to be expanded beyond just chemotherapies. Studies such as those performed by the TCGA and ICGC have highlighted the genetic heterogeneity within PDAC, but have also given an insight into strategies to overcome it. The likelihood of effectively treating PDAC using a single target is low. By tailoring therapeutic strategies to target multiple genetic aberrations or key nodal signaling pathways, we may find success in overcoming the inevitable resistance seen in this disease. Patient stratification into clinical trials based on molecular biomarkers remains an objective of utmost importance in order to more effectively discover and validate targeted therapies that may prove beneficial to these patients.

## The Clinical Burden of Advanced Pancreatic Cancer

In the Western world, pancreatic cancer remains one of the poorest prognostic malignancies with 5-year survival of ~10% [1]. Due to its relatively asymptomatic nature until at an advanced stage and the absence of validated screening techniques, more than 80% of pancreatic cancer cases continue to be diagnosed at an advanced stage, precluding potentially curative treatment [2]. Furthermore, with a projected rise from being the fifth to the second most common cause of cancer mortality (after lung cancer) in 2030, the role of optimal management of advanced pancreatic cancer will increase in significance [3]. Pancreatic cancer comprises two major groups of malignancies, the carcinomas and the neuroendocrine cancers. While carcinomas contribute more than 95% of cases and are often treated with chemotherapy, the neuroendocrine cancers (<5%) are often treated with hormonal and molecular targeted therapies, with chemotherapy reserved for the rare high-grade variant (<1%) [4]. This chapter will focus on the benefits and side effects of chemotherapy for advanced pancreatic carcinomas.

## The Management of Advanced Pancreatic Carcinoma

Advanced pancreatic carcinoma is often associated with significant disease-related morbidity, typically emerging during the weeks to months preceding its diagnosis. Prior to the establishment of a role for palliative chemotherapy, the median survival for advanced pancreatic cancer was universally poor at ~6 weeks with best supportive care alone [5]. The importance of optimal supportive care as a prerequisite to commencement of cancer-directed therapeutic measures cannot be overemphasized. In this respect, it is noteworthy that all clinical trials demonstrating benefit from treatment with systemic chemotherapy have only shown this benefit in conjunction with best supportive care. Furthermore, most patients of WHO performance status (PS) 3 and those of PS4 do not survive long enough to potentially benefit from chemotherapy. Thus, disease complications such as pain, obstructive jaundice, malnutrition (due to factors such as anorexia, pancreatic exocrine insufficiency, gastric outlet obstruction), diabetes, and psychosocial issues should be optimally managed alongside initiation of systemic chemotherapy treatment. Given the relatively similar manner of presentation, chemotherapy was initially approached in the same way across the entire spectrum of advanced pancreatic cancer. However, patients with locally advanced (LA) disease (locoregional vascular involvement precluding resectability) are now known to have a better prognosis than those with metastatic disease (distant spread) concomitant with advances in locoregional treatment approaches [6]. Therefore, surgical and locoregional ablative approaches are emerging for indolent or chemosensitive forms of LA disease such that its management approach may diverge from that of metastatic disease in the future. In this chapter, we will discuss the treatment of advanced pancreatic cancer with palliative chemotherapy. We will then discuss more recent chemotherapy regimens validated to be beneficial for metastatic disease and their role in LA disease including potential integration with locoregional treatment approaches. A schematic diagram of the approach to the treatment of advanced pancreatic

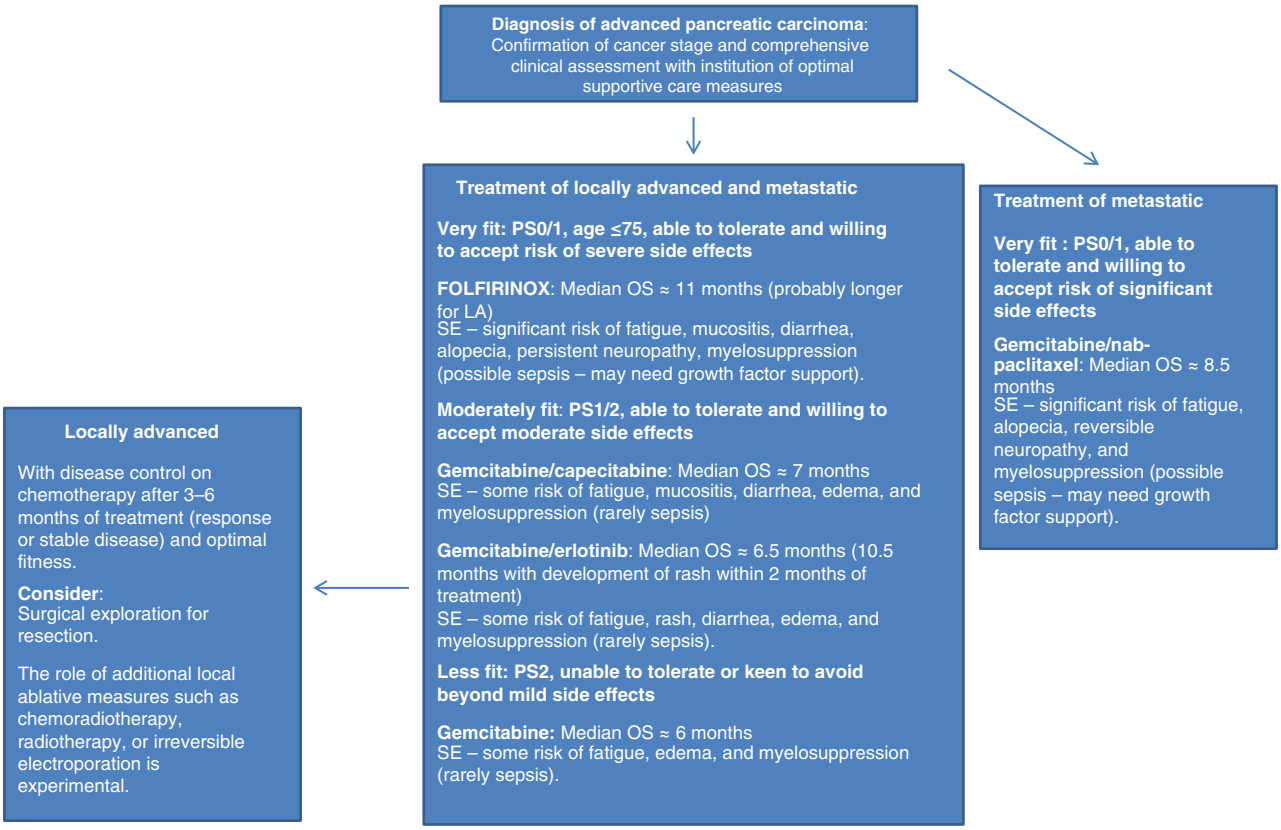

**Figure 116.1** Schematic diagram of the potential benefit and common side effects of chemotherapy treatment options for advanced pancreatic carcinoma. The broad selection criteria for different treatment options are also highlighted. LA, locally advanced; OS, overall survival; PS, WHO performance status; SE, side effects.

cancer including survival benefit and the potential adverse effects associated is shown in Fig. 116.1.

## First-Line Chemotherapy Treatment for Advanced Pancreatic Carcinoma

A multitude of chemotherapy regimens have been evaluated in advanced pancreatic carcinoma palliation over the past few decades. In trials, chemotherapy response rates have been low (5–32%) but rates of disease control (stabilization or response) have been higher (40–70%). Unfortunately, responses are not durable (median time to progression: 3–7 months) with a modest survival benefit (median: 6–11 months). The nucleoside analog gemcitabine became the standard of care for advanced pancreatic two decades ago based on marginally improved survival and quality of life compared with another nucleoside analog 5-fluorouracil (5-FU) [7]. In a population with KPS performance status (PS) ≥50 (76% metastatic), the response rate to gemcitabine was 5% with 45% disease stabilization rate and a median survival of 5.7 months. The gemcitabine control arms of several recent clinical trials have consistently reported similar survival benefit even in fitter populations. Gemcitabine is given as a 30 min one day a week infusion for 3 weeks in a 4-week cycle. Compared with many other chemotherapy regimens, it is relatively well tolerated with few common side effects, which tend to be cyclical including nausea, a flu-like feeling, rash, fatigue, and edema due to fluid retention [7]. Anti-emetics and supplementary steroids are routinely given with the regimen to ameliorate some of these, while diuretics as necessary can help with fluid retention. Myelosuppression can be observed, the risk of thrombocytopenia is significant but very rarely results in bleeding. Neutropenia is somewhat less common with low risk of febrile neutropenia. Anemia at times necessitating transfusion or treatment with erythrocyte colony-stimulating factor can be observed. Dose or regimen adjustments as well as periodic breaks of a few weeks can help with significant side effects despite optimal supportive care, particularly on protracted treatment. Pneumonitis is a very rare and idiosyncratic side effect for which high-dose steroid therapy and intensive care support may be necessary [8]. Hemolytic uremic syndrome (HUS) is another rare side effect [9]. It is very rare for HUS to be severe enough to

necessitate measures such as temporary transfusion support and renal replacement therapy. The optimal duration of a course of palliative gemcitabine treatment for advanced pancreatic cancer is not defined. However, treatment was continued as tolerated until progression in clinical trials due to the low response rate and risk of rapid clinical deterioration with progression off treatment. Consequently, many practitioners abide by this strategy in routine practice.

The survival benefit from 5-FU treatment was only marginally inferior to that of gemcitabine [7]. However, gemcitabine is generally preferred due to relatively improved quality of life. This may be due to less mucositis, diarrhea, and palmar-plantar erythrodysesthesia than 5-FU. Furthermore, 5-FU treatment (as currently administered) requires longer chemotherapy ward attendances for a few hours of bolus infusions twice-weekly, venous access lines, and an indwelling infusion pump for 2 days afterwards. Therefore, there are the additional risks of vascular access occlusion, thrombosis, and sepsis with 5-FU regimens. Consequently, despite the more frequent but brief hospital visits for gemcitabine administration, the burden of 5-FU treatment administration is greater overall, which becomes more of an issue for patients benefitting from long-term therapy. Capecitabine has been developed as a conveniently administered oral fluoropyrimidine that is bioequivalent to 5-FU [10]. However, there has not been direct trial comparison of the benefit of gemcitabine or capecitabine treatment for advanced pancreatic cancer.

Among various gemcitabine-containing chemotherapy doublets evaluated in populations of WHO PS1 and 2 with advanced pancreatic cancer, only two were reported to yield a marginal survival increment relative to single-agent gemcitabine treatment. In the Gem-Cap trial (gemcitabine-capecitabine combination) a significantly higher (19% vs. 12%) response rate was observed with the combination. Despite significantly longer time to progression, longer survival (log rank analysis hazard ratio [HR]: 0.86; median: 7.1 vs. 6.2 months) was not statistically significantly higher than for single-agent gemcitabine treatment [11]. However, pooled analysis with two similarly designed trials suggested that the marginal survival benefit was consistent and significant [10]. The main additional side effect on the combination arm was a higher rate of myelosuppression (but not sepsis). Diarrhea, mucositis, and palmar-plantar erythrodysesthesia, which are typically associated with fluoropyrimidines, were not significantly higher in the combination arm. In contrast, in the Gem-Erlotinib trial (gemcitabine-erlotinib combination [erlotinib is an oral epidermal growth factor receptor tyrosine kinase inhibitor]), combination treatment yielded relatively similar response rates to single-agent gemcitabine treatment (8%). However, a less than 2-week increment in median survival to 6.2 months (HR: 0.82) was statistically significant [12]. When the additional side effects of erlotinib therapy in the form of fatigue, diarrhea, rash, and a higher rate of rare pneumonitis are taken into consideration, the clinical significance of this marginal survival benefit is doubtful. Furthermore, the additional cost of erlotinib treatment (at the present time) for this marginal benefit has been prohibitive in most healthcare settings. Nevertheless, of particular interest was the observation that the subset of patients who develop a rash early on erlotinib treatment had longer median survival of 10.5 months, compared with 5.3 months in patients who did not develop a rash [12]. Therefore, some practitioners have adopted the development of a rash within 2 months of treatment with the regimen as a clinical biomarker of potential benefit from erlotinib. It is worth emphasizing that ~30% of patients had locally advanced disease in both the Gem-Cap and Gem-Erlotinib trials. Even though balanced between arms, their inclusion may have inadvertently masked survival differences between treatment arms due to their longer prognosis.

## Recent Advances in Chemotherapy Treatment for Metastatic Pancreatic Carcinoma

The most clinically meaningful survival increment for a gemcitabine-based combination treatment for advanced pancreatic cancer emerged in a trial on a relatively fit (KPS PS ≥ 70) metastatic patient population reported in 2013. Compared with gemcitabine alone, the addition of nab-paclitaxel (a modified taxane) was associated with higher response rates (23% vs. 7%), disease stabilization rate of ~50% with a longer time to progression, and longer survival (HR: 0.72; median: 8.5 vs. 6.7 months) [13]. Significant additional toxicity on this regimen include: fatigue, a higher rate of myelosuppression (including risk of neutropenic sepsis), and reversible peripheral neuropathy. These may necessitate temporary cessation of nab-paclitaxel therapy and dose adjustments. Alopecia, which rarely occurs with gemcitabine alone, is also common with the addition of nab-paclitaxel. Thirty-one percent of patients who received gemcitabine/nab-paclitaxel in this trial received second-line fluoropyrimidine treatment [14].

The role of fluoropyrimidine combinations in improving survival for advanced pancreatic cancer was uncertain until 2011, when FOLFIRINOX the combination of 5-FU with folinic acid (vitamin potentiator), irinotecan (a topoisomerase-1 inhibitor), and oxaliplatin (a platinum derivative) was evaluated in a trial on a fit (WHO PS ≤ 1) metastatic patient population. Compared with gemcitabine, a higher response rate (32% vs. 9%), disease stabilization rate of ~70%, with longer time to

progression and longer survival (HR: 0.57; median: 11.1 vs. 6.8 months) was reported [15]. Consequently, the longest median survival reported for metastatic pancreatic cancer chemotherapy treatment to date has been with the FOLFIRINOX regimen. FOLFIRINOX is administered as an alternate weekly infusional regimen with similar venous access requirements to 5-FU/FA, but with longer bolus infusions. Side effects such as nausea and vomiting are usually more severe than for gemcitabine regimens necessitating more effective antiemetic therapy. The risk of myelosuppression particularly neutropenic sepsis is ~50%, such that prophylactic granulocyte colony-stimulating factors are commonly used with the regimen. Furthermore, oxaliplatin cold-induced neurosenstivity is common, usually during the first few days of the cycle, relieved by avoiding cold stimuli and applying warm dressing if required. Perhaps of more clinical significance is the cumulative oxaliplatin-induced neuropathy, which is less readily reversible than neuropathy observed with nab-paclitaxel. As a result, most patients require dose adjustments or cessation of oxaliplatin after some months on the regimen. Mucositis, palmar-plantar erythrodysesthesia and diarrhea are common as for fluoropyrimidine regimens in general, which are managed symptomatically [15]. Alopecia is also common. While supportive care measures can help reduce the significance of such side effects, most patients require dose adjustment for side effects or significant fatigue on the regimen within the first few cycles. Indeed, many centers start with an attenuated regimen to reduce the risk of intolerable side effects (typically with omission of the 5-FU bolus). Some retrospective studies have suggested preservation of efficacy with attenuated forms of the regimen [16,17]. In the FOLFIRINOX trial, 47% of patients received second-line chemotherapy with gemcitabine after progression. However, outcomes for this subset were not reported. In a study of outcomes for selected patients fit enough to receive gemcitabine/nab-paclitaxel treatment after progression on FOLFIRINOX, median overall survival from starting FOLFIRINOX treatment was 18 months. However, rates of myelosuppression and neurotoxicity were significant [18].

There has not, as yet, been any reported comparison between first-line FOLFIRINOX and gemcitabine/nab-paclitaxel for metastatic pancreatic cancer such that the optimal first-line chemotherapy regimen for the treatment of metastatic pancreatic cancer in fit patients is yet to be fully defined. While nominally, FOLFIRINOX would appear to be superior, cross-trial comparison of survival for studies conducted in different settings is inadequate. Therefore, for fitter patients, the consensus in the medical community appears to be selecting either regimen in consultation with patients on a case by case basis after due consideration of comorbidities, discussion of potential benefit, potential side effects, administration requirements, and patient preference. For frailer patients (PS2 and selected patients of PS1, with particular comorbidities, or who choose to avoid the burden of toxicity associated with combination chemotherapy), gemcitabine remains an appropriate standard of care. However, infusional 5-FU/capecitabine may be substituted as necessary.

In the adjuvant setting, predictive biomarkers are showing promise in stratifying patients for the most appropriate form of chemotherapy. For example, expression of human equilibrative nucleoside transporter-1 (hENT1), which is required for active transport of gemcitabine into cells, detected by immunohistochemistry may predict benefit from adjuvant gemcitabine [19]. However, to date such predictive markers have not been validated for use in the palliative setting. Ongoing clinical trials may elucidate the utility of hENT1 and other biomarkers, in this context.

## First-Line Chemotherapy Treatment for Locally-Advanced Pancreatic Carcinoma and Locoregional Treatment Strategies

While the most efficacious regimens for advanced pancreatic cancer have, at the present time, undergone trial evaluation mainly in the metastatic population, FOLFIRINOX efficacy in particular has been extrapolated to LA disease. Its nominally higher rates of response and disease control have made it the regimen of choice particularly when potential downstaging of disease to resectability is a consideration. Even with FOLFIRINOX, low response rates and the extent of such responses assessed radiologically has made regression from LA disease to freedom from vascular invasion and resectablity possible only in a minority of cases [20]. However, a recent report suggests that residual local vascular invasion after FOLFIRINOX for a median of 6 months reflects a preponderance of stromal disease rather than active malignant tissue. With laparotomy and exploration in the absence of disease progression on FOLFIRINOX treatment, approximately 60% had resectable disease. Median survival (postoperatively) was 16 months (3-year survival of 28%) for patients who had surgical resection compared with 8.5 months in patients who did not undergo surgical resection [21]. Means to clearer identification of cases with resectable disease after chemotherapy are now required. In the meantime, more routine exploration to determine the nature of residual disease after chemotherapy would seem to be warranted.

The role of local ablative therapies to improve resectability and long-term survival with LA disease is

uncertain and remains largely experimental at the present time. What seems to be clear is that the proclivity of pancreatic cancer to early occurrence of micrometastatic disease even at the earliest stage precludes attempts at upfront locoregional treatment to the exclusion of chemotherapy for the control of systemic disease [22]. However, the role of interruption of chemotherapy for local ablative therapies in patients with responding or stable disease as well as those with mild local progression alone is unclear. Chemoradiation (CRT) has been the most widely investigated form of treatment in this setting with improved tolerability of capecitabine-based CRT compared with gemcitabine-based CRT regimens [23]. Nevertheless, in a study of an initial 4 months of gemcitabine ± erlotinib therapy followed by randomization to either continuation of chemotherapy or switching to high-dose capecitabine CRT, there was no survival benefit from CRT [24]. CRT is associated with gastrointestinal side effects and fatigue, which are worse than on chemotherapy and could lead to deterioration in quality of life for at least a 6-week period around such treatment [25]. Conversely, the short-term nature of CRT is such that a break from treatment with observation for a successful local ablative effect can be instigated whereas the continuous nature of chemotherapy may present a more long-term toxicity burden. A recent meta-analysis suggested that first-line FOLFIRINOX treatment for LA disease with subsequent local ablative treatment and/or surgery as appropriate, yielded median duration of disease control and overall survival of 15 and 24 months, respectively, which are nominally higher than for metastatic disease [26].

At the present time, further chemoradiotherapy trials utilizing the more recently validated chemotherapy regimens for better overall disease control, with optimization of radiotherapy doses and method of delivery are in progress. Furthermore, the role of alternative local ablative therapies such as stereotactic radiotherapy (SABR) and irreversible electroporation (IRE) are areas of clinical investigation beyond the scope of this chapter. Molecular predictors of propensity to localized rather than metastatic disease are also of interest to possibly help select between chemotherapy and local ablative treatment for LA disease. Loss of *SMAD4* has been proposed as one such predictor of metastases [27]. However, clinical data are conflicting and studies in genetically engineered mice suggest a complex role for *SMAD4* mutation in contributing to metastasis and rate of tumor proliferation. Heterozygous mutations attenuated metastatic potential whilst loss of heterozygosity promoted metastasis, such that its use in clinical practice at the present time cannot be recommended [22]. Other mouse models have suggested that Aldh1a3 expression may identify an aggressive subtype with a higher rate of distant metastases [28]. A subset of metastatic pancreatic ductal adenocarcinomas depends quantitatively on oncogenic Kras/Mek/Erk-induced hyperactive mTOR signaling [28]. This now warrants investigation in human resected cohorts as a potential predictor of early recurrence.

## Second-Line Palliative Chemotherapy for Advanced Pancreatic Carcinoma

With median time to progression on treatment of few to many months, patients with advanced pancreatic cancer require close monitoring to identify symptoms of progression with prompt radiologic assessment as necessary prior to clinical deterioration precluding further treatment. Furthermore, re-evaluation of supportive care needs will be crucial prior to initiation of further cancer-directed therapy. For patients who took a break after initially achieving disease control on first-line chemotherapy or completed CRT, retreatment with the first-line regimen for its proven benefit would be advisable, particularly with good tolerance. For patients with disease resistant to initial regimens, second-line chemotherapy treatment may be considered.

The best clinical trial evidence for second-line chemotherapy in advanced pancreatic cancer is in patients progressing on first-line gemcitabine treatment. A combination of 5-FU/FA and oxaliplatin increased the median survival after progression on first-line chemotherapy to 4.8 months from 2.3 months with best supportive care alone [28]. The adverse effect profile of the combination is as discussed for fluoropyrimidines in first-line treatment with additional fatigue, nausea/vomiting, and neuropathy from oxaliplatin treatment. Justification of the additional toxicity of oxaliplatin is debatable in this setting as its additional survival benefit is contentious [29]. Whether capecitabine can be substituted for 5-FU/FA for the convenience of oral administration with no detriment to survival is unknown. The most recent advancement in second-line therapy was from a trial suggesting that the addition of liposomal irinotecan to 5-FU/FA led to increment in median survival to 6.1 months compared with 4.2 months on 5-FU/FA alone with a slightly increased risk of diarrhea, fatigue, and neutropenia with the combination [30]. Therefore, fluoropyrimidine-containing regimens are potentially beneficial following progression on gemcitabine. However, clinical decisions on the exact regimen for individual patients are made taking into consideration their fitness levels to cope with combination treatment and (current) funding constraints for expensive novel treatment such as liposomal irinotecan for its marginal benefit.

There are to date no reported clinical trials to guide optimal second-line chemotherapy after progression on

FOLFIRINOX or gemcitabine/nab-paclitaxel treatment. However, the limited evidence to guide second-line treatment (gemcitabine-based regimens for FOLFIRINOX and fluoropyrimidine-based regimens for gemcitabine/nab-paclitaxel) have been discussed earlier.

### Strategies to Improve Survival Outcomes with Chemotherapy for Advanced Pancreatic Carcinoma

With median survival still under a year even for the fittest patients receiving the most efficacious chemotherapy regimens for metastatic pancreatic carcinoma, it is quite clear that the benefit from chemotherapy remains suboptimal. It is difficult to conceive further improving survival by adding extra chemotherapy agents to the established components of the FOLFIRINOX or gemcitabine/nab-paclitaxel regimens because of the potential additional toxicity from such. However, trials of modified nucleoside analogs to override cancer resistance mechanisms without increasing toxicity are an area of interest. Furthermore, the addition of appropriate cancer microenvironmental modulators to currently effective chemotherapy regimens is emerging as an attractive alternative strategy to improve on outcomes without adding significant toxicity. With improved understanding of the molecular and genetic basis of pancreatic cancer, treatment targeted at specific molecular alterations driving cancer progression and treatment guided by predictors of response to currently proven agents is also of immense interest [31–33]. However, the diverse nature of such abnormalities of variable functional significance has generated a significant hurdle which translational oncologists are working on surmounting.

In conclusion, despite its notoriously poor prognosis, advanced pancreatic carcinoma is in an era of expanding treatment options that have modestly improved survival outcome with tolerable adverse effects. Optimal utilization of currently proven chemotherapy agents discussed here will be crucial, while research effort may further enhance management of the increased burden of the disease anticipated over the coming decades.

## Anatomy and Physiology of Pancreas Cancer Pain

The pancreas, an organ that is uniquely both endocrine and exocrine in function, can be visualized as being divided into four main segments because it extends from the midline laterally: the head (including the uncinate process), neck, body, and tail. While pancreatic cancer pain varies by tumor location [1,2], extension [3], and stage [4], it is typically abdominal and can be referred to the epigastric region, upper abdominal quadrants, less frequently to the lower abdominal quadrants, or it can be diffuse in nature [5]. Back pain in the T10-12 region, often misattributed due to its prevalence in the age group most affected by pancreatic cancer [6], is not only very common but is also the presenting symptom in many cases [7].

Visceral nociceptive signals generated by tissue damage, inflammation, ductal obstruction, and glandular infiltration associated with pancreatic cancer are transmitted along afferent sympathetic fibers to the celiac plexus (T12-L2) where they synapse with the splanchnic nerves on their way to the T5-T12 dorsal root ganglia [8]. Metastatic disease reaching other upper abdominal solid organs shares these pathways. Tumor extension into non-organ surrounding tissues such as the peritoneum, retroperitoneum, and bones results in localized somatic pain [9]. Neuropathic pain may also be present as the result of perineural invasion (PNI) of cancer cells into the lumbosacral nerve plexuses, intrapancreatic nerve fiber destruction, and epidural spinal cord compression [10,11].

A variety of physiologic factors contribute to the generation and continuation of pancreas cancer pain. Histologically, cancer of the pancreas is characterized by extensive infiltration of inflammatory cells [12,13]. This inflammatory state, particularly the increased presence of macrophages, is associated with upregulation of nerve growth factor (NGF), the overexpression of which is correlated with both the extent of PNI and pain intensity [14,15].

Additionally, in the early stages of pancreatic cancer, NGF induces sprouting of calcitonin gene-related peptide (CGRP) expressing sensory fibers, which increase in density with disease progression [16]. In later stages of disease, the central pancreas, now densely innervated with new sensory fibers, gradually becomes necrotic [17]. This results in the destruction of the distal ends of the sensory and sympathetic nerve fibers that had innervated the now necrotic tissue, resulting in a significant neuropathic pain state [2].

## Pharmacologic Pain Management

The principal philosophy behind chronic cancer pain management focuses on maximizing analgesia while minimizing unnecessary risk and patient side effects. In order to achieve this balance, a gradual, stepwise approach is recommended, beginning with escalating pharmacotherapeutic treatments before progressing to more invasive interventions. The succession is paused for as long as satisfactory pain control is achieved. As 70–80% of cancer patients can be successfully managed with pharmacotherapy alone: analgesic medications, predominantly nonsteroidal anti-inflammatory drugs (NSAID) and opioids, are considered to be the first line of chronic cancer pain management [18–20].

In 1987, the World Health Organization (WHO) published guidelines for the pharmacologic treatment of cancer pain [21]. These guidelines, updated in 1997 [22] and validated by multiple prospective studies [23–26]

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

have served as the foundation upon which cancer pain pharmacotherapy has been based for nearly four decades. The guidelines outline a treatment strategy that is based upon five principles:

1) "By mouth": oral (least invasive) administration of analgesic medications should be chosen whenever possible.
2) "By the clock": analgesics should be given at regular intervals, titrated against the patient's pain such that pain is relieved by a given dose and does not return before the next dose is due. Additional rescue dosing may be given for incident and breakthrough pain.
3) "By the ladder": analgesics should be prescribed according to pain intensity as evaluated by a standardized scale.
4) "For the individual": while there are toxicity-limited doses for some medications, there are no standard doses for opioid class medications, and doses should be tailored to the individual needs of each patient.
5) "Attention to detail": each patient's medication regimen should be meticulously planned out over a 24-hour period and written out in full for the patient/family.

Principle three, "by the ladder," proposes that the first medication used in the treatment of cancer pain be a non-opioid (see Fig. 117.1) [22]. Though not specified, "non-opioid" has been interpreted to mean acetaminophen, acetylsalicylic acid (ASA), or an NSAID. These medications have the advantage of being widely available, familiar to patients, efficacious for a wide variety of etiologies, and easy to administer. Disadvantages of these medications include adverse side effects such as hepatotoxicity with acetaminophen and gastrointestinal bleeding and renal toxicity with NSAID. The latter two can largely be avoided with the use of selective cyclooxygenase (COX)-2 inhibitors.

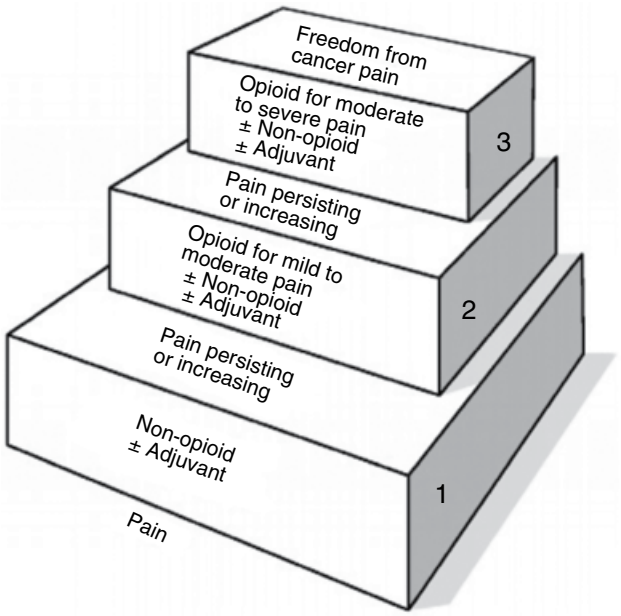

**Figure 117.1** The WHO three-step analgesic ladder. *Source:* World Health Organization 1997 [22].

If pain is not adequately controlled with one of these medications, an opioid for mild to moderate pain should be added. This step has been controversial insomuch as disagreement exists as to whether the addition of a "weak" opioid (with "ceiling" effects) to an NSAID decreases the necessary dose of either medication. The utility of this step seems to exist when either the ceiling effect or maximum safe dose of the nonopioid medication has been reached.

If satisfactory pain control has not been achieved with the addition of a weak opioid, step three recommends the addition of a strong opioid (morphine, hydromorphone, oxycodone). The WHO guidelines state that only one drug from each group should be used at the same time.

Despite or perhaps as a result of its widespread use, the WHO analgesic ladder has been the source of much debate [27]. Multiple adaptations have been proposed to include the elimination of the second level [28,29], adaptations of the analgesic scale to account for acute and chronic non-cancer pain [30,31], and the inclusion of a fourth step representing interventional treatments [32] (see Fig. 117.2) [33]. Though imperfect, when combined with sound clinical judgment, such a guideline for the pharmacologic treatment of cancer pain can serve as a foundation for the initial management of pancreatic cancer pain.

## Chemical Ablation of the Splanchnic Nerves or Celiac Plexus

Systemic analgesic therapy, per the WHO guidelines, is widely regarded as the standard of care for treating cancer pain. Unfortunately, not all cancer pain patients will achieve a satisfactory outcome by adhering to this algorithm, which has prompted some to challenge the clinical framework of the WHO guidelines for cancer pain [34]. A subset of patients with unresectable pancreatic cancer will suffer from medically refractory pain or develop intolerable side effects from opioids, which preclude their usage [22]. For these patients, a variety of minimally invasive techniques have been developed since the early twentieth century, the majority of which involve ablation of either the splanchnic nerves or celiac plexus, as these structures play a key role in the transmission of visceral pain from the pancreas.

A discussion of various technical approaches to either the splanchnic nerves or celiac plexus is beyond the

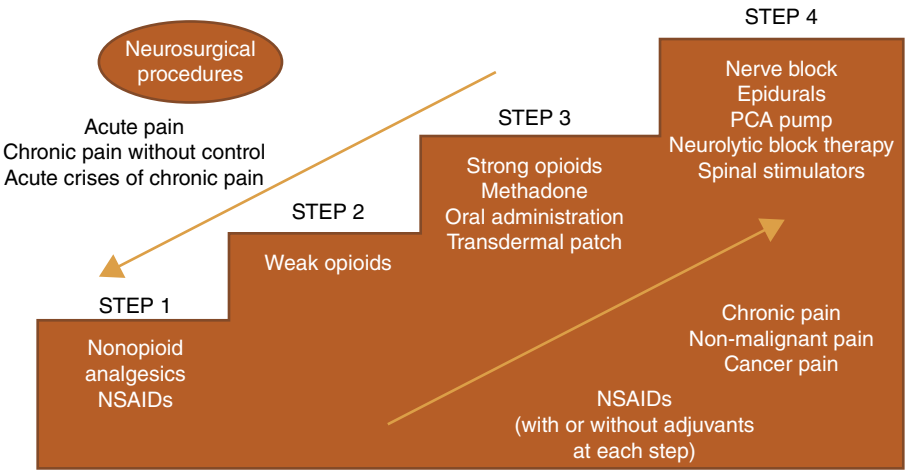

**Figure 117.2** New adaptation of the analgesic ladder. *Source:* Vargas-Schaffer 2010 [33], Fig. 2. Copyright © the College of Family Physicians of Canada.

scope of this chapter. These procedures can be subdivided into endoscopic and percutaneous techniques, with the latter consisting of anterior and posterior approaches. A common theme in all of these approaches is image-guided placement of one or more needles in close proximity to the targeted nerves and the use of a neurolytic solution, either phenol or concentrated alcohol. The former destroys nerves via protein denaturation, whereas the latter induces Wallerian degeneration; in either case, the nerves will ultimately regenerate but this process takes several months [35]. In the interim, patients can experience profound pain relief and markedly reduced side effects from systemic opioids.

Regardless of the technical approach, chemical ablation of these nerves tends to be quite effective in the setting of pancreatic malignancy. In the most recent systematic analysis of the literature by the Cochrane Group, the pooled experimental data on celiac plexus neurolysis reveals statistically significant reductions in reported pain scores, a difference that persists for at least 8 weeks postprocedure, and markedly reduced overall opioid consumption, which persists until the day before death. As a corollary to the observed reduction in systemic opioid usage, patients randomized to celiac plexus neurolysis tended to experience far fewer opioid-induced side effects such as constipation. Of note, the overall likelihood of a successful neurolysis is variable, but the published success rates generally range from 70% to 90% [36,37].

Although on meta-analysis, ablation of the celiac plexus is clearly effective regardless of the technical approach, the approach with the highest efficacy and lowest risk of patient harm remains quite controversial, especially with the advent of newer, endoscopic approaches to the celiac plexus (EUS-CPN) [34,38–41]. Endoscopic ultrasound celiac plexus neurolysis (EUS-CPN) is theoretically safer than posterior percutaneous approaches, as it allows more targeted deposition of the neurolytic agent in the vicinity of the celiac ganglia, real-time visualization of arterial vasculature in the targeted areas via Doppler, and potentially a reduced risk of anterior spinal artery syndrome. However, these theoretical advantages have not been definitely established in the medical literature as there are very limited data comparing endoscopic to percutaneous approaches for benign abdominal pain, and no experimental data thus far comparing the two approaches for treatment of pancreatic cancer pain. Randomized controlled trials are needed to determine the relative efficacy and safety of endoscopic versus percutaneous approaches in the treatment of severe pain due to pancreatic cancer [40,42].

The indications for chemical ablation of the celiac plexus (or splanchnic nerves) for pancreatic cancer pain are relatively straightforward. Given the palliative efficacy of surgical resection and the risks associated with chemical ablation of the splanchnic nerves or celiac plexus, traditionally these procedures have been reserved for a subset of pancreatic cancer patients with unresectable disease: more specifically, patients with neoplasm-related pain that is either (a) unresponsive to systemic analgesic medications or (b) associated with intolerable opioid-induced side effects [43–45].

Uncorrectable coagulopathy, lack of adequate resources for patient resuscitation, localized infection in

the anticipated trajectory of the needle(s), and sepsis are absolute contraindications. Markedly impaired cardiac reserve or inability to lie in the prone position are relative contraindications, as these conditions could increase the risk of ischemic or direct chemical injury to the spinal cord, respectively. Another key consideration is anatomic distortion from the pancreatic malignancy. In some cases, the distortion is so pronounced that certain approaches are not feasible. In other cases, severe tumoral invasion or displacement of the celiac plexus may increase the risk of a technical failure [46,47]. For this reason, a cross-sectional imaging study is recommended prior to the procedure itself.

There are a variety of complications associated with neurolysis of the splanchnic nerves or celiac plexus, but major complications from these procedures are rare. Temporary back pain, abdominal pain, hypotension, and diarrhea are fairly common occurrences, but are generally self-limited and respond quite well to supportive measures. Injury to the kidneys or ureters may occur, which can result in hematuria. Given the close proximity of various approaches to the diaphragmatic crura, pneumothorax is a described complication. There are some case reports in the medical literature of rare complications from celiac plexus neurolysis, including hemorrhagic gastritis/duodenitis, gastroparesis, and aortic dissection. These reported complications are so rare that the actual incidence of them remains unknown [48–50]. The most feared complication from celiac plexus neurolysis is permanent neurologic injury. The incidence of permanent paraplegia with posterior approaches is 0.15%. Bowel and bladder incontinence can also occur. Although one would expect inadvertent posterior migration of the alcohol into the spinal canal to result in permanent neurologic injury, with the advent of image guidance these mechanisms of neurologic injury can be avoided. Some have posited that the neurologic injury stems from alcohol-induced vasospasm of arteries feeding the spinal cord, resulting in an infarction of the spinal cord, a theory supported in part by basic science research involving the direct effects of alcohol and local anesthetics on vasomotor tone. If, in fact, neurologic injury from celiac plexus neurolysis stems from a vasospasm phenomenon, this risk would be nearly impossible to prevent [50–55].

## Surgical Options for Treatment of Pancreatic Cancer

Options for surgical treatment of refractory pancreatic cancer pain include thoracoscopic splanchnicectomy as well as intrathecal drug delivery.

### Thoracoscopic Splanchnicectomy

This procedure consists of the surgical interruption of the sympathetic chain via a thoracoscopic approach. Kang described 21 patients with unresectable upper abdominal malignancy and pain refractory to opioid analgesics who underwent bilateral thoracoscopic splanchnicectomy [56]. Baseline Karnofsky Performance Scale was greater than 60, and 71% of patients suffered from pancreatic cancer. NRS pain scores decreased from an average of 8.5 preoperatively to 1.7, while patients required bilateral chest tubes for an average of 3 days postprocedure.

Johnson reported 65 patients with unresectable upper abdominal malignancy who required opioid analgesia (58 with pancreas cancer) and were randomized to medical management, celiac plexus block, or thoracoscopic splanchnicectomy [57]. No significant differences were appreciated between the groups in pain scores or opioid consumption at 2 months. Limitations of the study include a failure to identify the presence of carcinomatosis in patients, use only of a fall in systemic blood pressure to identify a successful celiac plexus block, and a change in sample size from a calculated 324 necessary for analysis to only 65 due to slow recruitment.

### Intrathecal Drug Delivery Systems

IDDS (intrathecal drug delivery systems, i.e., intrathecal pumps) are an option for the treatment of patients with moderate to severe chronic refractory pain, and their use has led to improved quality of life, reduced pain, and increased satisfaction in those who have failed with other therapeutic options. IDDS have been shown to provide significant pain relief and statistically significant control of analgesic toxicity in cancer patients in a randomized study when compared with standard analgesic therapy, as well as a trend toward increased survival at 6 months [58].

The Polyanalgesic Consensus Conference (PACC) last issued guidelines on intrathecal (IT) analgesia use in 2012 [59]. Algorithms for nociceptive as well as for neuropathic pain (cancer pain may involve both) were issued, as well as recommended starting dose ranges, bolus trial ranges, and maximum daily dose and concentration ranges. Available IT analgesic medications for infusion include opioids, local anesthetics, clonidine, and ziconotide. IT therapy at the end of life is best weighed against surgical and infectious risk, as well as compared with home or institutional nursing care of externalized systems for those with a very limited life expectancy. Concentration and daily dose limitation is important to help prevent the development of an intrathecal granuloma at the catheter tip. Additional potential complications of IT therapy include respiratory depression and peripheral edema.

Trialing of IT analgesic medication has been described by both bolus dosing and continuous infusion [60], although some have argued a bolus trial is less representative of the long-term effects of IT therapy. Decrease in pain score by greater than or equal to 50% is a commonly used criterion for success of the trial. There exists debate regarding whether to continue, decrease, or eliminate existing systemic opioids in advance of IT trial. Typically, trials last between 3 and 7 days, with catheters placed at a spinal level corresponding with the vicinity of the patient's pain. Trials may consist solely of an opioid, but there is also the practice of adding an adjuvant agent such as bupivacaine and/or clonidine to the trial. Some have advocated the possibility of forgoing a trial in cancer patients due to the reported high success rates of cancer patients with IT therapy.

Complications may occur with implantation or pump management, drug reactions or side effects, device malfunction, and human error in programming or refilling the pump [61]. Use of IDDS is based on analysis of safety, efficacy, a goal of economic neutrality, and appropriateness for the patient. High concentrations of opioid or high daily dose predisposes to the risk of intrathecal granuloma, while the addition of adjuvant agents may lessen the risk by an opioid-sparing effect. Additional risks include infection, respiratory depression, peripheral edema, pump failure, and catheter obstruction or migration.

## Introduction

Amidst recent technological advances in radiation oncology, the role and optimal application of radiation therapy (RT) for pancreatic cancer (PCA) remains highly controversial. The origins of this controversy arise from key landmark trials with conflicting results regarding the relative merits of radiation. However, the manner in which these data should be applied to RT as delivered in the modern day using contemporary techniques is unclear. Nevertheless, fluency in the clinical literature exploring the role of RT for PCA across the disease's stages is critical. Equally important is an understanding of the way in which conformal radiation techniques and charged particle therapy can be used to improve the therapeutic window. Knowledge of these topics will yield both an appreciation of the value of modern RT for patients with PCA and an ability to better customize treatment regimens to individual patients. Herein, we review the role of RT in the adjuvant and neoadjuvant settings and discuss advanced modalities including proton beam therapy (PBT) and stereotactic body radiation therapy (SBRT).

## Radiation in the Adjuvant Setting

The optimal adjuvant management strategy for patients with resected PCA continues to generate considerable debate. Appreciation of the potential that modern RT may have for resected PCA requires a historical understanding of clinical trials that have explored the value of adjuvant chemoradiation (CRT). Early institutional reports demonstrated high rates of local failure (>50%) after surgical resection of PCA [1]. Predicated on these findings, the Gastrointestinal Tumor Study Group (GITSG) designed a randomized trial comparing adjuvant 5-fluorouracil (5-FU)-based chemoradiation with observation following Whipple resection. Patients in the CRT arm experienced improved 2-year OS (42% vs. 15%, $P = 0.03$), sparking adoption of adjuvant CRT in the United States [2]. However, this survival benefit could not be replicated in subsequent trials by the European Organisation for Research and Treatment of Cancer (EORTC) and the European Study Group for Pancreatic Cancer (ESPAC), with the latter trial suggesting improved survival with chemotherapy alone and inferior survival with CRT [3,4]. Importantly, key pitfalls of all of these trials must be acknowledged, including slow accrual and poor trial adherence. Perhaps most importantly, the radiation techniques employed in all three of these trials were antiquated by modern standards, including suboptimal doses, nonconformal techniques, and split-course schedules. As a result, the latter two trials failed to demonstrate decreased rates of local control in the CRT arms [3,4]. Nevertheless, European trials for patients with resected PCA have since focused on defining the optimal adjuvant chemotherapy-alone regimen. Indeed the Charité Onkologie (CONKO)-001 trial and subsequently the ESPAC-3 trial have established gemcitabine as the preferred adjuvant chemotherapeutic agent over bolus 5-FU, and the ESPAC-4 trial (ISRCTN96397434) is currently exploring adjuvant gemcitabine versus adjuvant capecitabine [5,6].

In the United States, outcomes with more conformal radiation techniques using higher doses without split-course schedules have been explored in both the nonrandomized and randomized settings. A pooled matched-paired analysis from the Mayo Clinic and Johns Hopkins demonstrated a survival benefit of adjuvant

CRT when delivered to a median dose of 50.4 Gy compared to observation [7]. Moreover, Radiation Therapy Oncology Group (RTOG) 9704, which randomized patients to initial chemotherapy with either 5-FU or gemcitabine, followed by 5-FU-based chemoradiation to 50.4 Gy, followed by additional chemotherapy with 5-FU or gemcitabine, resulted in fewer local recurrences in both arms (25–30%) [8]. This local failure rate compared favorably with historical controls despite a predominance of patients with risk factors for local recurrence, including 35% with positive margins, 66% with positive lymph nodes, and 75% with advanced T-stage. Importantly, RTOG 9704 was the first trial to evaluate whether radiation field design influenced outcomes [9]. Failure to adhere to specified RT guidelines was associated with reduced survival and, for patients receiving gemcitabine, a trend toward increased nonhematologic toxicity. In fact, nearly 50% of the RT plans deviated from protocol guidelines. Consensus panel guidelines are now available for clinical target volume design, but the subset analysis of RTOG 9704 underscores the importance of appreciating the quality of radiation delivered when interpreting results from clinical trials [10].

Despite improved results seen in RTOG 9704, reported acute toxicity was still substantial, with 70.5% patients experiencing any grade ≥3 toxicity and 59% experiencing grade ≥3 nonhematologic toxicity [8]. To this end, a more focused form of RT termed "intensity modulated RT" (IMRT) may be helpful in sparing organs at risk (OAR) and minimizing toxicity. Yovino et al. compared toxicity between a cohort of 46 patients treated with adjuvant capecitabine-based CRT to a dose of 50.4 Gy using IMRT and a cohort of patients treated per RTOG 9704 with conventional CRT; grade ≥3 acute nonhematologic was significantly lower in the cohort of patients treated with IMRT [11]. With reduced toxicity, IMRT may allow for dose escalation and improved local control. In fact, low rates of acute nonhematologic toxicity have been reported in patients treated with IMRT to doses ≥55 Gy. As an example, Abelson et al. reported an 8% rate of acute nonhematologic grade ≥3 toxicity in 47 patients treated with up to 56 Gy with IMRT. In another study, Ben-Josef et al. reported a 7% rate of acute nonhematologic grade ≥3 toxicity in 15 patients treated with IMRT up to 55 Gy [12,13]. Beyond allowing for dose escalation, less toxicity associated with IMRT allows for incorporation of more aggressive concurrent chemotherapy or targeted therapies. As an example, an early phase trial exploring the combination of adjuvant RT with the EGFR inhibitor gefitinib caused dose-limiting diarrhea, but the combination of capecitabine-based IMRT with erlotinib was subsequently proven to be tolerable for most patients [14,15]. Given the potential merits of IMRT, it was incorporated into the RTOG 0848 trial, which is currently examining whether gemcitabine plus erlotinib produces superior survival results when compared to gemcitabine alone and whether radiation to 50.4 Gy with 5-FU improves outcomes beyond gemcitabine chemotherapy alone. IMRT with volumetric arc therapy allows for more rapid treatment of therapy and further sparing of adjacent normal tissues including bowel, stomach, and kidneys. Whether these advances translate into clinically meaningfully outcomes for patients requires further study [16].

SBRT is another technique being evaluated in the adjuvant setting. In a pilot study, 19 patients were treated with adjuvant SBRT, a pancreatic vaccine (GVAX), and FOLFIRINOX [17]. While preliminary, the study suggests that SBRT can be safely utilized in the adjuvant setting with minimal acute or chronic side effects. The combination of these therapies also resulted in a favorable progression-free survival (19 months) and OS (median not met) despite a high proportion of patients having margin- and node-positive resections. Multicenter studies are needed to determine whether SBRT should be more widely used in this setting.

## Radiation in Borderline Resectable and Locally Advanced Disease

While standard fractionation CRT appears to be a promising method to safely achieve local control and achieve margin-negative resections [18], hypofractionated regimens have increasingly gained traction in the field of radiation oncology. In a malignancy as aggressive as pancreatic adenocarcinoma, timing is critical; therefore, pancreas stereotactic body RT (SBRT) is particularly attractive due to the short treatment course (3–5 days in comparison with 25–28 days in standard fractionation regimens), which limits the delay of full-dose chemotherapy and subsequent surgery.

In patients with borderline resectable (BRPC) and locally advanced PCA (LAPC) specifically, pancreas SBRT has evolved to become standard of care option per the newly developed National Comprehensive Cancer Network (NCCN) Clinical Practice Guidelines v.1.2016 and American Society of Clinical Oncology (ASCO) LAPC Clinical Practice Guideline [19]. Seminal studies of pancreas SBRT involved 1- and 3-fraction regimens in LAPC [20–30]. Early Phase I/II studies using single-fraction SBRT (25 Gy in 1 fraction) demonstrated excellent freedom from local progression (FFLP) at 1 year (>90%) and minimal acute toxicity, but high rates of late grade 2–4 gastrointestinal toxicity were reported. A single-arm Phase II multi-institutional study evaluated whether gemcitabine with fractionated SBRT (in 5 fractions of 6.6 Gy, total 33.0 Gy) could achieve reduced late grade

2–4 gastrointestinal toxicity compared with a historical cohort of patients treated with gemcitabine and a single 25 Gy-fraction of SBRT [26]. Forty-nine LAPC patients received up to three doses of gemcitabine (1,000 mg/m$^2$) followed by a 1-week break and SBRT (33.0 Gy in 5 fractions). Following SBRT, patients continued gemcitabine until progression or toxicity. Rates of acute and late (primary endpoint) grade ≥2 gastritis, fistula, enteritis, or ulcer toxicities were 2% and 11%, respectively. QLQ-C30 global quality of life scores remained stable from baseline to after SBRT (67 at baseline, median change of 0 at both follow-ups; $P$ 0.05 for both). Patients reported a significant improvement in pancreatic pain ($P < 0.001$) 4 weeks after SBRT on the QLQ-PAN26 questionnaire. Median serum CA 19-9 was reduced following SBRT (median time post-SBRT 4.2 weeks, 220 vs. 62 U/mL, $P < 0.001$). Median OS was 13.9 months (95% CI: 10.2–16.7). FFLP at 1 year was 78%. Four patients (8%) with LAPC at diagnosis were taken to surgery and underwent margin- and node-negative resections; a fifth patient was deemed resectable after multidisciplinary review but denied surgery.

Neoadjuvant SBRT has recently been studied in patients with BRPC in order to increase the likelihood of a margin-negative resection. A retrospective study included 73 patients with localized PCA (57 BRPC, 16 LAPC) who received induction chemotherapy followed by 5-fraction SBRT (25–30 Gy) at Moffitt Cancer Center was published in 2013 [31]. Most patients received induction GTX (66%) or gemcitabine alone (25%) whereas only 5% received induction FOLFIRINOX. Among the patients with BRPC, 56% underwent surgery with 97% achieving a margin-negative (R0) resection and 9% a pathologic complete response. Median OS in the patients who underwent a R0 resection was significantly higher than in unresected patients (19.3 vs. 12.3 months; $P = 0.03$). Furthermore, this approach was well tolerated with no acute grade ≥3 toxicity reported and only 5.3% late grade ≥3 toxicity. More recently, this single-institution series was updated to include a total of 159 patients (110 BRPC, 49 LAPC) [27]. Among the BRPC patients, 51% underwent surgery with 97% achieving a R0 resection and 7% a pathologic complete response. Median OS in the resected BRPC patients was 34 months. Acute grade ≥3 toxicity was 2% and late grade ≥3 toxicity was 5%.

Johns Hopkins reported on 88 patients (14 BRPC, 74 LAPC) who received induction chemotherapy followed by 25–33 Gy SBRT [28]. The majority (76%) of patients received gemcitabine-based chemotherapy as opposed to 5-FU (specifically, FOLFIRINOX)-based chemotherapy. Of the 19 patients (22%) who underwent surgery following SBRT, 84% had a R0 resection and 16% of patients had a pathologic complete response. Median OS of resected patients was 20.2 months versus 12.3 months in unresected patients ($P = 0.07$). Of note, 89% of resected patients had LAPC.

With the consideration that patients originally deemed unresectable may be taken to the operating room, a shift towards neoadjuvant therapy in LAPC has recently emerged. Of the 49 LAPC patients who were treated with induction chemotherapy and SBRT at Moffitt, 5 (10%) were resected with a 100% R0 resection rate. LAPC patients survived a median of 13.2 months [27]. Johns Hopkins reported 15 of 74 (20%) LAPC patients who went to surgery, with an 80% R0 resection rate and 13% pathologic complete response rate. Median OS in LAPC patients was favorable at 18.4 months [28].

## Proton Beam Therapy

The pancreas is adjacent to several radiosensitive organs including the duodenum, stomach, and small bowel. While IMRT can minimize the high doses received by these organs and therefore decrease the likelihood of adverse effects compared to 3D-CRT, pancreatic RT remains compromised by the proximity of these normal tissues [11,32,33]. Therefore, some have looked to proton beam therapy (PBT) as a means to improve the therapeutic ratio for PCA patients with encouraging early results.

Protons have an inherent advantage over photons in that they deliver the vast majority of their dose at a specified depth beyond which there is no dose to normal tissues. Because proton beams have no exit dose, as few as two beams are needed to create highly conformal dose distributions (Fig. 118.1). Therefore, PBT can significantly minimize or even completely eliminate radiation dose from large volumes of normal tissue.

Dosimetric studies have illustrated that PBT for PCA can significantly reduce dose to normal tissues compared to photon therapy, importantly without sacrificing target volume coverage. Nichols et al. compared IMRT and passive scattering PBT prescribed to 50.4 Gy for 8 patients with resected pancreatic head tumors [34]. PBT plans had significantly lower doses to adjacent structures such as the right kidney V18 Gy (27.3 vs. 50.5%; $P = 0.0156$), small bowel V20 Gy (15.4 vs. 47%; $P = 0.0156$), and stomach V20 Gy (2.3 vs. 20%; $P = 0.0313$). Ding et al. evaluated 3D-CRT, IMRT, passive scattering PBT, and a more conformal proton delivery technique called modulated scanning for 11 resected PCA patients [35]. Similar to the study by Nichols and colleagues, PBT (specifically the modulated scanning plans) had the lowest right kidney V18 Gy, stomach V20 Gy, and small bowel V15 Gy. A more recent comparison of 3D-CRT, IMRT, and passive scattering protons in resected patients from Loma Linda also had

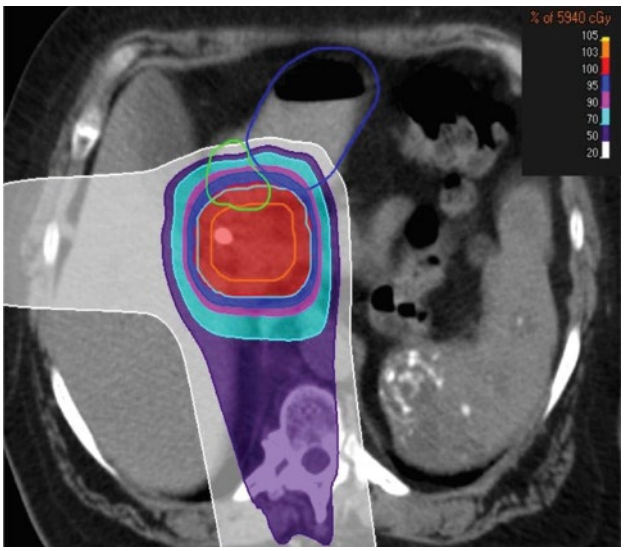

**Figure 118.1** PBT treatment plan illustrating the delivery of a highly conformal dose (to 59.4 Gy) to the tumor while minimizing dose to surrounding normal tissue.

similar results [36]. Proton plans delivered lower mean kidney dose, lower mean liver dose, lower maximum spinal cord dose, and lower small bowel dose (V15 Gy, V50 Gy). These findings are likely to be clinically relevant, especially with respect to reducing the volume of small bowel that receives lower doses. The small bowel is a major dose-limiting structure for pancreatic RT. In fact, a dose–volume relationship between small bowel dose and gastrointestinal toxicity has been described; it has been suggested that limiting the volume of small bowel that receives at least 15 Gy should be a priority [37,38]. The kidneys, liver, and stomach are also negatively affected by lower doses and thus the ability to spare these organs using PBT would likely add to the clinical significance of the dosimetric data presented earlier.

In addition to reducing toxicity, PBT may offer a means to safely escalate tumor dose for patients with LAPC and BRPC. Although higher tumor doses have been associated with improved treatment outcomes, the prescription dose for unresectable patients is limited to 50–54 Gy so that small bowel and stomach constraints can be achieved [39,40]. Hsiung-Stripp et al. compared passive scattering proton and 3D-CRT plans for patients with LAPC using 45 Gy for gross disease plus elective nodes followed by a 14.4 Gy boost to gross disease only for a total of 59.4 Gy [41]. Proton plans delivered lower dose to the spinal cord ($P = 0.003$), left kidney ($P = 0.025$), right kidney ($P = 0.059$), and liver ($P = 0.061$); small bowel was not evaluated. Bouchard et al. compared 3D-CRT, IMRT, and passive scattering PBT using a prescription dose of 72 Gy in 36 fractions and concluded that PBT could be beneficial, especially when treating tumors with anteriorly located small bowel [42]. Furthermore, PBT plans resulted in lower stomach V15 Gy (5 vs. 48%; $P < 0.0001$) and small bowel V15 Gy (9 vs. 61%; $P < 0.0001$). A group from the University of Pennsylvania recently published a comparison of IMRT, passive scatter PBT, and pencil beam scanning (PBS) PBT for 13 LAPC patients who were prescribed 55 Gy in 25 fractions [43]. Because PBS is the most conformal proton technique, it is not surprising that PBS resulted in less dose to some critical structures and was isoeffective with respect to others when compared to passive scattering; the clinical significance of this remains to be seen.

While the published clinical experiences using PBT for PCA are limited, the outcomes from these studies are encouraging (Table 118.1). Investigators from Massachusetts General Hospital (MGH) published outcomes of a Phase I trial that evaluated neoadjuvant hypofractionated PBT with concurrent capecitabine for resectable PC [44]. A total dose of 25 Gy delivered in 5 consecutive fractions was well tolerated; no dose-limiting toxicities occurred. There were no unexpected postoperative complications. In a similar trial, MGH compared neoadjuvant protons and photons with 5 Gy × 5 given with concurrent capecitabine. The study was closed early due to an unexpectedly high incidence of surgical complications seen in the photon group [45]. A subsequent MGH Phase I/II trial of neoadjuvant PBT (25 Gy in 5 fractions) with capecitabine for resectable PCA enrolled 50 patients with 35 being treated in the Phase II portion [46]. Grade 3 toxicity occurred in only two patients (4.1%). Of the 37 patients who had a pancreaticoduodenectomy, 81% had positive lymph nodes and 16% had positive margins. It is important to note that the lack of tumor downstaging was likely related to a 1-week break between RT and surgery. With median follow-up of 38 months for all patients, median progression-free survival was 10 months and median survival was 17 months.

The initial results of a Japanese Phase I/II trial of PBT with concurrent gemcitabine for LAPC were reported in 2012 [47]. Fifty patients were enrolled and were prescribed an aggressive treatment regimen; gemcitabine was given at 800 mg/m$^2$ weekly for 3 weeks concurrent with PBT and 80% of patients were prescribed 67.5 Gy in 25 fractions. With median follow-up of 12.5 months, outcomes were encouraging and included a grade 3 toxicity rate of ~10%. However, a subsequent publication that included 91 patients had a nearly 50% incidence of radiation-induced ulceration in the stomach and duodenum [48]. While margin expansions up to 5 mm were permitted during treatment planning to account for respiratory motion, no specific description of motion management usage was described in the manuscript. Therefore, the aggressive nature of the treatment regimen, and not PBT itself, is likely responsible for this high complication rate. Furthermore, this should serve as a reminder that despite

*Levels 2 and 3 treated on nonconsecutive days; level 4 treated on consecutive days.

the dosimetric advantages of PBT, we must remain vigilant about limiting dose to normal tissues and that motion management should always be considered.

The University of Florida also published early clinical outcomes of PBT for PC. Nichols et al. reported outcomes of 22 patients with resected and unresected PCA treated with PBT ranging from 50.4 to 59.4 Gy and concurrent capecitabine 1,000 mg twice daily [49]. With median follow-up of 11 months, no patient had any grade 3 toxicity. In fact, when proton treatment plans were altered to reduce bowel and stomach dose (posterior and right lateral beams were used instead of anterior and left lateral beams), no patient experienced grade ≥2 gastrointestinal toxicity. This beam arrangement was used by the same group to later treat unresectable patients using 59.4 Gy in 33 fractions and concurrent capecitabine and again there was no report of grade ≥2 gastrointestinal toxicity [50]. Despite the short follow-up and small patient numbers, these clinical data are certainly promising that the dosimetric advantages of protons may translate into clinically meaningful benefit.

These dosimetric and clinical outcomes suggest that PBT may be poised to have an expanded role in the management of PC. The reduction in normal tissue dose achieved by PBT could potentially transform the paradigm of PCA management perhaps through radiation dose escalation and/or novel combinations of PBT and multi-agent systemic chemotherapeutic regimens. While future studies will undoubtedly evaluate such uses of PBT, attention should also be paid to identifying patient subsets that are most likely to benefit from PBT as well as better understanding the effects of motion on PBT for abdominal targets.

While there is much potential to improve the therapeutic ratio for PCA patients with PBT, some practical proton planning and delivery considerations should not be overlooked. Proton dose deposition is strongly influenced by tissue densities within the beam path and changes in these densities such as from respiratory motion, setup errors, and even bowel peristalsis can potentially lead to underdosing of target and overdosing of normal tissues. As such, motion management strategies like respiratory gating, breath hold, or abdominal compression for targets in the upper abdomen should be used. Beam angles are selected in large part based on how reproducible the target and normal tissues will be within each beam on a daily basis. For example, beams that traverse large amounts of bowel are not ideal because the bowel shape and filling can be highly variable. Finally, image guidance for PBT is currently limited to only kV imaging at the majority of proton centers. This is not ideal for soft tissue assessment in PCA patients and therefore larger margins are typically used due to setup uncertainty. Cone beam CT (CBCT) has only recently become available at a few select proton centers and is expected to become more widely available over the next several years. CBCT will enable more selective margins to be used thereby further reducing normal tissue dose.

## Future Directions

Perhaps most critical to the appropriate use of radiation in patients with resected PCA is appropriate patient selection. Identifying those patients at greatest risk for local versus distant progression can help determine selective administration of RT and/or surgery. Development of predictive biomarkers that can identify those patients at greater risk for local failure is needed. One autopsy series of consecutive patients who succumbed to PCA demonstrated that roughly 30% of patients most likely died from locally destructive disease, highlighting the importance of achieving better local control [51]. In these patients, expression of Smad4 was highly associated with a locally destructive phenotype, findings which have also been replicated in a Phase II study of chemoradiation for LAPC [52].

As we await identification of more biomarkers, clinical investigation into treatment dose and fractionation may allow the benefit of time to understanding an individual patient's biology and risk of local failure. In addition to biomarkers, imaging modalities such as positron emission tomography (PET) may soon allow clinicians to further guide management decisions and practice personalized care. Historically delivered using photons, SBRT combined with PBT may have large clinical implications for patients with PCA. Future investigation will provide insight into the combination of SBRT and PBT as well as incorporation of SBRT and PBT with targeted therapy.

# Management of Cancer Recurrence

*Oliver Strobel and Markus W. Büchler*

*Department of General, Visceral and Transplantation Surgery, University of Heidelberg, Heidelberg, Germany*

## Introduction

Management of pancreatic ductal adenocarcinoma (PDAC) recurrence is a very relevant topic because even after resection with curative intention in combination with adjuvant therapy this cancer recurs in the majority of cases. Most patients eventually die from local, metastatic, or combined tumor recurrences resulting in median survival and 5-year survival rates of only 20–25 months and 20% after resection, respectively [1]. Several reasons are thought to contribute to the high recurrence rate and poor prognosis. An obvious reason for local recurrences is insufficient resection margin clearance reflected by the high rate of R1 resections identified by stringent margin assessment [2–5]. However, more importantly most patients succumb to early development of metastatic recurrence and the existence of undetectable micrometastatic disease at the time of resection is thought to be the main reason for this systemic failure. While this provides a clear rationale for the administration of systemic neoadjuvant or adjuvant therapies (see Chapters 112 and 113), results from randomized controlled trials show that systemic therapy can significantly delay but not prevent recurrence (see Table 119.1). Aggressive tumor biology and high chemoresistance are thought to be main reasons for the lack of efficacy of most currently available chemotherapy regimens.

With significant improvements in the surgical therapy and in accompanying (neoadjuvant or adjuvant) systemic treatment options the long-lasting controversy on the role of surgery in resectable PDAC has been resolved [1]. High-volume centers have reported actuarial survival rates after resection of 20% overall and of up to 60% in patient subgroups with a favorable combination of prognostic factors [5–8]. There is clear evidence that surgical resection in combination with systemic treatment remains the only chance of cure in patients with PDAC.

In contrast, although PDAC recurrence is a pressing problem affecting the majority of patients, its management remains poorly studied, highly controversial, and is far from being evidence-based. A part of the underlying problem is a certain therapeutic nihilism towards PDAC recurrence that is reflected by the fact that current treatment guidelines do not even clearly endorse structured surveillance programs after resection due to a lack of evidence for effective treatment options or a survival benefit by regular follow-up examinations [9,10].

This chapter aims to give an overview of current treatment options for PDAC recurrence with a focus on isolated local recurrence. We also give an overview of several aspects that are relevant in this context, including incidence and pattern of recurrence after resection, and the potential value of structured surveillance after resection.

## Incidence, Timing, and Pattern of Recurrence

Due to the lack of structured surveillance programs after resection for PDAC our knowledge of the true incidence, timing, and pattern of PDAC recurrence is limited. The best information is available from randomized controlled trials on resection and adjuvant therapy (Table 119.1; [11–18]), from autopsy series [19,20], and from some observational studies dedicated to the topic of recurrence [21].

Data from randomized controlled trials (RCT) give the best reference with respect to the "clinical" pattern of recurrence that we would expect to see based on

structured follow-up programs with assessment of patient history, physical examination, cross-sectional imaging (usually contrast-enhanced computed tomography), and serum values of tumor markers, especially carbohydrate antigen 19-9 (CA 19-9). The follow-up results of selected RCT published since 2000 are summarized in Table 119.1 and allow several important conclusions on incidence, timing, and pattern of recurrence after resection for PDAC. Data on disease-free survival from RCT comparing adjuvant therapy versus observation show that without adjuvant therapy 50% of patients develop clinically detectable cancer recurrence within 5–10 months [11,13,14] and chemotherapy with gemcitabine or 5-fluorouracil [5-FU] monotherapy can delay this to 11–15 months. With patient selection based on known prognostic factors recurrence is observed later, at 14.4 months without and at 18 months with adjuvant therapy [12]. Even in the more recent RCT the median disease-free survival remains at 12–15 months [16,18]. Up to 90% of patients without and still about 70% with adjuvant therapy develop PDAC recurrence within a follow-up time of 30–50 months. While reporting on the pattern of recurrence in different RCT is heterogeneous, 20–30% of patients appear to first develop isolated local recurrence, while the majority of patients present with systemic progression. In summary, the data on recurrence from RCT show that even with adjuvant therapy most patients develop recurrence within 1.5 years after resection. The data also suggest that based on structured surveillance programs it may be possible to identify a subgroup of 20–30% of patients who first develop isolated local recurrence.

A multicenter observational study in 1,130 patients undergoing resection between 2000 and 2010 reported a median actuarial overall survival of 25.9 months (median follow-up 18 months) [21]. In this study the local recurrence rate was 22% and the distant recurrence rate was 41% based on radiographic evidence, pathologic confirmation, and/or tumor marker elevation, confirming the observations from RCT. The most relevant risk factor associated with local recurrence in this study was positive lymph node status. This suggests that many patients with "local recurrence" may in fact have progression of preexisting lymph node metastases and may be good candidates for re-resection.

While the RCT and observational clinical studies give us an indication of the clinically detectable pattern of recurrence, the few available autopsy series demonstrate the "true" pathologic pattern of recurrence and the relevance of the sites of recurrence for death. In a Japanese autopsy study in 24 patients who died after resection of pancreatic cancer 75% of patients had local recurrence, 75% had distant metastases (50% hepatic), and the local recurrence was the cause of death in 17% of patients [19]. Another autopsy study in patients with PDAC included 22 patients after resection [20]. At autopsy, 2 patients (9%) had died of unrelated causes and had no evidence of recurrence, 3 (14%) had isolated local recurrence, 4 (18%) had only metastatic recurrence, and 13 (59%) had both local and systemic recurrence. In this study, expression of DPC4 in the tumor was highly correlated with metastatic but not with localized disease [20].

These autopsy studies confirm that after resection and adjuvant therapy for pancreatic cancer most patients die of systemic disease, but a subgroup of patients develop and die from isolated (or predominantly) local recurrence. Molecular properties of the tumor appear to contribute to the pattern of recurrence [20].

It will be interesting to see how the neoadjuvant or adjuvant administration of more aggressive chemotherapy regimens such as FOLFIRINOX and advances in radiation oncology will affect incidence, timing, and pattern of PDAC recurrence [22]. Translational studies characterizing the molecular properties of PDAC in the context of the pattern of disease may identify biomarkers for the prediction of the pattern of recurrence that may be useful for decision making as a step towards precision oncology.

## Surveillance After Resection for Pancreatic Cancer

Current evidence-based clinical guidelines on PDAC therapy do not clearly endorse structured surveillance programs after resection and completion of adjuvant treatment, mainly because there is no available data showing that earlier detection and treatment of recurrence lead to better patient outcomes [9,10]. Population-based or single high-volume center studies from the United States demonstrated no significant survival benefit but increased costs from regular surveillance computed tomography (CT) scans [23,24]. While the German guidelines do not recommend a structured follow-up at all [10], the American NCCN guidelines recommend history and physical examination every 3–6 months for 2 years, then annually and, as category 2B recommendations (lower-level evidence), CT scans and CA 19-9 measurements every 3–6 months for 2 years after surgical resection based on the consensus that earlier detection of recurrence may facilitate patient eligibility for investigational studies or other forms of treatment [9].

It has to be acknowledged that such clinical guidelines have to be based on current evidence and have to include socioeconomic considerations and that there is currently little evidence for any of the treatment options for pancreatic cancer recurrence discussed later (Table 119.2). But how should such evidence ever be generated if not

**Table 119.2** Treatment options for recurrent pancreatic cancer.

| Treatment | Potential indications | Intention | Comments |
|---|---|---|---|
| **Chemotherapy** | Any recurrence<br>Systemic recurrence | Palliation | Most frequently used for pancreatic cancer recurrence irrespective of pattern.<br>No evidence based on RCT in the setting of recurrence.<br>Choice for best regimen has to be based on previous chemotherapy, performance status, etc. (see Chapters 113 & 116). |
| In multimodal setting with re-resection | Isolated local recurrence | Medium- to long-term control<br>Potential "cure" | Similar rationale as for neoadjuvant and adjuvant therapy in primary pancreatic cancer.<br>No evidence based on RCT.<br>Data from retrospective studies in selected patients with recurrence available (see Table 119.3b) |
| **Chemoradiation** | Isolated local recurrence | Palliation<br>Local control<br>Pain therapy | Preferred for isolated local recurrence in many centers, especially in a setting of unresectable perivascular recurrence.<br>No evidence from RCT.<br>Data from retrospective studies in selected patients with recurrence available (see Table 119.3a) |
| In multimodal setting with re-resection | Isolated local recurrence | Medium- to long-term control<br>Potential "cure" | May be used in a "neoadjuvant" setting and in a multimodal concept involving external and intraoperative radiotherapy.<br>Data from observational studies in selected patients with recurrence available (see Table 119.3b) |
| **Surgery**<br>- *Local re-resection*<br>In multimodal setting with chemotherapy or chemoradiation | Isolated local recurrence | Medium- to long-term control<br>Potential "cure" | Performed by only a few specialized surgical centers,<br>No evidence from RCT.<br>Data from retrospective studies in selected patients with recurrence available (see Table 119.3b) |
| - *Metastasectomy*<br>In combination with chemotherapy | Oligometastatic systemic recurrence | Medium- to long-term control | Literature restricted to case reports and small retrospective studies with mixed cohorts including synchronous metastases.<br>Several small series with favorable survival after resection of isolated lung metastases. |
| **Locally ablative therapies** | Isolated local recurrence (in combination with chemotherapy) | Palliation<br>Local control | Different modalities (radiofrequency ablation, irreversible electroporation, etc.) are currently evaluated in some centers.<br>Literature restricted to case reports and retrospective studies with mixed cohorts of primarily unresectable tumors and local recurrences. |

based on structured surveillance for early detection of PDAC recurrence?

Even with the limitations of cross-sectional imaging and serum levels of tumor markers in detecting metastatic disease known from the primary diagnosis of pancreatic cancer, the aforementioned data from RCT suggest that a structured follow-up program based on these tools would allow for earlier detection of localized recurrence.

In our center we offer a structured follow-up program to all patients with PDAC resection and we assess its potential value for early detection of recurrence and its impact on the clinical management of patients. Heye et al. [25] demonstrated that the comparison of sequential follow-up CT scans allows for early detection of local recurrences by observation of subtle but progressive changes at typical predilection sites for perivascular and lymphatic local recurrences (Fig. 119.1).

In an analysis of 940 postoperative follow-up visits of 618 patients over a 1-year period recurrence was detected in 74 (40%) of 184 patients after PDAC resection, of whom only 26% had symptoms [26]. In all of these patients a cancer-directed therapy was initiated. Of 16 patients with isolated local recurrence 12 (75%) were without symptoms and 11 were referred for re-resection.

These data have important implications, because they show that most recurrences are at first asymptomatic, will

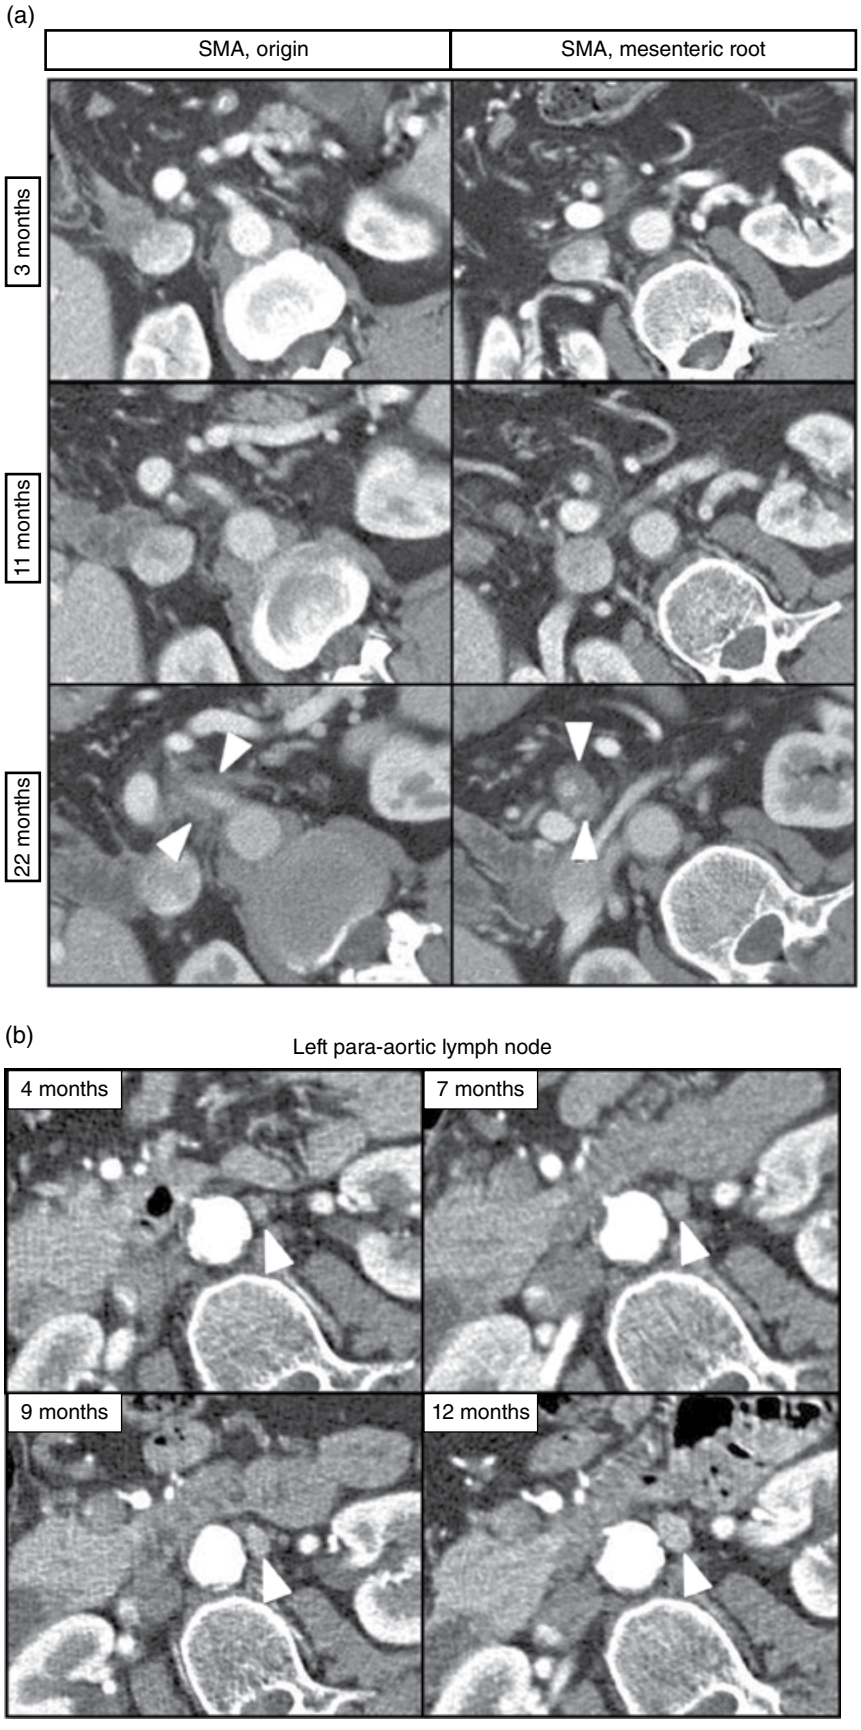

**Figure 119.1** Typical findings of local recurrence during sequential CT scans for surveillance after pancreatic resection for cancer. (a) Perivascular recurrence around the superior mesenteric artery (SMA) at different time points after pancreatoduodenectomy for pT3pN1 adenocarcinoma in a 69-year-old patient. Unsuspicious findings after 3 months, gentle density around the SMA at 11 months, development of dense tissue incasing the SMA as evidence of recurrence after 22 months. (b) Lymph node recurrence in a left para-aortic lymph node at different time points after pancreatic left resection for cancer. Gradual increase in lymph node size from 9 mm at 4 months to 16 mm at 12 months. *Source:* Modified from Heye et al. 2011 [25]. Reproduced with permission of Baishideng Publishing Group.

be detected earlier with regular surveillance including cross-sectional imaging, offering the opportunity for earlier initiation of oncologic therapy. While it appears logical that earlier detection of recurrence and initiation of therapy may result in better outcomes, future studies will have to assess how the treatment options discussed later affect survival and quality of life of patients with PDAC recurrence.

With advances in treatment options and diagnostic tools, the potential of structured surveillance programs will have to be reevaluated in the future. Novel analytic targets such as exosomal markers and cell-free DNA that are currently being evaluated in the early detection of PDAC may also be promising tools for postresection surveillance [27,28].

## Treatment of Systemic Recurrence of Pancreatic Cancer

The treatment options for PDAC recurrence after resection are based on little evidence. The literature is restricted to mostly small retrospective studies in selected patients and in multiple case reports, suggesting a considerable publication bias. Table 119.2 provides an overview of available treatment options for PDAC recurrence. Based on common sense the appropriate treatment options depend on multiple parameters including the pattern and localization of recurrence, the clinical performance status and comorbidity of the patient, previous treatment, and timing (i.e., interval between resection and recurrence).

Clearly, systemic chemotherapy is the appropriate palliative therapy for the majority of patients with PDAC recurrence, because they present with systemic disease. There is little evidence from the literature as to the best regimen in this situation. However, this is a palliative situation and depending on the time of recurrence (during or after adjuvant therapy), previous therapy, and performance status, the same principles as outlined for second-line adjuvant and palliative chemotherapy (Chapters 113 and 116) may be recommended. While metastastectomy for systemic PDAC recurrence is highly controversial, favorable survival has consistently been reported after resection of the rare cases of isolated lung metastases [29–31]. With respect to quality of life, adequate pain therapy and supportive care are very important aspects of palliative therapy in patients with PDAC recurrence (Chapter 117).

## Treatment of Isolated Local Recurrence of Pancreatic Cancer

While the current NCCN guidelines recommend inclusion in a clinical trial (preferred), chemoradiation (if not previously performed), switch to an alternative systemic chemotherapy, or best supportive care for local recurrence [9], the German S3 guidelines recommend the evaluation of local therapy options for isolated local recurrence based on the retrospective studies available [10].

Available treatment options for local recurrences include chemoradiation, re-resection, and locally ablative therapies (Table 119.2). In the following we will focus on chemoradiation and re-resection. While feasibility and safety of different locally ablative therapies are currently being tested for locally advanced PDAC, little is known on efficacy and long-term outcome [32] and data on locally ablative therapies for local recurrence are restricted to case reports.

## Rationale for "Local" Therapy Options

PDAC is a systemic disease and most patients will eventually die from metastatic disease. This notion has led to a long-lasting debate as to the value of resection even in resectable PDAC. Based on good evidence and with advances in both surgery and systemic therapy, resection in combination with systemic therapy has now been established as the only therapy with the potential for long-term survival or cure [1]. With further advances the limits for surgery are today being pushed towards extended resections and resections after aggressive neoadjuvant therapies with promising results for locally advanced PDAC [22,33]. Strategies of neoadjuvant treatment have the advantage that patients with early systemic progression who have no benefit of surgical resection are selected out before surgery. Together with the pattern of recurrence and survival, data from molecular studies suggest that patients with isolated local recurrence may have biologically distinct PDAC subtypes of a less aggressive phenotype with slower systemic progression [20,34]. This notion provides a good rationale to test localized treatments such as re-resection and chemoradiation in this biologically selected subgroup of patients. However, the majority of patients presenting with suspected isolated local recurrence may also have micrometastatic disease and develop systemic progression later. Therefore, as for primary pancreatic cancer, local therapies for recurrence have to be embedded in multimodal treatment strategies that include systemic chemotherapy.

## Chemoradiation for Isolated Local Recurrence

Chemoradiation is discussed by many as the main alternative to merely palliative chemotherapy for treatment of local recurrence. The evidence for chemoradiation is based on retrospective series of limited size (Table 119.3a).

**Table 119.3(a)** Retrospective series of chemoradiation for local recurrence of pancreatic cancer.

| Author | Year | *N* included | Radiotherapy | Chemotherapy | Oncologic ouctomes |
|---|---|---|---|---|---|
| Wilkowski [38] | 2006 | 18 | 45 Gy | 5-FU (*n* = 4)<br>5-FU, Gem (*n* = 6)<br>Cis, Gem (*n* = 8) | OS: 17.5 months<br>PFS: 14.7 months<br>CR: *n* = 6 (33%) |

Included are studies with >5 patients undergoing re-resection.
[#]The cohort by Kleeff et al. is from the same center and included in the follow-up study by Strobel et al.
[$]Mixed cohort of local and distant recurrence. Only data of patients with local recurrence included here.
OS, overall survival; DFS, disease-free survival; ILR, isolated local recurrence without evidence of systemic disease confirmed by surgical exploration.

The actuarial overall median survival reported for chemoradiation is around 16–18 months, with median progression-free survival of 6.9 months in the two larger out of four studies [35–38]. A poorer median overall survival of only 8.8 months in the only series with a low reported rate of systemic therapy (28%) [37] supports the notion that any local therapy for recurrence has to be accompanied by systemic chemotherapy in order to achieve favorable survival results.

## Re-resection for Isolated Local Recurrence

The evidence for re-resection for the treatment of local PDAC recurrence is also based on retrospective series of limited sample size (Table 119.3b; [31,34,39–43]). However, the reported outcome with median overall survival rates of 25 to >30 months after re-resection in the most recent series [34,41–43] appear to be superior to the outcome reported after chemoradiation. It should be noted that these differences may in part be explained by selection bias due to the exclusion of patients with radiologically undetectable metastatic disease in the resection series. While most series did not report on resection rates, the series from Heidelberg initially reported a resection rate of 50%, which dropped to 42.3% in the larger series, mainly due to intraoperative diagnosis of metastases [34,39]. Disease-free survival after resection was not consistently reported. However, the summarized results demonstrate that re-resection was safe with 0–2% mortality and associated with very encouraging survival outcome at least in the selected patients who underwent re-resection. It should be emphasized that these results originate from specialized referral centers for pancreatic surgery and may not be commonly applicable.

We have reported our initial experience with re-resection in 2007 [39] and the so far largest series on surgery for isolated local PDAC recurrence in 2013 [34]. Analysis in this series allowed for several relevant observations. Of 97 patients with preoperatively suspected isolated local recurrence and histologic proof of recurrence, 57 (59%) had isolated local recurrence by surgical exploration, while distant metastases were identified in 40 (41%) patients. This again highlights the necessity of better diagnostic tools to detect small metastatic deposits, a problem known from primary PDAC staging. Of 57 isolated local recurrences, 41 (72%) were resected while 16 (28%) were locally unresectable. Median postoperative survival was 16.4 months in isolated local recurrence versus 9.4 months in metastatic recurrence, confirming the better prognosis of isolated recurrence that had been described previously [44]. Importantly, median survival in isolated local recurrence was significantly longer after resection (26.0 months) versus exploration for local unresectability (10.8 months). This observation in isolated local recurrence points to a potential survival benefit from re-resection. R0 re-resection was achieved in 18 patients and resulted in 30.5 months median survival.

While a true benefit of re-resection can only be demonstrated by RCT, these results suggest that selected patients with suspected isolated local PDAC recurrence may benefit from re-resection.

## Selection of Patients for Local Therapy

Several studies have identified the disease-free interval between primary tumor resection and recurrence to be associated with survival after re-resection or chemoradiation with different cutoffs from 9 to 20 months [31,36,39,41]. In the largest available series disease-free interval was not associated with prognosis while CA 19-9 was predictive for survival [34].

While exact cutoff values remain to be defined, early recurrence versus prolonged disease-free survival may be indicators for rapidly progressing versus less aggressive tumors and should be considered in decision making.

As in primary pancreatic cancer, CA 19-9 appears to be associated with survival in cancer recurrence. As discussed earlier, novel diagnostic tools and biomarkers may improve patient selection in the future [20,27,28].

## Conclusions

Pancreatic cancer recurrence is a pressing concern affecting the vast majority of patients even after resection and completion of systemic therapy. While the majority of patients develop metastatic recurrence, a significant subgroup of 20–30% of patients first develop isolated local recurrence. These patients may have tumors of less aggressive subtypes with slower systemic progression and may, therefore, benefit from a multimodal treatment strategy that includes local therapy. As most recurrences are at first asymptomatic structured follow-up programs are needed to identify these patients. Although the literature provides little evidence with respect to the management of PDAC recurrence, both chemoradiation and surgical re-resection have been suggested to be safe and effective by several retrospective series. The best "standard" management for cancer recurrence can only be determined based on RCT, which will be difficult to conduct for this indication. More likely, the therapy for PDAC recurrence will remain a matter of interdisciplinary, personalized

decision making. Novel effective treatments for PDAC therapy and novel biomarkers for early diagnosis will hopefully also advance the fields of surveillance after resection, and result in earlier detection and more effective management of isolated and systemic PDAC recurrence.

# Long-Term Outcome After Treatment of Pancreatic Cancer

## 120

## Survival and Late Morbidity After Resection of Pancreatic Cancer

*Avinoam Nevler, Charles J. Yeo, and Jordan M. Winter*

*Department of Surgery, Jefferson Pancreas, Biliary and Related Cancer Center, Thomas Jefferson University, Philadelphia, PA, USA*

### Introduction

Pancreatic cancer is currently the third leading cause of cancer death in the United States [1]. In light of the decreasing trend in cancer deaths from other common cancer types, pancreatic cancer deaths are expected to become second only to lung cancer within the next decade. Pancreatic ductal adenocarcinoma (PDAC) is a highly lethal cancer with an overall 5-year survival for affected patients estimated to be only 7% [1]. Approximately 20% of patients with PDAC have localized and resectable disease at diagnosis. This subgroup has the best long-term outcome. In this chapter, we will review the survival of patients with resected PDAC, and highlight trends in survival over time. We will examine advances in prognostic markers, which can inform survival projections. As increasing numbers of patients achieve prolonged survival after resection for PDAC in the future, an understanding of late morbidity after pancreatic resection will become increasingly important. We will summarize the literature on delayed complications, although this body of work is relatively sparse and generally limited to studies of patients who underwent resections for benign disease.

### Survival after Resection for Pancreatic Cancer

Reported long-term survival outcomes after pancreatic resection for PDAC vary based on the specific characteristics of the patient cohort under investigation. Frequently, oncologists quote survival data from highly cited randomized, large, multi-institution adjuvant trials that include patients who have undergone a resection with curative intent, such as ESPAC-3 [2], RTOG 9704 [3], and CONKO-001 [4] (these trials are detailed elsewhere in this book). The reported median overall survivals in these studies were 23.2, 20.0, 22.8 months, respectively. In the ESPAC-1 trial the median survival was 14.0 months with no adjuvant chemotherapy [5] while in the recent CONKO-001 trial the no-treatment arm had a median survival of 20.2 months.

These results might be favorably skewed, however, compared with patients treated outside clinical trials because they are confounded by rather strong selection and entry biases related to strict eligibility criteria. For instance, these studies typically exclude patients with the most unfavorable cancers that are associated with either early recurrence at the time of eligibility screening, or in the case of CONKO-01 markedly elevated postoperative serum CA 19-9 levels. In addition, patients with significant medical comorbidities, or patients who recover poorly after pancreatectomy (including those who suffer a perioperative death), are excluded from these studies. Indeed, the ability to receive adjuvant therapy after resection for PDAC may be an important prognostic marker that is independent from the potential therapeutic benefits of such therapy (about 80–90% of patients in most high-volume centers in the United States receive adjuvant treatment). Population-based (nonrandomized) studies that suggest a strong benefit to adjuvant therapy should take this point into consideration [6].

Taken together, adjuvant trials reveal that modern single-agent adjuvant chemotherapy confers an average median survival advantage of perhaps 3–5 months over best supportive care [7,8]. Recurrences typically occur around 13 months after resection for patients who receive adjuvant therapy, as compared with around 7 months for patients off therapy [4]. Unfortunately, this difference (around 6 months) merely approximates the

Companion website: www.wiley.com/go/beger/thepancreas

time patients spend on adjuvant therapy in many cases, suggesting that modern treatments often fail to provide a durable benefit that lasts beyond completion of therapy. In other words, in many cases the disease is kept at bay only while patients are receiving treatment.

Retrospective single-institutional experiences provide real-world survival data compared with prospective clinical trials, even though follow-up of these patients may be less rigorously collected. In contrast to prospective adjuvant trials, these retrospective studies are usually not confounded by the same degree of selection bias, as they generally include all patients who are candidates for resection at a given institution. Thus the results may be more generalizable. As would be expected, long-term survival outcomes reported by these studies tend to be worse. In a large, single-institution study of 1,175 PDAC resected at the Johns Hopkins Hospital (JHH) over 25 years, the median survival was just 18 months; 1-year, 2-year, 3-year, and 5-year overall survival rates were 65%, 37%, 27%, and 18%, respectively [9]. The overall survivals in a series of 555 resected patients from the Memorial Sloan Kettering Cancer Center (MSKCC) (1983–2000) were virtually identical [10].

In recent years, the results of retrospective studies of patients undergoing resection *after* neoadjuvant therapy have been reported and outcomes are often impressively long in comparison to historical retrospective data of patients who received adjuvant therapy following resection. However, there is a strong selection bias in these cohorts that should be acknowledged (just as with prospective, randomized adjuvant trials). A substantial portion of patients in the intent-to-treat neoadjuvant group fail to undergo resection, either due to disease progression or poor performance status. As a result, the neoadjuvant treatment model enriches the study cohort (i.e., patients undergoing subsequent resection) with the most favorable patients. Christians et al. recently published results from a retrospective analysis of 69 patients with resectable PDAC treated with neoadjuvant chemoradiotherapy from 2009 to 2013 at a single institution [11]. The reported median survival from this relatively small cohort was an astounding 44.9 months for patients who completed the neoadjuvant course and successfully recovered from pancreatic resection. However, the intent-to-treat analysis for the whole cohort was 13.5 months shorter (31.5 months), albeit still impressive. The survival of the 9 patients (15%) who failed to advance to surgical resection was just 8.1 months, and on a par with patients having advanced disease. Importantly, patients included in this study satisfied strict inclusion criteria of having "resectable" PDAC, which comprised a relatively favorable group when compared with large institutional series of patients receiving adjuvant therapy. In an earlier prospective, and nonrandomized study by Evans et al. published in 2008, 86 patients with resectable PDAC received preoperative neoadjuvant chemoradiotherapy [12]. Median survival was 34 months for patients who completed neoadjuvant chemotherapy and underwent a resection (64 patients). In the intent-to-treat group, overall survival rates were comparable with studies of patients who get resection first (22.7 months). In this study, a larger proportion of patients failed to undergo resection (25%) than the more recent report by Christians et al., suggesting improved patient selection in the later study. It is difficult to conclude from single-institution studies of neoadjuvant therapy such as these that the treatment is the principal driver of superior reported outcomes for resectable PDAC, because most of the patients only received gemcitabine or 5-FU-based monotherapy (marginally effective therapies). Tumor biology and patient selection likely play a more predominant role. As chemotherapy improves, the rationale for a neoadjuvant approach will probably gain greater traction, as the need for early systemic control is likely critical for improved survival in many patients. Randomized trials are needed to better assess the value of the neoadjuvant approach. We eagerly await such studies, including the ongoing German NEOPA trial, which varies the sequencing of gemcitabine and resection in patients with resectable PDAC [13]. Neoadjuvant treatment has become the standard approach for borderline resectable disease at most centers. A meta-analysis of 18 studies of patients undergoing neoadjuvant therapy for borderline resectable disease revealed that the resection rate is 65%, and the median survival is 26 months in the patients who achieve this result (18 months for the whole group [14]).

## How Commonly are Patients Cured of PDAC by Resection?

While many patients with localized disease may not be helped by resectional therapy (as 25% of patients die within a year after resection for PDAC [9,15]), there is no question that this surgical intervention provides the best opportunity for long-term survival for many patients. A randomized, patient-blinded study of 42 patients from Japan compared the effect of resection with that of chemoradiation without resection for patients with resectable PDA. The study revealed just a 3-month *median* survival benefit (which is comparable to the meager median survival benefit of adjuvant therapy) [16]. However, the *mean* survival advantage was an impressive 12 months, revealing that a significant proportion of favorable outliers received a substantial benefit from resection. In fact, there were no long-term survivors (>2 years) in the no-surgery group (vs. 35% in the surgery group), just as there are seldom any long-term survivors in historical studies of patients with advanced disease.

**Table 120.1** Five- and 10-year survival rates for patient with pancreatic cancer after surgical resection.

| | Study period | N | 5-year survival | 10-year survival |
|---|---|---|---|---|
| CONKO-001 (Adjuvant Group) | 1998–2004 | 168 | 20.7% | 12.2% |
| Shimada et al. [18] | 1990–2013 | 229 | 17% | 10% |
| Kimura et al. [19] | 1988–2012 | 149 | 13.40% | 3.60% |
| Ferrone et al. [20] | 1985–2006 | 499 | 19% | 10% |
| Dusch et al. [21] | 1972–2004 | 360 | 19.20% | 6.10% |
| Schnelldorfer et al. [22] | 1981–2001 | 357 | 18% | 13% |
| Adham et al. [23] | 1983–2000 | 30* | – | 30% of 5 yr survivors had ≥10 yr survival |
| Riall et al. [17] | 1970–1999 | 564 | 17% | 9% |

This and other outcome studies raise the question of cure rates associated with resection for PDAC. A handful of studies shed light on this question with survival outcomes reported to 10 years and beyond (Table 120.1). Similar to studies with shorter follow-up, 5-year survival rates are consistently around 18–20%. Reproducibly, the data also indicate that overall survival 10 years after resection is roughly half this rate, or 10%. The largest study to date on this subject was published by Riall et al., where the authors reported on the long-term survival of 564 patients with PDA [17].

Our own unpublished analysis of the publically available data from the Surveillance, Epidemiology, and End Results (SEER) cancer database (1975–2012) yields further insight into this question [24]. These data show that patients have roughly a 50% chance of doubling their own survival throughout their lifetime (starting at the 1 year point). For example, an individual who survives 4 years has a 50% chance of living another 4 years. This observation has several implications. First, the longer an individual lives, the greater their chance of surviving a further year. On the other hand, the data indicate that a 10-year survivor still carries a real risk of late recurrence. In an analysis of 30 five-year survivors, Adham et al. observed survival at 10, 15, and 20 years to be 30%, 13%, and 7% respectively. These outcomes are substantially worse than would be predicted from age-matched life tables, where a 65-year-old individual would be expected to have a 50% survival at 20 years. Ferrone et al. [20] analyzed a cohort of 499 patients resected at the Massachusetts General Hospital for PDAC (in a study entitled "Pancreatic ductal adenocarcinoma: long-term survival does not equal cure"), and also observed a number of recurrences beyond 10 years. Moreover, some cases of long-term survival on further pathologic review have been attributed to an incorrect diagnosis at the index resection, as exemplified by a patient on the CONKO-001 trial found later to have a neuroendocrine cancer [25]. While a patient can never be fully assured that they are free of recurrence risk, our analysis of life expectancy tables [26], superimposed with historical PDAC survival data after resection, suggests that the survival curves overlap after patients have lived for roughly 13 years after resection (~8% of patients achieve this outcome, with a median projected 19-year overall survival in this subgroup). After this time point, patients are just as likely to die from nonpancreatic cancer causes. Practically speaking, these patients then are "cured" of their disease. Therefore, we believe that the "cure rate" of pancreatic resection for PDA can be estimated to be around 8% for most patients.

## Survival Trends Over Time

A large, single-institution study from the Memorial Sloan Kettering Cancer Center [15] revealed that short (30-day) and intermediate (1-year) survivals after resection for PDAC have improved between the 1980s and 2000s. The authors concluded that over time, surgery had become safer with fewer perioperative deaths (i.e., early mortality); additionally, the authors hypothesized that patient selection had improved, perhaps as a result of modern imaging techniques used to stage patients with fewer early recurrences (i.e., intermediate mortality). However, there was no improvement observed in long-term mortality in this study, particularly when these other survival determinants (perioperative mortality and patient selection) were excluded from the analysis by focusing just on patients who survived at least 1 year. A subgroup analysis of SEER pancreatic cancer relative survival data over the past 40 years [24] also indicates that there has been no improvement in the survival of pancreatic cancer patients when we evaluated all patients with pancreatic cancer who survived at least 1 year (Fig. 120.1). Our review of pancreatic cancer survival statistics from a separate large data set, published

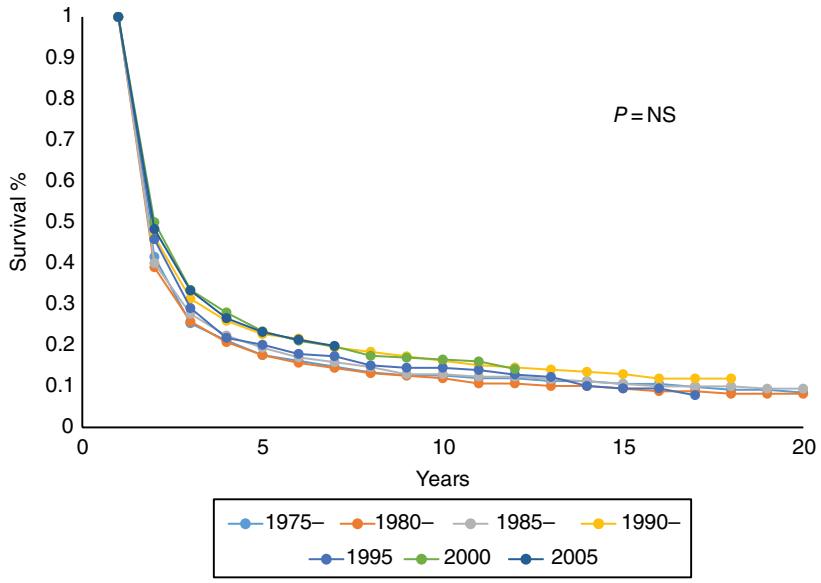

**Figure 120.1** Conditional relative survival for PDA patients surviving ≥1 year. Data from SEER database. Note the minimal change in relative conditional survival (≥1 year) over 30-year period compared with conditional survival in 1975–1979. NS, nonsignificant.

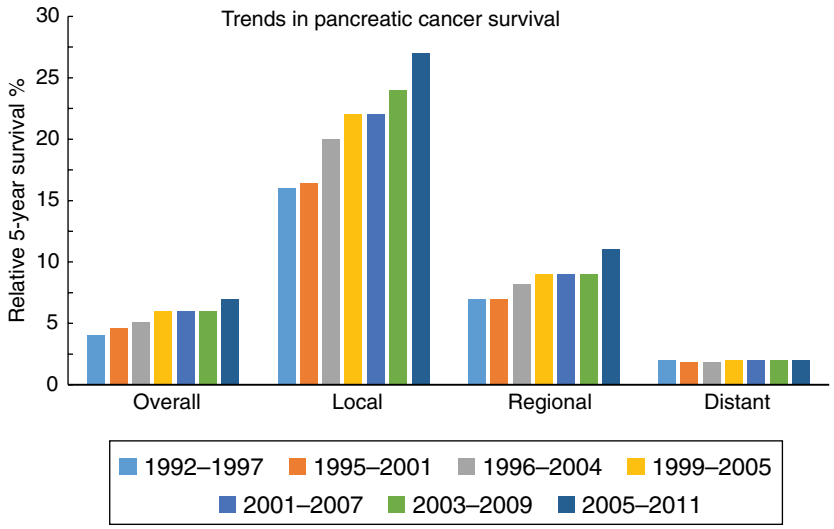

**Figure 120.2** Trends in 5-year survival of pancreatic cancer (1992–2011). American Cancer Society (ACS) published data. (Note the overlap in the time periods.)

by the American Cancer Society (ACS) between 1992 and 2011, adds further support to these observations [27]. The overall cancer 5-year survival (i.e., including all patients) rose from 4% in the period between 1992 and 1997, to just 7% between 2005 and 2011 (Fig. 120.2). Notably, there was virtually no improvement for metastatic disease, and only minimal improvement for regional disease. The greatest increase in survival was apparent for patients with localized disease (16% to 27% over the time interval). Again, the absence of any significant and widespread advances in chemotherapy over this time frame points to progress outside the domain of cancer therapeutics (e.g., safer surgery and patient selection) as principal drivers for positive change. Greater access to care (surgery and chemotherapy) may also have played an important role.

## Prognostic Risk Factors

Prognostic factors are key aspects to any discussion of survival, mainly due to the information they provide regarding the natural history of the disease. On occasion, prognostic information can be used to guide treatment decisions. Certain prognostic features have been consistently validated in patients with PDAC. However, it is important to note and discuss with patients that these factors are marginal at best at forecasting outcome. Patients with unfavorable features often achieve long survival after resection, while many with favorable features suffer an unfortunate early recurrence and death.

Pathologic features that are reproducibly found to be associated with worse long-term survival include increased tumor diameter, regional lymph node

metastases (including alternative metrics of lymph node burden such as lymph node ratio) [28–34], poorly differentiated histology, positive resection margin, and perineural invasion [17,35–37]. In multivariate models, each of these has associated hazard ratios below 2, reflecting their weak prognostic capabilities, and their limited utility for treatment-related decisions. Indeed, in a study that contrasted 137 patients with short survival (<12 months, $n = 58$) and long survival (>30 months, $n = 79$) after resection for PDAC, no pathologic features proved to be significant predictors for the survival group. Interestingly, 65% of the long-term survivors and 17% of the short-term survivors had regional lymph node metastases, respectively [38]. Aside from conventional pathologic features, the only other validated prognostic marker is the serum-based carbohydrate antigen 19-9 (or CA 19-9). This protein is a secreted sialylated Lewis A (sialyl $Le^A$) antigen that is produced in high amounts by pancreatic cancer cells. Elevated post-resection levels are associated with early recurrence and worse overall survival [39–41]. In fact, an ad hoc analysis of patients enrolled in the RTOG 9704 adjuvant trial [3,39] revealed that a level >180 U/mL is associated with an adjusted hazard ratio of 3.6 (which is substantially more powerful than conventional pathologic features). This finding has been replicated in multiple studies [40–43].

Scientists have tried to identify molecular prognostic markers that can enhance conventional staging strategies, although none have been validated to date. Winter et al. determined that high MUC1 and mesothelin (*MSLN*) expression were both associated with early cancer-specific mortality in a comparative analysis of short- and long-term survivors after resection for PDAC [38]. These immunohistochemical markers showed a greater prognostic ability compared to conventional pathologic features such as tumor size, regional lymph node metastases, resection margin status, and histologic grade [38]. Smith et al. performed a meta-analysis of several immunohistochemical prognostic markers (P16, SMAD4, VEGF, EGFR, bax, and bcl-2) in resected pancreatic cancer patients (11 eligible studies) and found vascular endothelial growth factor (VEGF) to be the most informative prognostic marker [44].

A separate study by Stratford et al. analyzed gene expression data in resected samples, and compared the profile to metastatic deposits found at autopsy. The authors identified a six-gene signature as prognostic for advanced disease. This gene cluster (*FOSB*, *KLF6*, *NFKBIZ*, *ATP4A*, *GSG1*, and *SIGLEC11*) proved to be predictive of worse outcome in a small validation cohort of patients with resected PDA, with an adjusted hazard ratio of 4.1 [45]. Recently, Chen et al. [46] described a prognostic 15-gene signature in early stage PDAC (hazard ratio 3.26), which was also validated in the Stratford cohort [45].

## Long-Term Morbidity

Studies on postoperative morbidity after pancreatectomy have historically focused on early complications after resection (addressed elsewhere in this book). Along these lines, the International Study Group of Pancreatic Surgery has published a series of consensus papers on various complications. *Late morbidity* after pancreatic surgery, however, has been considerably less studied. Relevant studies have naturally focused on patients undergoing resection for benign disease, since larger numbers of patients remain alive at long-term follow-up. The most common late complications that have been observed include gastrectomy-associated complications (e.g., dumping syndrome, bile reflux gastritis, marginal ulcers, bleeding, and gastric remnant cancer), bile duct strictures, pancreatic duct strictures, pancreatogenic diabetes mellitus, pancreatic exocrine insufficiency, nonalcoholic fatty liver disease (NAFLD), incisional hernia, and pyogenic liver abscess.

### Gastrectomy-Associated Complications

A classic pancreaticoduodenectomy (to include a distal gastrectomy) may carry a risk of delayed complications typically associated with a distal gastrectomy. These include afferent limb syndrome, bile reflux gastritis, marginal ulcers (associated with bleeding, stricture, or perforation), dumping syndrome, and gastric remnant cancer (Table 120.2).

Some early studies suggest that the rates of reflux gastritis, marginal ulcers, and dumping syndrome may be lower with a pylorus-preserving pancreaticoduodenectomy as compared with those after a classic pancreaticoduodenectomy [47,48]. Other studies, however, have shown no clear difference in the risk for marginal ulcers or reflux gastritis [49]. The principle etiology of afferent limb syndrome after pancreaticoduodenectomy is tumor recurrence, followed by radiation-induced stricture [50], and should be equally prevalent with either reconstruction technique.

The risk of gastric remnant cancer in patients undergoing a classic Whipple is a theoretical one, because the

**Table 120.2** Gastrectomy-associated complications for patients post-pancreatoduodenectomy.

| Complication | Prevalence |
|---|---|
| Alkaline reflux gastritis | 11–25% [49,51] |
| Marginal ulcer | 1–9% [49,51,52] |
| Afferent loop syndrome | 13% [50] |
| Dumping syndrome | 10% [47] |

supporting evidence is an extrapolation of literature based on prior gastrectomy for peptic ulcer disease. The incidence is believed to be around 7% [53–55], and the average latency is about 20 years [55]. Most gastric remnant cancers occur at or near the prior anastomosis, and the cause is believed to be related to combined reflux of bile and pancreatic secretions. While a similar risk has not been documented after a classic pancreaticoduodenectomy, the purported mechanism of pancreatobiliary reflux is nonetheless exacerbated when the pylorus is resected. The relevance of this complication is probably low with the present survival rates for PDAC (roughly 5% of patients, or less, will survive to 20 years), but will likely become an increasingly common issue for the current generation of hepatobiliary surgical trainees as treatments improve. Data from patients undergoing gastric resections for peptic ulcer disease suggest that surveillance should be performed in appropriately selected patients starting 5 years after their distal gastrectomy [53].

As a case in point, Dr. James J. Mezhir (1973–2016) suffered this very fate. He was an accomplished pancreatic surgeon and scientist, and in fact reported the largest series of gastric remnant cancers as a surgical oncology fellow at Memorial Sloan Kettering [53]. He underwent a pancreaticoduodenectomy as a teenager for the management of non-Hodgkin lymphoma causing bile-duct obstruction [56,57]. Sadly, he developed an aggressive gastric remnant cancer 25 years after the index operation, and recently died after a 2-year battle with the disease [56].

### Biliary Anastomotic Strictures

Biliary strictures occur in 3–8% of patients following pancreaticoduodenectomy [58–60], with the median time to stricture formation being just over 1 year. This complication is best managed initially, when possible, by nonoperative interventions including endoscopic or percutaneous balloon dilatation and biliary stents. Surgical revision is appropriate in cases where these interventions fail (approximately 5–24% of the time). Reported risk factors for biliary strictures include small bile-duct diameter at the time of the index resection (<5 mm) [60], preoperative biliary stenting, and postoperative biliary stenting [58].

### Pancreatic Anastomotic Strictures

Pancreatic anastomotic strictures occur at an almost similar rate (roughly 2–3% after pancreaticoduodenectomy) [59,61]. This complication typically presents as abdominal pain in the setting of pancreatitis, and manifests an average of 4 years after the index operation. MRCP or CT provide visual images to secure the diagnosis [61]. Pancreatic anastomotic strictures may be managed initially by endoscopic stenting (guided by ERP or EUS) in selected cases [62,63]. However, a definitive operative revision is at times required. Effective options include a revision of the pancreaticoenterostomy or a lateral pancreaticojejunostomy [61].

### Pancreatogenic Diabetes Mellitus

Pancreatogenic diabetes mellitus (Type 3c) is a subtype of secondary diabetes (Type 3) and refers to any diabetogenic process that results from damage or loss of pancreatic tissue. Notably, this form of diabetes is unique in that glucagon (α-cells), pancreatic polypeptide-producing cells, and exocrine acinar cells are also lost. Diabetes mellitus (DM) and PDAC have a close "reverse causality" relationship [64]; while diabetes mellitus has been associated with increased risk for pancreatic cancer, PDA has also been associated with inciting new-onset DM both through pancreatic tissue destruction (Type 3c), as well as through a paraneoplastic phenomenon that results in the inhibition of insulin secretion and the exacerbation of peripheral insulin resistance (Type 2-like DM) [65].

Table 120.3 shows the reported prevalence of new-onset pancreatogenic diabetes after pancreatectomy across multiple studies. Exacerbation of existing diabetes is also observed in a large proportion of these patients. The occurrence of new-onset DM may be slightly higher after distal pancreatecomy, as compared to pancreaticoduodenectomy. Paradoxically, resection of the pancreatic tumor may also lead to resolution of diabetic symptoms of DM in a small number of patients (although etiology is unclear, this may be related to the nearly universal weight loss of 10–15% after pancreatectomy) [66,67]. Due to the high frequency of new-onset or worsening of diabetes after pancreatic resection, this complication should be specifically addressed with patients prior to resection, via education and discussion.

### Pancreatic Exocrine Insufficiency

Pancreatic exocrine insufficiency occurs in roughly half of patients undergoing pancreaticoduodenectomy [70,73,74]. The mechanism of parenchymal loss is similar to pancreatogenic diabetes, and in fact, exocrine insufficiency is one of the major criteria used to make the diagnosis of Type 3c DM [64]. Symptoms may include abdominal pain and bloating; pasty, floating, and foul-smelling stools; and fat-soluble vitamin deficiency (vitamins A, D, E, and K). Reported risk factors for post-pancreaticoduodenectomy exocrine insufficiency include preoperative pancreatic endocrine impairment, preoperative decreased pancreatic parenchymal thickness, hard gland texture, postoperative imaging showing decreased pancreatic parenchymal

**Table 120.3** Prevalence of pancreatogenic diabetes mellitus after pancreatectomy.

| Hirono et al. [74] | 199 | 59/90 (66%) | 38/99 (38%) | Type pancreatic reconstruction (PEI in PJ > PG), hard gland texture |

PPPD, pylorus-preserving pancreatoduodenectomy; PEI, pancreatic exocrine insufficiency; PG, pancreatogastrostomy; PJ, pancreatojejunostomy.

thickness, and postoperative dilatation of the main pancreatic duct [73–76]. A summary of reported rates and risk factors of pancreatic exocrine insufficiency is provided in Table 120.4. This complication, although not fatal or debilitating, has been shown to be associated with a significant reduction in the quality of life [77]. The treatment consists of oral pancreatic enzyme replacement with meals. Recommended doses are in the range of 18,000 to 30,000 USP units of lipase. Of note, gastric pH should be maintained above 4.0 to prevent enzyme inactivation [78].

## Nonalcoholic Fatty Liver Disease

Increased hepatic fat deposition is a newly reported complication after pancreaticoduodenectomy [80], and in some cases it can progress to nonalcoholic fatty liver disease (NAFLD). NAFLD attributable to pancreaticoduodenectomy is defined as hepatic steatosis (proven by imaging or by histology) without other causes for secondary hepatic fat accumulation, such as significant alcohol intake, steatogenic medications or genetic disorders [81]. As this chronic condition progresses, the functional reserve of the liver diminishes and hepatic insufficiency may ensue [82]. This may assume increased relevance in patients with PDAC who receive chemotherapy, which itself carries an independent risk of hepatotoxicity [83,84]. The prevalence of post-pancreaticoduodenectomy NAFLD has been estimated at between 8% and 40% [85–88], although the exact mechanism of this complication remains unknown. Sato et al. evaluated postoperative imaging studies in 110 patients who underwent a pancreaticoduodenectomy over a 6-month period, and observed that decreased pancreatic volume was associated with NAFLD. Tanaka et al. [88], studied the physical and biochemical profiles in patients with NAFLD after pancreaticoduodenectomy, and noted a low BMI, decreased insulin resistance [89], and decreased serum levels of cholesterol, apolipoprotein B, and albumin. Since these findings are consistent with pancreatic exocrine insufficiency, an increased dosage of oral pancreatic enzyme supplements was evaluated as a possible therapy, and the intervention indeed reversed these biochemical abnormalities in a number of patients. Additionally, associated imaging findings of steatohepatitis improved. The findings were reproduced by Nagai et al. in a separate study [90]. Therefore, it may be advisable to initiate or

augment oral pancreatic enzyme supplementation in patients with post-pancreaticoduodenectomy NAFLD. Future studies are needed to determine if enzyme supplementation should be recommended indefinitely in all patients (or only those at highest risk) in order to prevent this complication.

### Incisional Hernia

Available literature regarding the incidence of incisional hernia post-pancreatic surgery is scarce, yet in our experience, the complication is frequently encountered. The risk can be extrapolated from the overall abdominal surgical literature. A meta-analysis of 14,618 patients (56 studies) undergoing a wide variety of surgical procedures reported a prevalence rate of 12.8% [91] at approximately 2 years after the index procedure. Risk factors for incisional hernia after abdominal surgery include obesity, history of smoking, previous abdominal surgery, and postoperative wound infection [92–94]. The incisional rate would be expected to improve substantially when a minimally invasive approach is utilized [95,96].

### Pyogenic Liver Abscess

Biliary-enteric anastomoses result in chronic colonization of the biliary tract with enteric flora (bactibilia) due to the absence of the sphincter of Oddi. This is generally of no clinical consequence, because of continuous biliary drainage and decompression. However, colonized bile ducts place patients with infarcted, injured, or necrotic liver parenchyma at risk for pyogenic liver abscesses. This can occur due to liver infarction from a retractor injury at the time of a pancreaticoduodenectomy, or as a result of parenchymal injury related to liver-directed therapies used to treat hepatic metastases, such as hepatic arterial embolization or ablative procedures. Of note, these therapies are rarely performed for patients with conventional PDA at this time, and are more relevant for patients with metastatic neuroendocrine carcinoma. In a large study from Memorial Sloan Kettering Cancer Center, the liver abscess rate in patients undergoing hepatic arterial embolization was 33% for patients with prior biliary-enteric anastomosis, but just 0.05% in other patients [97]. The risk of a liver abscess with any liver-directed therapy after pancreaticoduodenectomy was observed to be around 10% in a separate large multi-institution study [98]. Patients found to have zones of infarct identified after pancreaticoduodenectomy, either from retractor injury or typically accessory hepatic arterial ligation should be vigilantly monitored for the development of potentially life-threatening liver abscesses that can develop with immunosuppression related to adjuvant chemotherapy. Extra caution is necessary for patients who develop liver abscesses in the early postoperative period. Most liver abscesses can be managed effectively with antibiotics and percutaneous drainage if diagnosed in a timely manner.

## Conclusions

Long-term survival has only marginally improved after resection for pancreatic cancer, but this progress cannot be attributed to significant advances in pancreatic cancer medical therapy. The possibility of recurrence persists, even after many years. Novel effective therapies will likely emerge from ongoing innovative basic and translational work in the near future. As patients experience improved survival, the aforementioned late complications will become increasingly important. Pancreatic surgeons should be mindful of the rates and risks of each of these complications and discuss them with their patients. Future studies aimed at reducing these risks are therefore needed.

## Introduction

Neuroendocrine tumors (NET) of the pancreas are a heterogeneous group of epithelial neoplasms with a highly variable clinical presentation, malignant potential, and prognosis. Pancreatic NET (PanNET) range from small, slow-growing, incidentally detected nonfunctional and/or functional tumors to frank aggressive malignancies. These lesions were earlier described as "islet-cell tumors" based on the belief that they originate from the cells in the islets of Langerhans. They were later considered to be "pancreatic endocrine tumors" when evidence suggested that they might originate from pluripotent cells in the ductal epithelium [1,2]. The latest World Health Organization (WHO) 2010 classification system [3] recommended the use of the term "neuroendocrine" to describe these tumors as they are now considered to arise from cells that are part of the diffuse neuroendocrine cell system of the gastrointestinal tract and pancreas; these cells share certain unique biochemical (capability to synthesize, store, and secrete a number of amines and peptides) and immunohistochemical properties (documentation of markers of neuroendocrine differentiation, mainly expression of antigens commonly expressed by neuronal elements such as chromogranin A and synaptophysin, together with neuron-specific enolase) [4].

## Epidemiology of Pancreatic Neuroendocrine Tumors (Table 121.1)

Data on the epidemiology of PanNET is limited. Variations in coding and classification over time, and between different countries, have resulted in difficulties in precisely understanding the true epidemiology of these tumors. Moreover, various national, regional, and institutional cancer or NET registries, with their inherent deficiencies in data collection, happen to be the major sources of epidemiology of PanNET. The PanNET are rare tumors that possibly constitute <3% of all pancreatic tumors [5], and approximately 4–8% of all neuroendocrine tumors [6]. The annual incidence rate of PanNET is reportedly less than one per 100,000 person-years in population studies [5]. The absolute annual incidence rate of PanNET varies among registries in various countries, with PanNET ranging from the most common to the second most common site among gastroenteropancreatic NET.

The incidence of PanNET is higher in autopsy studies, ranging from 0.1 to 10% [5]. Grimelius et al. in Sweden reported 13 pancreatic "islet cell adenomas" at autopsy among 1366 adults (0.8%) [7]. Kimura et al. in Japan found 20 "endocrine tumors of the pancreas" among 800 autopsy cases (mean age 78.7 years); the incidence of tumors was higher among the 60 randomly selected cases that had 5 mm thick sections of the pancreas; six (10%) of them were found to have an endocrine tumor as opposed to only 12 out of 738 cases (1.6%) that had histologic studies of three random sections of the pancreas [8]. Lam and Lo in Hong Kong found 13 cases (0.1%) of "pancreatic endocrine tumors" among 11472 autopsies performed from 1972 to 1995 [9].

There has been a rise in the incidence and prevalence of PanNET over the past few decades; this could either reflect a true increase in incidence or be the result of an increased awareness of these tumors together with availability of more sensitive imaging techniques leading to their increased detection [10,11]. The PanNETs are most

common between ages 60 and 80 years, with an earlier age of onset in patients with multiple endocrine neoplasia type 1 (MEN1).

## Classification

The classification of PanNET has changed periodically since the first attempts at classification of these tumors were made in the early 1960s. They can be classified based upon:

I) Functionality as "functional or nonfunctional."
II) Association with inherited syndromes as "sporadic or syndromic."
III) Tumor biology and morphologic features.
IV) Evaluation of spread as "tumor–node–metastasis (TNM) classification."

### I. Functional Versus Nonfunctional PanNET (Table 121.2)

"Functional PanNET" are associated with a hormone-secreted clinical syndrome. The clinical presentation of these tumors is dominated by the metabolic effects of the excess hormone(s) secreted by the tumor, and they are classified based upon the predominant clinical syndrome produced by the hormone secreted by the tumor. There is a poor correlation between peptide expression on immunohistochemical staining of the tumor and the circulating levels of the respective secretory products; thus, the mere presence of positive immunohistochemical staining is not a defining criterion for a "functional" PanNET. The European Neuroendocrine Tumor Society (ENETS) Consensus Guidelines for the management of functional PanNET syndromes divides functional PanNET into "most common functional PanNET syndromes," "established rare functional PanNET syndromes," and "possible rare functional PanNET syndromes" [12]. Of the many established and possible functional PanNET, the two that are more commonly seen in clinical practice are insulinomas and gastrinomas.

"Nonfunctional PanNET" do not produce any specific hormone-secreted clinical syndromes. They are either detected incidentally during imaging or present with symptoms attributable to the mass effect due to tumor bulk or distant metastases. Although some of them do not produce any amines or peptides, most do secrete substances such as chromogranin, pancreatic polypeptide, neurophysin, neuron-specific enolase, alpha subunit of human chorionic gonadotropin, and other peptides that do not result in any specific clinical syndrome.

Earlier reports suggested a preponderance of functional PanNET as they presented with recognizable clinical syndromes and were thus easier to identify. However, over the past two decades, nonfunctional PanNET have become the more common PanNET as a result of improvements in imaging techniques and increased detection rates [10,11].

The differentiation of PanNET based on functionality does not shed light on their biological behavior or help predict their long-term prognosis in the majority of situations; the one exception is insulinoma, which in the majority of cases runs an indolent course. As such, the biological behavior of functional PanNET should also be classified as one would classify a nonfunctional PanNET, including the grade and stage of the tumor. However, it is essential to identify and classify functional PanNET because they produce classic hormone-secreted clinical syndromes that require dedicated investigations, therapeutic interventions, and structured long-term follow-up.

### II. Sporadic Versus Syndromic PanNET (Table 121.3)

Less than 10% of PanNET are associated with inherited disorders. The four common inherited disorders that manifest a PanNET are multiple endocrine neoplasia type 1 (MEN1), von Hippel–Lindau syndrome (VHL), neurofibromatosis type 1 (von Reclinghausen disease) (NF1), and tuberous sclerosis complex (TSC) [13].

Approximately 80–100% of patients with MEN1, 10–17% of patients with VHL, up to 10% of patients with NF1 and 1% of patients with TSC will develop a PanNET within their lifetime [13]. The PanNET associated with inherited disorders are frequently multifocal. As with functional PanNET, the association of these tumors with a specific

**Table 121.2** Functional pancreatic neuroendocrine tumors.

| Tumor type | Endocrine hormone secreted | Approximate incidence (patients per million per year) | Likelihood of malignancy (%) |
|---|---|---|---|
| **More common** | | | |
| Insulinoma | Insulin | 2 | <10 |
| Gastrinoma | Gastrin | 1 | >50 |
| **Less common** | | | |
| Glucagonoma | Glucagon | 0.05 or more | >50 |
| VIPoma | Vasoactive intestinal peptide | 0.05 | >50 |
| Somatostatinoma | Somatostatin | Rare | >50 |
| ACTHoma | Adrenocorticotrophic hormone | Rare | >50 |
| GRFoma | Growth hormone-releasing hormone | Rare | >50 |
| "Classical" carcinoid syndrome | Serotonin | Rare | >50 |
| PTHrPoma | Parathyroid hormone-related peptide | Rare | >50 |
| **Rare** | | | |
| Calcitoninomas | Calcitonin | Very rare | >50 |
| **Others (may be mixed)** | | | |
| Hormones | "Big IGF-II," erythropoietin, luteinizing hormone, renin | Very rare | Unknown |

*Source:* Adapted from Jensen RT et al. Neuroendocrinology 2012;95:100.

**Table 121.3** Pancreatic neuroendocrine tumors associated with hereditary syndromes.

| Syndrome | Gene location | Incidence (%) | Tumor type | Location |
|---|---|---|---|---|
| MEN1 | 11q13 | 80–100 | Nonfunctional, gastrinoma, insulinoma | Pancreas Duodenum |
| VHL | 3p25 | 12–17 | Nonfunctional | Pancreas |
| NF1 | 17q11 | 6 | Somatostatinoma | Pancreas |
| TSC | 9q34 (TSC 1) 16p13.3 (TSC 2) | <5 | – | Pancreas |

*Source:* Adapted from Chen M et al. J Gastrointest Oncol 2012;3:184.

inherited syndrome does not help predict their biological behavior or long-term prognosis. However, it is important to recognize a syndromic PanNET not only to help initiate a diligent search in the index patient to identify the multifocal pancreatic and extrapancreatic tumors but also to allow early and periodic surveillance of family members.

## III. Based on Tumor Biology and Morphologic Features (Tables 121.4–121.8)

Over the years, the classification of this rare group of tumors has evolved and a number of earlier classification systems exist. Most classification systems do make a clear and sharp distinction between well-differentiated PanNET and poorly differentiated neuroendocrine carcinoma (PD-NEC) that have an aggressive course with poor prognosis. Morphologic features of the tumor, extent of local/distant spread, and aggressiveness of the tumor are common to most classification systems. It should be emphasized that almost all PanNET are potentially malignant, and can metastasize, even after many years.

The salient classification systems proposed over the years for PanNETs include the following:

1) Capella classification system 1995 [14].
2) Armed Forces Institute of Pathology (AFIP) classification system 1997 [15].
3) Memorial Sloan Kettering classification system 2002 [16].
4) WHO classification system 2004 [17].

**Table 121.4** WHO classification of pancreatic neuroendocrine tumors (2004).

| Factor | Well-differentiated endocrine tumor: benign behavior | Well-differentiated endocrine tumor: uncertain behavior | Well-differentiated endocrine carcinoma | Poorly differentiated endocrine carcinoma | Mixed exocrine and endocrine tumors |
|---|---|---|---|---|---|
| Biological behavior | Benign behavior | Uncertain behavior (benign or low-grade malignant) | Low-grade malignant | High-grade malignant | |
| Infiltration/ metastases | Confined to the pancreas | Confined to the pancreas | Invasion of adjacent organs and/or metastases | Gross local invasion and/or metastases | |
| Tumor size | <2 cm | ≥2 cm | | | |
| Vascular/ perineural invasion | No vascular invasion<br>No perineural invasion | Vascular invasion<br>Perineural invasion | | | |
| Mitoses | <2 mitoses per 10 HPF | 2–10 mitoses per 10 HPF | | | |
| Ki-67 labeling index (%) | <2 | >2 | | | |
| Functionality | Insulinoma or nonfunctional | Functional or nonfunctional | Functional or nonfunctional | - | |

*Source:* Adapted from Klöppel et al. 2004 [17].

**Table 121.5** ENETS 2006 grading proposal for pancreatic neuroendocrine tumors.

| Grade | Mitotic count per 10 HPF[a] | Ki-67 labeling index (%)[b] |
|---|---|---|
| Grade 1 (G1) | <2 | ≤2 |
| Grade 2 (G2) | 2–20 | 3–20 |
| Grade 3 (G3) | >20 | >20 |

[a] 10 HPF = 2 $mm^2$, at least 40 fields (at 40× magnification; evaluated in areas of highest mitotic density).
[b] MIB1 antibody; percentage of 2000 tumor cells in areas of highest nuclear labeling.

5) ENETS TNM staging and grading system 2006 [18].
6) WHO classification 2010 [3].
7) Union for International Cancer Control (formerly International Union Against Cancer)/American Joint Cancer Committee and WHO (UICC/AJCC/WHO) TNM classification 2010 [19].

We shall restrict ourselves in this chapter to describing in detail the WHO 2004 classification system [17], the WHO 2010 classification system for GEP-NET [3], the ENETS TNM staging and grading classification system proposed in 2006 (ENETS 2006 TNM) [18], and the UICC/AJCC/WHO 2010 TNM classification [19]. It will become evident that although considerable efforts have been made to arrive at a consensus, no single classification system has gained universal acceptance.

#### WHO Classification of PanNET 2004 (Table 121.4)

The WHO 2004 classification system divided PanNET into well-differentiated endocrine tumors with benign behavior, well-differentiated endocrine tumors with uncertain behavior, well-differentiated endocrine carcinomas (WDEC), poorly differentiated endocrine carcinomas (PDEC), and mixed exocrine and endocrine tumors [17]. Unlike the earlier 1995 Capella classification system [14], apart from staging parameters (such as tumor size, invasion of adjacent structures, and metastases), grading parameters (such as the aggressiveness of the tumors, as assessed by the mitotic activity, and/or Ki-67 labeling index) were introduced to refine prognostication. Unlike the earlier 2002 Memorial Sloan Kettering classification system [16], which included presence of necrosis for grading, the WHO 2004 classification was based solely on the proliferative rate of the tumor as reflected by the mitotic activity and/or Ki-67 labeling index for grading. This classification was tested clinically and was found to have prognostic relevance [20].

The WHO 2004 classification system for PanNET was a hybrid of staging and grading; an attempt at classification of PanNET was made based not only on staging parameters but also on the grade of the tumor. However,

**Table 121.7** TNM classification and disease staging for endocrine tumors of the pancreas (ENETS 2006).

| Definition | ENETS TNM |
|---|---|
| T definition | Primary tumor |
| TX | Primary tumor cannot be assessed |
| T0 | No evidence of primary tumor |
| T1 | Limited to the pancreas and size <2 cm |
| T2 | Limited to the pancreas and size 2–4 cm |
| T3 | Limited to the pancreas and size >4 cm or invading duodenum or bile duct |
| T4 | Invading adjacent organs (stomach, spleen, colon, adrenal gland) or the wall of large vessels (celiac axis or superior mesenteric artery) |
| – | For any T, add (m) for multiple tumors |
| N definition | Regional lymph nodes |
| Nx | Regional lymph node cannot be assessed |
| N0 | No regional lymph node metastasis |
| N1 | Regional lymph node metastasis |
| M definition | Distant metastasis |
| Mx | Distant metastasis cannot be assessed |
| M0 | No distant metastasis |
| M1 | Distant metastasis |
| Stage definition | |
| Stage I | T1, N0, M0 |
| Stage IIa | T2, N0, M0 |
| Stage IIb | T3, N0, M0 |
| Stage IIIa | T4, N0, M0 |
| Stage IIIb | Any T, N1, M0 |
| Stage IV | Any T, any N, M1 |

tumor stage and grade have independent prognostic significance. Moreover, the WHO 2004 classification system did not allow for the application of the grading system to advanced stages of the disease; an advanced PanNET need not necessarily be very aggressive; this is evident especially in metastatic PanNET, wherein, depending upon tumor grade, some metastatic diseases remain indolent for prolonged periods whereas others progress rapidly.

#### ENETS TNM Staging and Grading System 2006 (Tables 121.5 and 121.7)

In 2006, the ENETS proposed a TNM staging system of foregut NET (including PanNET), which also included a grading system [19]. The ENETS 2006 TNM classification system effectively separated staging from grading. It was realized that unlike poorly differentiated endocrine carcinomas (PDEC), where the behavior of the tumor is more aggressive and predictable, it was difficult to predict the behavior of well-differentiated PanNET, which could range from being indolent to the more aggressive forms. It was therefore decided to subdivide well-differentiated PanNET into two grades to help prognosticate them better based on proliferation markers of mitoses and Ki-67 labeling index. They proposed that mitoses should be counted in at least 40 high-power fields (HPF) in areas where they are most frequent, and expressed as number of mitoses per 10 HPF (2 $mm^2$). Only clear-cut mitotic figures should be counted. For Ki-67 protein assessment, they recommended that the labeling index should be assessed in 2000 tumor cells in areas where the highest nuclear labeling is observed. Ki-67 is a nuclear protein expressed in dividing cells closely associated with the nucleolus and heterochromatin. The monoclonal MIB-1 antibody is used for labeling.

Pancreatic NET were divided into three tumor categories: grade 1 (G1), grade 2 (G2), and grade 3 (G3) based on the number of mitoses seen per 10 HPF and/or the percentage of tumor cells that stain for Ki-67. In general, G1 and G2 refer to well-differentiated PanNET and G3 indicates poorly differentiated neuroendocrine carcinoma.

#### WHO Classification 2010 (Table 121.6)

The updated WHO 2010 classification aimed to standardize the classification system for GEP-NET [3]. It uses a proliferation-based grading system together with the classical histologic features-based classification. It emphasizes the malignant potential of PanNET.

It divides PanNET into "neuroendocrine tumors" (NET), which include low to intermediate-grade, well to moderately differentiated PanNET, and "neuroendocrine carcinomas" (NEC), which include high-grade, moderately to poorly differentiated PanNET. The WHO 2010 classification endorsed the grading system proposed by the ENETS 2006 TNM staging and grading system; based on the proliferative rate of the tumor (mitotic count per 10 HPF and/or Ki-67 labeling index), PanNET were divided into three grades, G1–G3. Grade 1 (G1) and grade 2 (G2) tumors referred to NET, whereas NEC were all uniformly high-grade tumors (G3). In cases of discordance between mitotic count and Ki-67 labeling index in assessing proliferation rate, the WHO 2010 classification system recommends using the higher grade of either mean.

Unlike the WHO 2004 classification, the updated WHO 2010 classification system separated grading from staging. Classification is based primarily upon the proliferative rate of the tumor rather than stage-pertinent features such as size of tumor, regional invasion, or distant metastases. Instead, the WHO recognized the need for a

separate staging system and, in 2010, together with the AJCC, endorsed the TNM staging system developed in 2009 by the UICC (UICC/AJCC/WHO 2010 TNM) [19]. This separation of grading from staging, which was earlier proposed by the ENETS in the 2006 TNM classification system, allows for prognostication of PanNET even when sufficient information is not available for staging, a not too infrequent scenario in clinical practice, when only small biopsy specimens are available for assessment of the grade of the tumor but detailed clinical assessment, including size and invasion, is lacking.

#### TNM Staging System (Tables 121.7 and 121.8)

The TNM staging system is an instrument for prognostication, allowing death-risk assessment at diagnosis, and guiding therapy. The ability to stratify patients into different stages at diagnosis reflecting increasingly worsening prognosis allows for planning of progressively more aggressive therapy. The success of the TNM staging system depends to a large extent on its ability to reflect the biology and natural history of the cancer. Well-differentiated PanNET, which are much more common than the more aggressive poorly differentiated PanNET, are biologically different from adenocarcinoma of the pancreas: they are larger in size, more indolent, late to metastasize, run a long course despite widespread metastases, and overall have a much better prognosis than adenocarcinoma of the pancreas.

A TNM staging system for PanNET was first proposed in 2006 by ENETS [18]. Subsequently, in 2009, the UICC released the seventh edition of the TNM classification of malignant tumors, which included a TNM staging system for well-differentiated PanNET [19]; this staging system was subsequently endorsed by both the AJCC and the WHO (UICC/AJCC/WHO TNM 2010). Tumor definition and the derived stages differ slightly between the two staging systems; as a result, although both systems use identical TNM terminology, they refer to slightly different extents of disease.

The ENETS TNM 2006 staging system has subsequently been validated by a number of series reporting on PanNET [21,22]. Since its introduction over 10 years ago, it has been widely used in Europe, with good prognostic discriminatory power among the various stages of PanNET. In contrast, the UICC/AJCC/WHO TNM 2010 staging system was introduced more recently; although a number of centers in the United States have been mandated to use this system, independent validation of this system is currently limited [23].

Overall, both TNM staging systems are predictive of patient outcome and, when combined with classification based on histologic and proliferative features, help stratify PanNET into groups of increasing malignant potential. However, a comparison between the two TNM staging systems, analyzing 891 patients from eight European centers, found the ENETS 2006 TNM staging system to be superior and more accurate than the UICC/AJCC/WHO 2010 TNM staging system [24]. However, this used a retrospective dataset and the management of PanNET was not standardized amongst the eight participating centers. Further modifications of the TNM staging system should be undertaken only after carefully analyzing the ability of the two existing systems in prognosticating PanNET, which should be assessed by collecting data using uniform protocols in a prospective manner. Until the adoption of such a unified TNM staging system, when reporting one should clearly mention which of the two systems was used for TNM staging. Since the discrepancy between the two staging systems is primarily limited to "tumor" staging, it is important to record the features that contributed to the "tumor" staging (tumor size and extent of invasion) to allow comparison between reported series using the alternative TNM staging system.

## Conclusions

Pancreatic NET should be classified based upon the WHO 2010 classification system into NETs (G1 or G2) and NECs (G3). Grading should be assessed using both the number of mitoses per 10 HPF and also the Ki-67 labeling index; however, if the specimen size is small, such as a biopsy specimen, with insufficient HPF for examination for mitoses, then grading can be based solely on the Ki-67 labeling index. In the rare event of discordance between the two markers of proliferation rate, the higher grade should be used. PNET should also be staged, whenever possible, using one of the two existing TNM staging systems (ENETS 2006 or UICC/AJCC/WHO 2010 TNM staging system). When reporting, care should be taken to mention the TNM staging system used, and details of the tumor size and extent of spread should be clearly recorded. The WHO 2010 classification and a TNM staging system should be applied to all PanNETs irrespective of whether they are functional or nonfunctional, syndromic or sporadic.

Future refinements in classification can be expected because the current existence of two parallel TNM staging systems that describe different extents of disease while using the same TNM terminology is confusing. Moreover, the current classification systems do not allow a clear separation of tumors, fortunately few in number, that predominantly exhibit features of a well-differentiated NET with low proliferative rates but have a few regions that have a much higher proliferative rate and increased cytologic atypia. Recently, it has also been noted that the clinical behavior of a small subset of

PanNET that are G2 by mitotic count (<20 mitoses per 10 HPF) but G3 by Ki-67 labeling index (>20%) is intermediate between that of G2 and G3 PanNET [25]. It would therefore seem that G3 PanNET as defined by the WHO 2010 classification are heterogeneous and need better delineation; they not only include a small subset of tumors that are well differentiated but have a higher proliferation index, but also another subset of tumors that are G3 but have a Ki-67 labeling index between 20 and 55% that seem to survive longer than those with Ki-67 index >55%. Moreover, currently it remains unclear whether well-differentiated G1 and G2 NET can transform and evolve into poorly differentiated NEC.

Collection of prospective data using unified management protocols over the coming years should lead to refinement of the classification system in the future and, it is hoped, the emergence of a unified TNM staging system. However, until that time, the WHO 2010 classification system, together with the use of either one of the two TNM staging systems, should remove much of the earlier controversy surrounding the classification of these rare endocrine tumors of the pancreas, allowing proper prognostic stratification, guiding appropriate stage- and grade-specific therapy, and enabling evaluation of new therapies and comparison of results of published therapeutic trials on PanNET.

## WHO Classification and TNM Classification

The World Health Organization (WHO) classification published in 2017 divides pancreatic neuroendocrine neoplasms (PanNENs) into well-differentiated and poorly differentiated neuroendocrine neoplasms. The former is further subclassified into neuroendocrine tumor (NET) G1, NET G2, and NET G3, based on the mitotic and Ki-67 indices (NET G1: mitoses<2/10 HPF (high-power view) and Ki67 index <3%; G2 NET: mitoses 2–20/10 HPF or Ki67 index 3%–20%; NET G3: mitoses >20/10 HPF or Ki67 index >20 %) (Table 122.1) [1]. NET G3 is a newly introduced tumor category in the 2017 WHO classification that retains well-differentiated histology but presents high proliferative activity. The latter is high-grade pancreatic neuroendocrine carcinoma (PanNEC) presenting high proliferative activity (mitoses >20/10HPF or Ki67 index >20%), and categorized as NEC G3. NEC G3s are subtyped into small cell and large cell NEC based on the cell size and cellular feature. Both NET G3 and NEC G3 demonstrate high proliferative activity (Ki67 index>20%) but the clinical presentations of patients with NET G3 are more indolent than those with NEC G3 [2–4]. The morphological and immunohistochemical characteristics of the two high-grade neoplasms will be discussed in the Immunohistochemistry and Differential Diagnosis section. Nuclear labeling of Ki-67 should be counted in 500–2000 tumor cells. The Ki-67 index is usually higher than the mitotic index for identical tissues. Because the determination of the Ki-67 index of the tumor is highly significant for the estimation of aggressiveness and determination of therapeutic strategies, optimal evaluation methodologies, including automated counting, have been discussed [5,6]. Despite the high expected reproducibility of automated digital evaluation, it does not seem to be a realistic tool for routine diagnosis because of the low cost–benefit and its operator-dependent acquisition of morphology and/or color of the image [5]. Manual counting on the printed image may improve an "eyeball estimate" under microscopic observation. Based on the original proposal published by the European Neuroendocrine Tumor Society (ENETS), the mitotic index is defined as the total mitotic counts per $2\,mm^2$. Mitosis may distribute heterogeneously; therefore, it is recommended to observe a wider area (50 HPF) and select areas with the highest density of mitosis.

Mixed tumors of endocrine and exocrine components are categorized as a unique entity of mixed neuroendocrine-nonneuroendocrine neoplasm (MiNEN), which was termed mixed adenoneuroendocrine carcinoma (MANEC) in the previous classification [7]. MiNEN comprises at least 30% of both endocrine and exocrine components. The histology of NENs and MiNENs is further described in the Microscopy section.

In the 8th edition of TNM classification for malignant tumors by Union for international cancer control (UICC TNM), the TNM classification systems for PanNETs (NET G1, G2, G3) and PanNECs were separately stated. However, the differences between the two classifications were limited, only seen in pT1, pN1, and pM1 categories (Table 122.2) [8].

## Macroscopy

The macroscopic features of PanNENs are variable. Well-circumscribed tumors displaying a whitish tan to yellowish cut surface are most commonly encountered (Fig. 122.1a). The tumor size at the time of surgery varies

Companion website: www.wiley.com/go/beger/thepancreas

from <1 to 20 cm in diameter. Insulinomas are generally detected as small lesions (<2 cm), whereas nonfunctioning PanNET are usually detected as larger lesions. Cystic degeneration is often associated with glucagon production by the tumor cells (Fig. 122.1b) [9]. PanNECs usually exhibit unclear boundaries (Fig. 122.1c). Necrosis is not uncommon in PanNECs (Fig. 122.1c).

**Table 122.1** WHO 2017 classification of pancreatic neuroendocrine neoplasms [1].

| | Mitotic index (per 10HPF) | Ki-67 index (%) |
|---|---|---|
| Well-differentiated NENs | | |
| NET G1 | <2 | <3 |
| NET G2 | 2–20 | 3–20 |
| NET G3 | >20 | >20 |
| Poorly differentiated NENs | | |
| NEC G3 | >20 | >20 |

## Microscopy

Initially, morphologic observation is used to determine histopathologic differentiation, which should be further confirmed by immunohistochemistry.

G1 and G2 NET display well-differentiated morphology. Tumor cells of well-differentiated NENs are uniform in size and shape, having round to oval nuclei, with a coarsely granular (so-called salt-and-pepper) chromatin pattern (Fig. 122.2a). Nucleoli may be observed but are mostly inconspicuous (Fig. 122.2a). The cytoplasm of the tumor cells is mostly granular and appears to be slightly eosinophilic. The tumor cells form characteristic architectural patterns, such as anastomosing ribbon-like nests (Fig. 122.2b), trabecular nests (Fig. 122.2b), a glandular pattern (Fig. 122.2c), and a gyriform or solid growth pattern (Fig. 122.2d). Capillary or fibrocapillary stroma intervenes within tumor cell nests (Fig. 122.2a–h). The extent of fibrosis or hyalinosis varies among cases. Amyloid-like deposition of islet amyloid polypeptide is a characteristic feature of functioning NEN, especially

**Table 122.2** Two TNM classification of pancreatic neuroendocrine neoplasms listed in the 8th edition of Union for International Cancer Control (UICC) TNM classification for malignant tumors. The two different TNM classifications, one for well-differentiated tumor (NET G1, G2, G3), the other is for poorly differentiated neuroendocrine carcinoma and other pancreatic neoplasms [8].

| | Well-differentiated neuroendocrine tumors | Poorly differentiated neurondocrine carcinoma |
|---|---|---|
| Primary Tumor (T) | | |
| TX | Cannot be assessed | Cannot be assessed |
| T0 | Not evident | Not evident |
| T1 | Limited to the pancreas, <2 cm | T1a Limited to the pancreas, 0.5 cm or less |
| | | T1b Limited to the pancreas, 0.5 cm ≤, < 1 cm |
| | | T1c Limited to the pancreas, 1 cm ≤, < 2 cm |
| T2 | Limited to the pancreas, 2-4 cm | Limited to the pancreas, 2-4 cm |
| T3 | Limited to the pancreas, >4 cm, or invasion of duodenum or bile duct | Limited to the pancreas, >4 cm, or invasion of duodenum or bile duct |
| T4 | Invading adjacent organs (stomach, spleen, colon, adrenal grand) or the wall of large vessels (celiac axsis or the superior mesenteric artery) | Invading adjacent organs (stomach, spleen, colon, adrenal grand) or the wall of large vessels (celiac axsis or the superior mesenteric artery) |

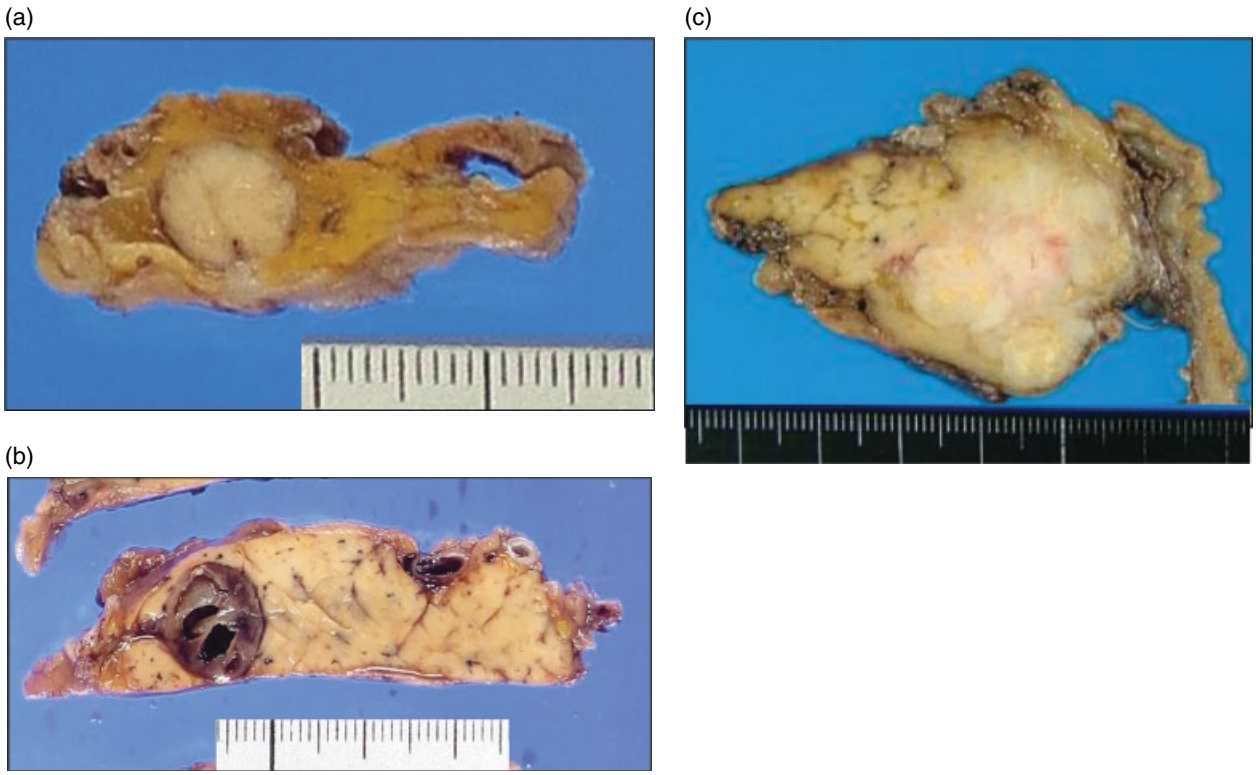

**Figure 122.1** Macroscopic images of pancreatic neuroendocrine neoplasms (PanNENs). (a) A round to oval-shaped, well-circumscribed tumor with a whitish tan cut surface observed in NET G1. (b) A well-demarcated tumor with cystic changes observed in G1 PanNET NET G1. (c) A tan–white and focally yellowish tumor with unclear boundaries observed in large-cell neuroendocrine carcinoma (large cell NEC G3).

insulinoma (Fig. 122.2e). Psammomatous calcification may be identified in gland-like small cavities of the tumor nests. Psammomatous calcifications suggest somatostatin production by the tumor cells, which is more frequently observed in the duodenum than in the pancreas. Tumor cells exhibiting abundant eosinophilic cytoplasm are regarded as an oncocytic variant of PanNEN, which is caused by abnormal mitochondrial accumulation. Oncocytic NENs tend to display larger nuclei and conspicuous nucleoli (Fig. 122.2f). This variant has been reported to be associated with a higher incidence of lymph node metastasis; however, the biological implication of this particular variant remains unknown [10]. The differential diagnosis of oncocytic NENs and acinar cell carcinoma (ACC) is described in the Differential diagnosis section. A PanNEN characterized by abundant clear cytoplasmic vacuoles or foamy microvesicular cytoplasm is known as a clear cell or lipid-rich variant of NEN (Fig. 122.2g). Nuclei are pushed by lipid vacuoles and appear to be polygonal and pyknotic; therefore, characteristic round or oval nuclear features are not necessarily recognized. The association of this variant with von Hippel–Lindau syndrome (VHL) has been described. It is important to note that the morphology of this variant is similar to those of other pancreatic neoplasms displaying clear cytoplasm, such as a serous cystic neoplasm (SCN), clear cell variant of solid pseudopapillary neoplasm (SPN), and metastasis of clear cell renal cell carcinoma, or foamy cytoplasm, such as adrenocortical neoplasm (see Differential diagnosis section). The tumor that presents large and hyperchromatic nuclei with marked pleomorphism, without high proliferative activity or necrosis, is known as a pleomorphic variant of PanNEN (Fig. 122.2h). It is important to distinguish this variant from highly aggressive neoplasms, such as anaplastic carcinoma or large-cell NEC.

The heterogeneity of histologic and clinical presentations of PanNENs that present high proliferative activity (NET G3 and NEC G3) has been a contentious subject [2–4,11,12]. NET G3s morphologically remain well-differentiated neuroendocrine patterns, but often present larger nuclei and more conspicuous nucleoli than NET G1/G2s. NET G3s also often demonstrate large solid nests and necrosis. These morphologic features can result in difficulty in differentiating them from NEC G3s. Tumor cells of NEC G3 comprise cells with a high degree of nuclear pleomorphism, nuclear enlargement, and high nuclear–cytoplasmic ratio. Necrosis is abundant in most cases of PanNECs. Characteristic architectural patterns are less evident and mostly comprise diffuse growth patterns or large nests (Fig. 122.3a, b). Based on cell size, PanNECs are further divided into small-cell NEC

(Fig. 122.3a) and large-cell NEC (Fig. 122.3b). Because of the rarity of these high-grade neoplasms, the biological, molecular, and clinical differences between small- and large-cell NEC have not been fully established; however, small-cell NEC seems to display a higher proliferative index and has a more aggressive clinical course than large-cell NEC. Proliferative activity, especially the Ki-67 index of small- and large-cell NEC, is extremely high, mostly exceeding 50%. A possibility of transformation from PanNET to PanNEC has also been suggested [11]. Given the difficulty of defining absolute cut-off values of proliferative indices, it is reasonable to expect that NET G2 and NET G3 share common biological mechanisms and clinical presentations.

MiNEN is a heterogeneous neoplasm comprising both endocrine and exocrine components in which either component must represent at least 30%. Endocrine components of MiNEN can be present as either NET or NEC, and its exocrine components can also vary, for example, tubular adenocarcinoma, poorly differentiated adenocarcinoma, or ACC. Histogenesis of MiNEN in the pancreas is still not clear. Currently, the following two theories have been hypothesized: (i) multiple components arise independently and (ii) heterogeneous components originate from common multipotent progenitor cells. The clinical course of the tumor is generally defined by the most aggressive component of MiNEN; in most cases, the endocrine component is the most aggressive.

Multiple endocrine neoplasia type 1 (MEN1) is an autosomal dominant tumor syndrome characterized by multiple endocrine tumors arising in the

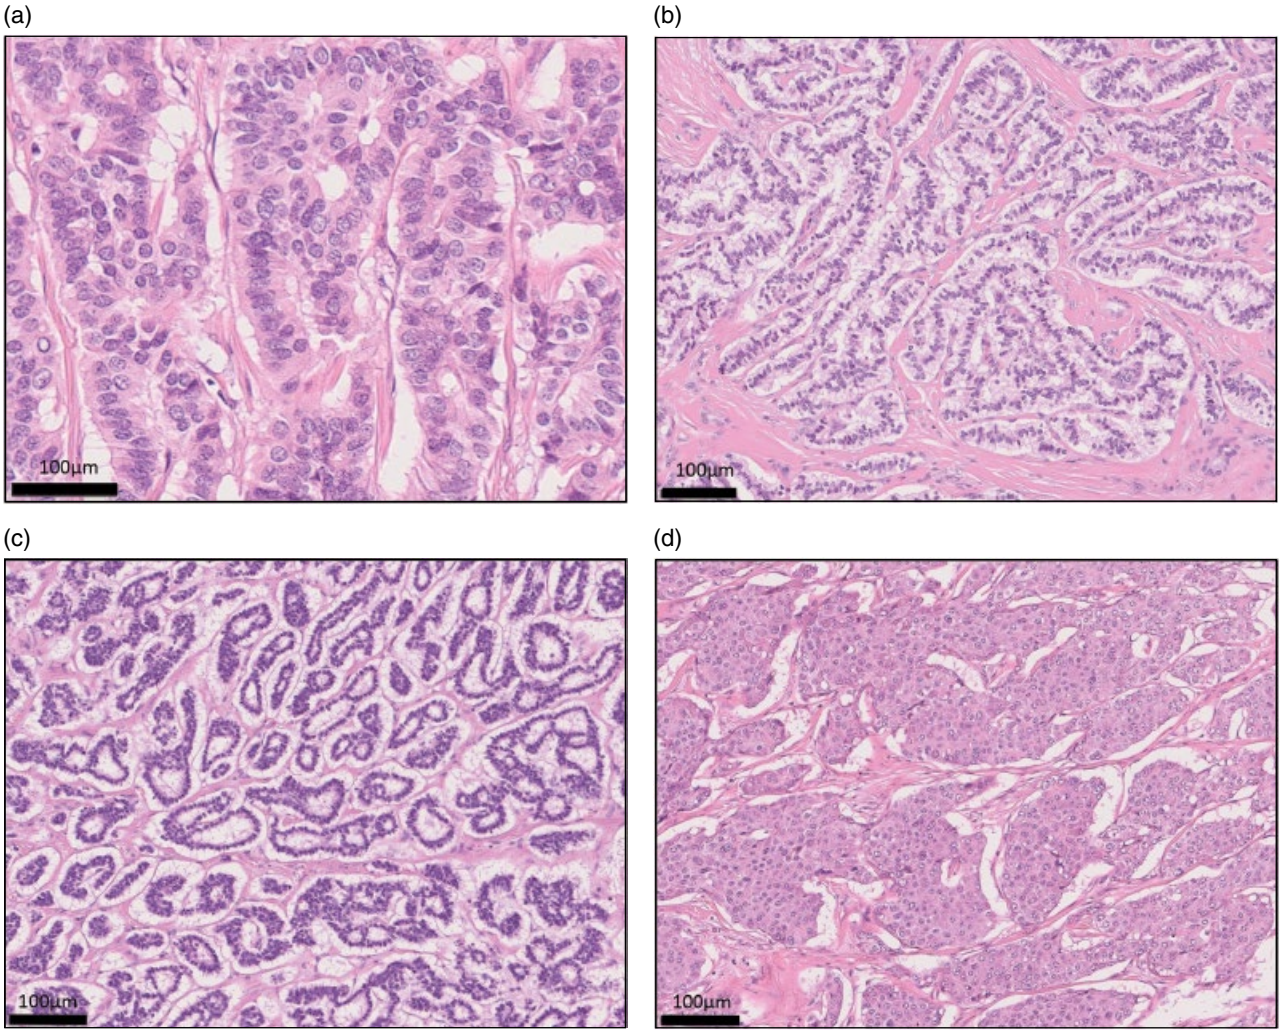

**Figure 122.2** Microscopic images of well-differentiated pancreatic neuroendocrine neoplasms (PanNENs) (NET [neuroendocrine tumor] G1 and G2). (a) Tumor cells display round to oval-shaped nuclei with coarsely granular so-called salt-and-pepper chromatin distribution. Tumor cells arranged in (b) anastomosing ribbon-like nests, (c) gland-like features, or (d) solid cell nests. (e) Marked amyloid-like deposition in insulinoma detected by direct Fast Scarlet staining. (f) An oncocytic variant of PanNEN. (g) A lipid-rich variant of PanNEN. (h) A pleomorphic variant of PanNEN. Abundant capillary or fibrocapillary stroma observed within tumor cell nests (a–h).

parathyroid, gastrointestinal tissue, pancreas, anterior lobe of the pituitary gland, and adrenal cortex. The histopathology of pancreatic lesions in patients with MEN1 is characterized by multiple microadenomas (microadenomatosis usually accompanied by macronodules) [13]. The multiple tumors observed in identical tissues of patients with MEN1 may produce variable hormones. Microadenomatosis of the pancreas is also associated with patients with VHL [13].

## Cytology

Owing to the development of the endoscopic ultrasound-guided fine-needle aspiration technique, cytology assessments have become a standard pathologic diagnostic tool for PanNEN. Cytology is one of the most powerful tools to determine the diagnosis of endocrine tumors, especially because of the characteristic nuclear morphology. Nuclei of tumors display a monotonous appearance; they are uniformly round to oval shaped, with a salt-and-pepper chromatin pattern or, often, plasmacytoid epithelial cells (Fig. 122.4a, b). Tumor cells of PanNETs are observed as variably sized, loosely cohesive clusters. Single cells are also frequently observed (Fig. 122.4a). Tumor cells surrounding and loosely attached to capillary vessels are frequently seen (Fig. 122.4b). A rosette-like arrangement is highly specific to PanNET, but similar arrangements may also be observed in ACC. Small- and large-cell NEC apparently exhibit higher nuclear pleomorphism and enlargement, often showing a necrotic background. PanNECs show low intercellular cohesiveness.

## Immunohistochemistry and Differential Diagnosis

Neuroendocrine differentiation of PanNEN is mostly suggested by morphologic assessment, but it must be further confirmed by immunohistochemistry. Chromogranin A

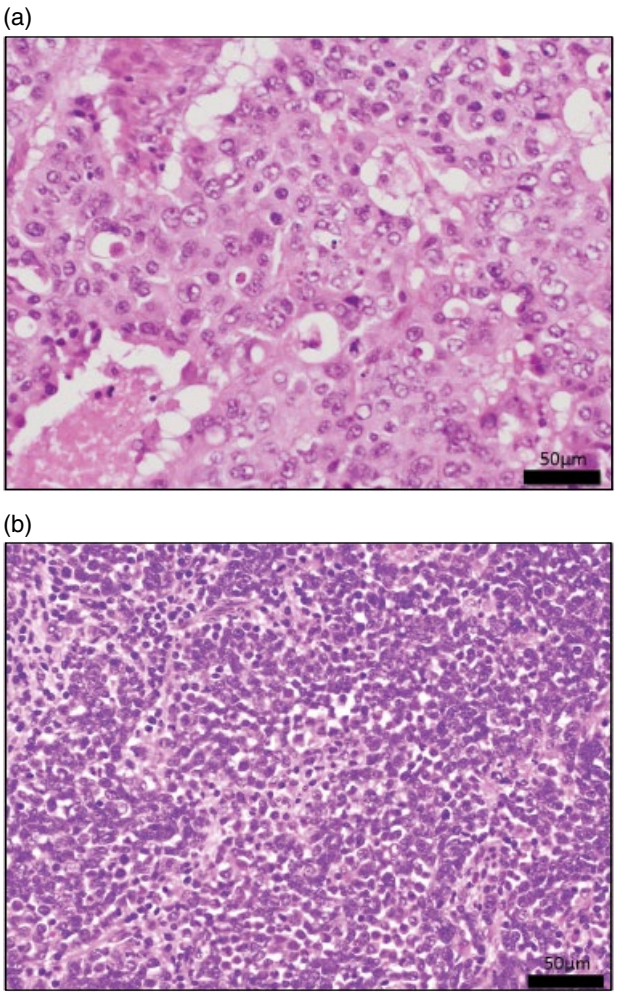

**Figure 122.3** Microscopic features of poorly differentiated neuroendocrine carcinoma (PanNEC). (a) Large-cell NEC displaying highly pleomorphic tumor cells showing a diffuse growth pattern. Necrosis is also observed. (b) Small-cell NEC composed of small, round tumor cells with a high nuclear–cytoplasmic ratio.

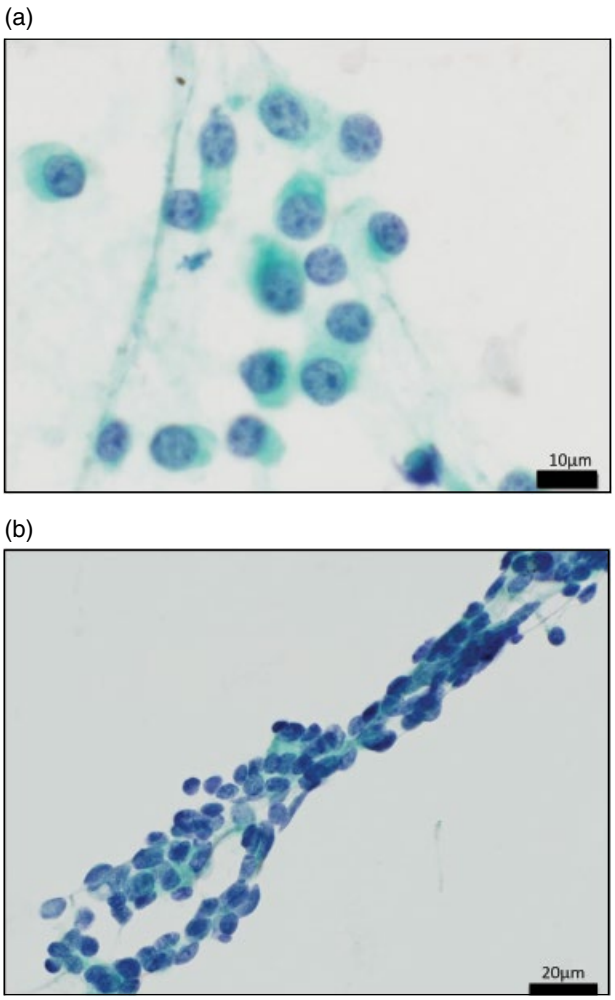

**Figure 122.4** Cytology images of pancreatic neuroendocrine tumors. (a) Loosely cohesive plasmacytoid epithelial cells with round to oval-shaped nuclei showing a salt-and-pepper chromatin pattern. (b) Tumor cells surrounding capillary vessels.

shows the highest specificity among neuroendocrine markers. The sensitivity of chromogranin A is also high in PanNETs, but its expression in PanNEC is usually weak and focal. Synaptophysin is a highly sensitive neuroendocrine marker, but its expression is also observed in non-neuroendocrine tumors, such as SPN, SCN, paraganglioma, and ACC; therefore, a panel immunohistochemical evaluation is useful to exclude the possibility of these tumors. CD56 and neuron-specific enolase (NSE) are not recommended for determination of PanNEN because of their limited specificity. PanNETs produce hormones, which are better revealed via clinical rather than pathologic analysis/examination. Consequently, clinical information should be considered in the pathologic evaluation. PanNETs usually do not demonstrate abnormal TP53 expression or loss of retinoblastoma 1 protein (RB1) by immunohistochemistry [12]. In contrast, PanNECs usually do not produce hormones, without showing abnormal TP53 expression or loss of Rb1 [12].

Positivity for cytokeratins, including CK8, CK18, CK AE1/AE3, and CAM5.2, observed in PanNENs is helpful to exclude the possibility of paraganglioma, mesenchymal neoplasms, or hematopoietic malignancies.

Low-grade cellular atypia and intervening capillary structures of SPN are common features of PanNET, although SPN is usually composed of heterogeneous growth architectures. Variable stromal changes, such as fibrosis, hyalinosis, cystic degeneration, and calcification, can be observed in both SPN and PanNET, but marked myxoid degeneration or solid and large calcification suggest the possibility of SPN rather than PanNET. Nuclear features of SPN are distinct from those of PanNET; chromatin is finely stippled, the salt-and-pepper pattern is not evident, and nuclear grooves may be observed in SPN. It is probably difficult to distinguish

these two neoplasms on small biopsy specimens, unless "pseudo-papillary structures" of SPN are finely observed. Nuclear expression of β-catenin is highly specific for SPN, whereas it is expressed only in the cell membrane of tumor cells of PanNET. It should be noted that SPN may express synaptophysin, but chromogranin A expression is mostly negative or very limited.

The architectural pattern of ACC is variable; an acinar growth pattern is most commonly observed, but solid, trabecular, and diffuse growth patterns may also variably intermingle. Tumor cells of ACC present hyperchromatic nuclei and higher pleomorphism than PanNET. Eosinophilic granular cytoplasm, because of zymogen granules, can be similar to the cellular features of the oncocytic variant of PanNET. Acinar differentiation should be defined by immunohistochemistry, for example, trypsin, lipase, and BCL10. ACC may also focally coexpress chromogranin A and synaptophysin. ACC, of which neuroendocrine expression is observed in more than 25% of all tumor cells, is regarded as mixed acinar-neuroendocrine carcinoma. The clinical and histopathologic features of mixed acinar-neuroendocrine carcinoma are more closely associated with ACC than PanNENs; therefore, mixed acinar-neuroendocrine carcinoma is considered to be a histologic subtype of ACC [14].

Pancreatic neoplasms that exhibit clear cytoplasm, such as clear-cell variant of SPN, metastasis of clear-cell renal cell carcinoma, and solid type of serous cystic neoplasm, can be mimics of the clear-cell variant of PanNET. Tumor cells that contain abundant lipid vacuoles appear to be mimics of adrenocortical neoplasm.

Ewing sarcoma is composed of small, round-shaped hyperchromatic tumor cells, and is histologically similar to small-cell NEC. It should be noted that Ewing sarcoma occurring in the pancreas often expresses cytokeratin and may be positive for neuroendocrine markers, such as synaptophysin, CD56, or NSE [15]. Malignant lymphoma is also composed of small, round-shaped tumor cells but it can be distinguished by immunohistochemical expression of leukocyte common antigen.

## Introduction

Low-grade pancreatic neuroendocrine tumors (PanNETs) are the second most common malignancy of the pancreas, accounting for approximately 2% of newly diagnosed pancreatic malignancies. The increased diagnosis of patients with this disease has mainly been due to better imaging and diagnostic tools and a larger number of incidental findings [1–4]. Although PanNETs are not as lethal as pancreatic ductal adenocarcinoma (PDAC), more than 50% of patients have distant disease at diagnosis and the 10-year survival rate is about 40% [5]. High-grade neuroendocrine carcinomas (NECs) of the pancreas are extremely rare and highly lethal [6–9].

Well-differentiated PanNETs are classified as functional or nonfunctional, with the latter group being most common [10]. Functional PanNETs produce syndromes with systemic effects related to the hormones that they secrete. The most common functional PanNETs are insulinomas, and glucagonomas, gastrinomas, somatostatinomas, VIPomas, and some PanNETs of mixed histology comprise the rest of this group. Nonfunctional PanNETs do not secrete clinically significant hormones; rather, they grow silently, and patients often present with either an asymptomatic abdominal mass or abdominal pain resulting from compression due to a large tumor. Surgery can be curative in the case of primary cancers and some cases of metastasis, but many patients present with unresectable tumors or extensive metastatic disease.

Most of PanNETs are sporadic; however, they can also arise in patients with familial syndromes, most commonly in patients with multiple endocrine neoplasia type 1 (MEN1), followed by von Hippel–Lindau syndrome (VHL), neurofibromatosis type 1 (NF1), and tuberous sclerosis complex (TSC) [11–13]. As a result, the genomes of patients with PanNETs with the syndromes mentioned have germline mutations in the gene(s) that are responsible for the predisposition to the familial syndromes.

High-grade neuroendocrine carcinomas, defined as neuroendocrine neoplasms with proliferation rates >20%, are highly malignant neoplasms, and include entities previously defined as "small-cell" and "large-cell" neuroendocrine carcinomas [6–9]. There are some neoplasms that technically have proliferation rates >20%, but which retain an otherwise well-differentiated morphology, and these neoplasms likely have genetic alterations similar to well-differentiated PanNETs, and not those of the high-grade NECs [14,15].

We now know that cancer takes many years to develop, and is caused by the sequential alteration of a small number of genes that affect a smaller number of cellular processes [16]. The genomic landscapes of many tumor types have been determined, and although not everything is yet understood, these studies have provided sufficient information for developing effective approaches for reducing cancer morbidity and mortality. For similar reasons, much progress has been made in understanding the genetic alterations that underlie PanNET and NEC tumorigenesis. This chapter describes what is known about the genetic landscape and epigenetics of PanNET and NEC, and their clinical applications.

## Genetics of Sporadic PanNET

In order to gain insight into the genetic basis of PanNETs, whole-exome sequencing (WES) was performed in 10 clinically homogeneous nonfunctional PanNETs [17]. Then, the most commonly mutated genes were analyzed for mutations in 58 additional nonfunctional PanNETs. The most commonly mutated genes identified encode

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

proteins that are involved in chromatin modification. *MEN1* had inactivating mutations in 44% of the samples. *ATRX* and death domain-associated protein (*DAXX*) genes had mutually exclusive inactivating mutations in 18 and 25% of the samples, respectively, resulting in the inactivation of the ATRX/DAXX complex in 43% of the PanNETs. Approximately 14% of the samples had mutations that should result in the activation of the mammalian target of rapamycin (mTOR) pathway. Tuberous sclerosis complex 2 (*TSC2*) was inactivated in 9% of the samples, and phosphatase and tensin homolog (*PTEN*) was inactivated in 7% of the samples. In addition, there was an activating mutation in *PIK3CA*, which encodes the p110 alpha catalytic subunit of PI3K. *TP53* was inactivated in only 3% of the PanNETs (Table 123.1). Overall, there were about 8–23 mutations per tumor with a mean number of 16 mutations, which is low compared with other solid tumors. Mutations in oncogenes are rare in most solid tumors, so it was not unexpected that only one sample had an activating oncogenic mutation [16]. This lack of activating mutations in oncogenes underlies the overall challenge for developing targeted therapies for PanNETs. As a result, understanding the pathways involved in the development and progression of cancers has become pivotal for developing therapeutics. A good example is the mTOR pathway. Existing therapeutic agents that inhibit this pathway do not target commonly mutated genes in the pathway; rather, they target mTORC1 as a shared downstream effector in the pathway.

Although the WES study greatly increased our understanding of the genetic alterations underlying PanNET tumorigenesis, it had its limitations. For example, the study did not identify chromosomal rearrangements, copy number variations, or foreign sequences. Comparative genomic hybridization studies have shown that PanNETs, much like other solid tumors, have a number of chromosomal gains and losses [18,19]. Some studies have reported that the number of chromosomal gains and losses is larger in metastatic lesions compared with the primary tumor from the same individual [18]. However, it remains unclear if these additional gains and losses are drivers, or just passengers, representing the continuous accumulation of genetic lesions in the advanced lesions.

Another limitation of WES studies is the difficulty in identifying large deletions in tumor suppressor genes. As will be discussed later, inactivating mutations in *ATRX* and *DAXX* correlated with the alternative lengthening of telomeres (ALT) phenotype. In fact, protein expression studies in 68 PanNETs indicated that all samples with *ATRX* or *DAXX* inactivating mutations exhibited the ALT phenotype [20]. Interestingly, tumors negative for nuclear staining of either ATRX or DAXX also showed the ALT phenotype, indicating that *ATRX* or *DAXX* genes were inactivated either by a rearrangement such as large deletions not identifiable by exome sequencing, or via epigenetic mechanisms. This study indicated that inactivation of *ATRX* or *DAXX* occurred in approximately 60% of the PanNET samples, of which 43% were caused by exomic mutations and the remaining cases most likely resulted from large deletions or epigenetic gene inactivation.

Mutations in the regulatory regions of genes were also not identified in the WES study. The best-studied mutations of these types are those in the telomerase reverse transcriptase (*TERT*) promoter. Two nucleotides account for almost all of the *TERT* promoter mutations that have been associated with human carcinogenesis [21,22]. These mutations result in changes in the chromatin state of the promoter, which, in turn, allow binding of transcription factors that promote TERT expression [23]. This expression is derived from the allele with the mutation, while the other allele remains silent [24]. In glial tumors, *ATRX* inactivating mutations and *TERT* promoter mutations are mutually exclusive, presumably because each type of mutation results in preservation of a the telomeric length appropriate for cell growth [25]. To evaluate the possibility of this occurring in PanNET, the samples analyzed for *ATRX* and *DAXX* mutations were also evaluated for *TERT* promoter mutations. None of the 68 PanNETs had *TERT* promoter mutations at the hot spots were shown to be mutated in many other tumor types; therefore, we presume that TERT is expressed in these tumors.

The exome of sporadic functional PanNET has only been sequenced in insulinomas. In a set of ten insulinomas, the most commonly mutated gene was the transcription factor Yin Yang 1 (*YY1*) [26]. Sequencing of *YY1* in an additional 103 insulinomas identified a hot spot mutation in 31 of them. Overall, 30% (34/113) of the insulinomas possessed the T372R mutation [26]. A more recent study focusing on the Caucasian instead of the Asian population, identified a much lower prevalence (13%) of *YY1* mutations in sporadic insulinomas. In the Caucasian population, the T372R mutation appeared to stratify with women and older age [27].

## Pathways Altered in PanNETs

### ATRX/DAXX Pathway

Approximately half of PanNETs have inactivating mutations in *ATRX* or *DAXX*. *ATRX* is located on chromosome X, and only the active copy needs to be inactivated to result in total loss of the ATRX protein. On the other hand, *DAXX* is located on chromosome 6, and both copies need to be inactivated for DAXX protein loss. The mutations that occur in the *DAXX* gene include single nucleotide base substitutions and indels that create frameshifts,

**Table 123.1** Comparison of commonly mutated genes and their prevalence in PanNET and other pancreatic neoplasms.

| Gene | Nonfunctional PanNET (%) | Syndromic microadenomas (%) | NEC (%) | PDAC (%) | Insulinomas (%) | Intracellular pathway | Clinical application | Future opportunity |
|---|---|---|---|---|---|---|---|---|
| *MEN1* | 44 | 100 | 0 | 0 | 2.50 | Chromatin methylation | Not available | Synthetic lethality |
| *ATRX* | 18 | 0 | 0 | 0 | 2.50 | Chromatin remodeling—ALT | Prognostic/diagnostic | Synthetic lethality |
| *DAXX* | 25 | 0 | 0 | 0 | 0 | Chromatin remodeling—ALT | Prognostic/diagnostic | Synthetic lethality |
| *TSC2* | 9 | Not tested | Not tested | 0 | 0 | mTOR | Target treatment—mTOR inhibitors | Improved mTOR inhibitors |

| *YY1* | 0 | Not tested | 0 | 0 | 13–30 | Transcription | Not available | Target therapy |

larger deletions of single or multiple exons, and loss of heterozygosity. All of the mutations in both *ATRX* and *DAXX* lead to inactivation of the respective gene and lack of nuclear protein immunolabeling in PanNETs, in accordance with them being tumor suppressors. The mutations are also mutually exclusive, consistent with the two genes working within the same pathway [17,20].

ATRX is a chromatin remodeling protein that interacts with DAXX and together they function as a histone chaperone complex that deposits the histone variant H3.3 into pericentric, telomeric, and ribosomal repeat sequences [28–31]. Although the mechanism underlying the action of ATRX remains unclear, recent progress has been made. ATRX is thought to be recruited, perhaps by interacting with histones, to G-quadruplex DNA, where it is involved in chromatin remodeling, with consequences on gene expression, and relief of replication fork stalling [31,32]. Consequently, its absence can impair both nonhomologous end joining DNA repair and formation of protein complexes, resulting in changes to the epigenetic state of the DNA [33–35].

Perhaps more intriguing is the connection between the lack of ATRX or DAXX protein expression with the ALT phenotype [36]. There is telomere length attrition with every cell division resulting in telomeric lengths that are not compatible with further growth. Cancer cells must circumvent this issue. Telomeric length is usually maintained by TERT [37]; however, TERT is not always active. Cells with the ALT phenotype have very long telomeres whose lengths are maintained by recombination instead of the enzymatic action of TERT [38]. Mutations in *ATRX* or *DAXX* that abolish protein expression in PanNETs correlated with ALT [20,25,39]. *ATRX* inactivating mutations concomitant with ALT have also been identified in extra-pancreatic tumor types including glial tumors, neuroblastomas, and sarcomas, in cancer cell lines, and also in *in vitro* immortalized ALT cell lines [25,40]. Furthermore, loss of wild-type ATRX expression in somatic cell hybrids segregated with ALT, whereas ATRX expression led to inhibition of ALT [41,42]. A greater understanding of how ATRX loss may result in the ALT phenotype and its connection to increased chromosomal instability was provided by a study that showed that loss of ATRX in cancer cells lines can promote sister telomere cohesion associated with increased recombination between sister telomeres [43].

*ATRX* was first identified to cause an X-linked hereditary syndrome [44]. The germline mutations did not result in an increased cancer incidence in these patients, and cells from these patients did not demonstrate the ALT phenotype. This could be because the spectrum of mutations in these individuals was mostly missense, and even some of the presumably inactivating mutations retained expression of the protein. In alpha-thalassemia myelodysplastic syndrome (ATMDS), *ATRX* mutations are also mostly missense [45]. It is possible that because individuals with myelodysplastic syndrome tend to be older, some or most of the mutations are passenger mutations. In contrast, all of the mutations identified in solid tumors, including PanNETs, CNS tumors, and sarcomas, are inactivating and all correlate with ALT.

PanNETs are also unique in that *DAXX* mutations are predominant over *ATRX* mutations, even though *DAXX* mutations are extremely rare in other tumor types with ALT, which almost exclusively have *ATRX* mutations [17,46]. The differences in the spectrum of *ATRX* mutations in various diseases, and the preferential inactivation of *DAXX* in PanNETs, provide fertile ground for understanding the intricacies of this pathway and its tumor-specific ALT phenotype, with the hope that a deeper understanding will lead to the therapeutic targeting of the pathway.

### MEN1 Pathway

*MEN1* is the most frequently somatically mutated gene in PanNET [17,47]. This gene encodes the transcriptional regulator menin, which recruits the H3K4me3 histone methyltransferase mixed-lineage leukemia (MLL) complex [48,49]. Menin interacts with many proteins and regulates gene expression and intracellular cell signaling and it is associated with numerous cellular processes including the regulation of SMAD3 to inhibit TGFβ1-mediated inhibition of proliferation, and repression of JunD activity, regulation of homeodomain gene expression, and repression of telomerase expression [50–53]. Mutations in PanNETs inactivate both alleles either by inactivating mutations or by a combination of mutation coupled with loss of heterozygosity. Thus, by definition, *MEN1* is a tumor suppressor.

It appears that tumorigenesis in PanNETs is driven by alterations in both histone modification and chromatin remodeling as the overlap of *MEN1* with *ATRX/DAXX* mutations is significant (74%). *MEN1* and *ATRX/DAXX* are epigenetic drivers of cancers, resulting in a plethora of epigenetic changes in the cell. Hence it is important to determine which epigenetic alterations are the key drivers of PanNET tumorigenesis, which has obvious implications for therapeutic exploitation of the associated pathways.

### mTOR Pathway

The mTOR signaling pathway integrates environmental signals to regulate growth and homeostasis. mTOR is an atypical serine/threonine protein kinase that interacts with several proteins to form two key complexes in the pathway, named mTOR complex 1 (mTORC1) and 2 (mTORC2), each of which mediates different upstream inputs and which have different downstream outputs. A number of tumor suppressors and oncogenes commonly

mutated in cancers are upstream of mTORC1, including the PTEN/PIK3CA pathway, the RAS/RAF pathway, TSC1/2, NF1, and LKB1. Sequencing of PanNET revealed mutations in *TSC2*, *PTEN*, and *PIK3CA* genes in 16% of samples, all which activated the mTOR pathway, consistent with its pro-growth effects on cells. Downstream effectors of the pathway involve 4E-BP1, which in turn regulates hypoxia-inducible factor 1 (HIF1a), a target of VHL, and S6K1, resulting in increased proliferation signals, regulation of metabolism, and increased protein synthesis (reviewed in [54]). Inhibitors of the mTOR pathway have shown benefit in patients with different tumor types, including PanNET; however, correlations between pathway mutations and the observed benefits have not yet been established [55]. Based on results from other tumor types, we hypothesize that patients with tumors with mTOR pathway mutations will respond better to therapies targeting this pathway [56]. However, in clinical trials, the number of patients with PanNETs that benefited from treatment with everolimus, which targets the mTOR pathway, was larger than the number of PanNETs with mutations in the mTOR pathway [17,55]. However, this is an extrapolation as the PanNETs from the patients included in the study were not tested for mutations. It is worth noting that for such a complicated pathway, there could be other means of activation besides mutations. Related to this, expression studies resulted in the observation that expression of genes in the mTOR pathway are upregulated in PanNETs [57]. Nevertheless, a good study to test the companion diagnostic potential of the mutational status of the pathway would be important.

## High-Grade Neuroendocrine Carcinomas

In contrast to well-differentiated PanNETs, the *DAXX/ATRX* and *MEN1* genes are not targeted in most high-grade NECs [6,58,59]. Instead, the *RB1* and *TP53* genes are commonly somatically mutated in NECs [6]. Yachida et al. extensively studied a series of pancreatic NECs (PanNECs) (small- and large-cell neuroendocrine carcinomas), and found that the p53 expression was altered in 95% and Rb in 74% of the NECs [6]. Abnormal immunolabeling of p53 and Rb proteins correlated with the intragenic mutations in the *TP53* and *RB1* genes. By contrast, DAXX and ATRX labeling was intact in virtually all of these same carcinomas. These genetic differences indicate that the biology and process of tumorigenesis are distinct in PanNET and PanNEC, and the poorly differentiated PanNECs do not result from the progression of the well-differentiated PanNETs to a less differentiated state.

Genetic analyses, when integrated with histopathology and clinical outcomes, have helped further dissect the neoplasms lumped together as "grade 3 NEC" in the 2010 World Health Organization (WHO) classification. The nuclear morphology of some NEC with proliferation rates only slightly above 20% are very similar to that of the well-differentiated PanNETs, while the nuclear morphology of neuroendocrine neoplasms with very high proliferation rates (i.e., >50%) has a small- or large-cell appearance. The former group (those with nuclear features similar to those of well-differentiated PanNET) appear to have genetic changes closer to those of the well-differentiated PanNETs, whereas the latter neoplasms (those with proliferation rates >50%) are those of NECs, with *RB1* and *TP53* targeted. This has led some to propose a new four-tier classification system in which lesions previously lumped together as grade 3 NEC are now separated into two groups—those with proliferation rates slightly over 20% and with mutations seen in well-differentiated PanNETs (*DAXX/ATRX*, *MEN1*) and those with very high proliferation rates and *RB1/TP53* mutations [6–9,60,60b].

## Comparison of the PanNET Genetic Landscape with Other Pancreatic Neoplasias

The genetic landscape of well-differentiated PanNET is fundamentally different from that of the more aggressive pancreatic adenocarcinoma (PDAC) (Table 123.1). *KRAS* mutations that are not found in neuroendocrine tumors are present in almost 100% of PDACs. In addition, PDAC have a high rate of mutations in *SMAD4*, *CDKN2A*, and *TP53* genes, but no mutations in *DAXX*, *ATRX*, or *MEN1* [61,62].

The genetic alterations found in PanNETs are also distinct from those found in the other neoplasms of the pancreas. Serous cystic neoplasms are characterized by *VHL* gene mutations, solid-pseudopapillary neoplasms by *CTTNB1* mutations, intraductal papillary mucinous neoplasms by alterations in *KRAS*, *GNAS*, *RNF43*, *p16/CDKN2A*, and *TP53*, mucinous cystic neoplasms by mutations in *KRAS*, *RNF43*, *p16/CDKN2A*, and *TP53*, and acinar cell carcinomas by multiple complex alterations including mutations in *JAK1*, *BRAF*, and *APC*, among others [61,63,64].

The distinct mutational profile of each tumor type of the pancreas suggests that mutational analyses may be used to help classify tumor type in the future [65].

Finally, among neuroendocrine tumors, the targeting of the *ATRX/DAXX* pathway and ALT is relatively specific for those tumors that arise in the pancreas. This suggests that ALT status could be used to clarify the organ of origin in metastatic neuroendocrine tumors of unknown primary site [66].

## Familial Syndromes

The majority of PanNETs are sporadic; however, they can occur in individuals who are predisposed to certain syndromes. Most syndromic PanNETs occur in patients with MEN1, followed by those with VHL and NF1, and occasionally with TSC [7–9]. Perhaps not surprisingly, germline mutations that predispose individuals to these syndromes are in genes related to pathways that are somatically mutated in sporadic PanNET.

MEN1 is an autosomal dominant syndrome caused by germline mutations in *MEN1* gene on chromosome 11, which is the gene most frequently mutated in sporadic PanNETs [67]. As mentioned previously, *MEN1* is a tumor suppressor gene that follows the two-hit paradigm. The first hit in individuals with MEN1 is an inactivating inherited mutation. The second hit, which is an inactivating somatic mutation or loss of heterozygosity of the remaining wild-type allele, occurs in the tumors. Tumors of the pancreas are the second most common manifestation of the MEN1 syndrome. Most of the PanNETs in patients with MEN1 are nonfunctional, although about 10% of them are insulinomas. They typically appear as multiple microadenomas (<0.5 cm); however, in many cases, like the sporadic PanNETs, they can grow larger and even spread to other organs [11,68,69]. Study of the genetics of PanNET in the context of the MEN1 syndrome has shown that *MEN1* inactivation precedes *ATRX/DAXX* inactivation and the concomitant appearance of ALT [39]. In this study, 109 well-differentiated PanNETs from 28 patients with MEN1 syndrome were tested for the expression of ATRX and DAXX and for the presence of ALT by immunostaining as a proxy for the genetic inactivation of the genes that encode for these proteins. The lesions included 47 neuroendocrine microadenomas (<0.5 cm), 50 pancreatic neuroendocrine tumors (>0.5 cm), and 12 pancreatic neuroendocrine tumor lymph node metastases. All of the lesions had loss of function of the MEN1 protein by definition, since they were present in patients with MEN1 syndrome; hence this was the first and presumably the initiating event in these tumors. ATRX/DAXX expression was intact in all of the 47 microadenomas, which were also negative for ALT. On the other hand, ATRX/DAXX expression was lacking in 6% of the PanNETs, but all losses were in tumors larger than >3 cm. These tumors were also ALT positive, which is consistent with the already documented role of ATRX/DAXX loss in the development of ALT. In addition, in the samples with concurrent metastases, the genetic alterations in the primary and metastatic tumors were the same. The progression from *MEN1* inactivation to *ATRX/DAXX* inactivation and appearance of ALT as the tumor size and the risk of metastasis increased, which was observed in the MEN1 syndrome-associated PanNET, most likely also exists in the sporadic PanNET. However, *ATRX/DAXX* inactivation in sporadic pancreatic neuroendocrine microadenomas was much higher [70].

VHL is caused by germline mutations in the tumor suppressor *VHL* on chromosome 3. The VHL protein controls the degradation via ubiquitination of HIF1, and loss of VHL leads to tumor growth and angiogenesis. HIF1 regulation also has been proposed to be downstream of the mTOR pathway. Patients with VHL develop a number of different benign and malignant neoplasms, and approximately 12–15% of them develop nonfunctional PanNETs. Most of these tumors are well differentiated, but some are aggressive and they can metastasize [71,72].

PanNETs also arise, albeit less frequently, in patients with NF1 and TSC syndromes [12,13]. NF1 is caused by germline mutations in *NF1*, whereas TSC results from germline mutations in *TSC1/TSC2.* Both of these genes are tumor suppressors and are associated with the extensive mTOR pathway [73,74]. NF1 acts more distally upstream of the mTORC1 regulating the KRAS arm of the pathway. The TSC1/TSC2 complex inhibits mTORC1 activation. Mutations in *TSC2* were the most common mTOR pathway mutations observed in sporadic PanNETs.

If indeed the initiating event of PanNET development is a germline mutation that predisposes individuals to NF1 or TSC syndrome, it is likely that more than one route to PanNET tumorigenesis exists. It is possible that the mutations in *VHL*, *TSC2*, and *NF1* genes affect the mTOR pathway. The prevalence of PanNETs in these syndromes is in accordance with the presence of the affected pathways in sporadic PanNETs, with *MEN1* mutations occurring in 44% and mTOR only occurring in 16% of PanNETs [17]. Further studies on the genetic changes in syndromic PanNETs will provide an understanding of the pathways that drive PanNET tumorigenesis.

In a recent study, whole-genome sequencing of 102 presumed somatic PanNETs revealed the presence of rare germline mutations in *MUTYH* and even more rarely in *CHEK2* and *BRCA2* genes [75].

## Epigenetics

PanNETs can be classified into three groups according to their RNA profiles: well-differentiated islet cell tumors/insulinomas, poorly differentiated tumors, and gene mutation-enriched subtypes. The first two classification groups are not surprising as PanNET and NEC are two different tumor types. The differences between well-differentiated and gene mutation-enriched groups are intriguing in that they could reflect groups with different clinical behaviors. The well-differentiated and poorly differentiated groups were also seen in the RIP1-TAGs mouse model, in which PanNETs are induced by

expression of the SV40 T-antigen oncogenes in insulin-producing islet β cells, suggesting that this model may mimic a subset of human PanNET development [76].

Genome-wide methylation analysis of 53 PanNET identified significant differences in methylation profiles between tumors of different grade and between tumors with or without *ATRX*/*DAXX* mutations. However, this clustering was not perfect as some tumors with mutations in these genes clustered with normal controls. Interestingly, there were significant differences in the methylation profiles between PanNETs with *ATRX* mutations and those with *DAXX* mutations [46].

## Clinical Implications

The genetic landscape reflects the different biology and clinical manifestations of the pancreatic neoplasms, and has clinical ramifications. First, genetics can be used to classify the different lesions unambiguously. Second, the differences in the genetics suggest different types of treatments. Unfortunately, treatments are not available that can target the most common mutations in PanNETs, *MEN1* and *ATRX/DAXX* mutations. The relationship between loss of *ATRX/DAXX* with ALT, recombination, and DNA repair suggests that synthetic lethality could be feasible with agents that interfere with these pathways. However, this has not yet been proven.

*ATRX/DAXX* mutations in PanNETs have been associated with prognosis. In a study of 142 well-differentiated PanNETs, loss of ATRX and DAXX and presence of ALT correlated with higher tumor stage and a worse prognosis, perhaps a reflection of *ATRX/DAXX* mutations being a late event in PanNet tumorigenesis [77]. However, when only the subset of metastatic patients was considered, loss of ATRX and DAXX was associated with longer survival [77]. This latter observation is in accordance with the initial observation that patients with metastatic PanNETs harboring *MEN1*, *ATRX*, and *DAXX* mutations showed better prognosis and longer survival [17]. Similarly, in an independent study of 43 patients with liver metastasis managed with resection, loss of ATRX/DAXX was associated with better overall survival [66]. One interpretation of this is that tumors with *ATRX/DAXX* inactivating mutations demarcate a subgroup with a different clinical presentation than the PanNETs without inactivation of these genes.

Furthermore, as noted earlier, in a comparison between metastatic lesions in the liver from patients with PanNETs or gastrointestinal carcinoid tumors, the presence of ALT in the metastatic lesion was a useful biomarker to predict that the site of origin of metastatic lesions to the liver is a neuroendocrine tumor of the pancreas in cases where the primary site is unknown [66].

Of all the mutations identified in PanNETs, those in the mTOR pathway show promise as therapeutic targets, as it is thought that PanNETs with mTOR pathway mutations upstream of mTORC1 will derive benefits from mTOR inhibitors. However, this has yet to be proven in clinical trials. A recent trial has been described that will test this hypothesis [78]. It is worth noting the mTOR pathway is complex, hence mutations in other genes or via epigenetic mechanisms may activate this pathway in PanNETs. Even so, not only people with the described mTOR pathway mutations will show benefit from the therapies, but also people with "cryptic," at least for now, alterations of the mTOR pathway.

Everolimus is indicated as a treatment in several solid tumors, including hormone receptor-positive HER2-negative breast cancer and advanced renal cell carcinoma. Recent data from the BOLERO-1 and BOLERO-3 trials suggest that patients with human epidermal growth factor receptor 2-positive advanced breast cancer, having tumors with *PIK3CA* mutations, *PTEN* loss, or hyperactive PI3K pathway, could derive progression-free survival benefit from everolimus treatment [56].

Everolimus was approved by the US Food and Drug Administration in 2011 for use in patients with advanced PanNETs, based on the results of the RADIANT III trial [55]. In this trial, single therapy with everolimus was compared with the best supportive care for advanced PanNETs. The majority of patients had previously been treated with different therapies. Compared with placebo, everolimus led to increased progression-free survival (11 versus 4.6 months).

## Conclusions

Over the last several years, the studies mentioned in this chapter have increased our understanding of the genetic alterations and intracellular pathways that drive PanNET tumorigenesis. Although much remains to be determined, for example, identification of the driver genes in PanNETs that do not have mutations in *MEN1*, *ATRX*, or *DAXX*, we have sufficient information to develop clinical applications based on the genotype of these tumors (Table 123.1) [79]. Future studies should clarify which companion diagnostics should be available for therapies, such as everolimus, as many patients do not respond to this drug. In those who are responsive, the overall increase in survival is months not years. New therapies are needed for the management of patients with PanNETs. Therefore, efforts should be invested in understanding and therapeutically targeting the ATRX/DAXX and MEN1 pathways. It is clear that molecular genetics have provided new opportunities to improve the clinical management of patients with PanNETs.

## Introduction

"Neuroendocrine tumor" (NET) is a collective term for tumors originating in nerve and endocrine cells that are widely distributed in the body; these tumors develop in various organs such as the pancreas, digestive tract, lungs, and pituitary gland. As such, they are generally called gastroenteropancreatic neuroendocrine tumors. This chapter focuses on pancreatic neuroendocrine tumors (i.e., pancreatic NET or PanNET). Although PanNET represent a relatively rare disease with slow progression, it is important to treat them as malignant tumors in the clinical setting owing to their capacity to metastasize. These tumors are broadly categorized into functional PanNET, which are associated with excessive hormone secretion, and nonfunctional PanNET, which do not involve hormone secretion. Functional PanNET present with specific clinical symptoms because of the excessively produced and secreted hormones. This chapter describes the clinical manifestations of PanNET.

## Epidemiology of PanNET

In the West, PanNET represent 1–2% of all pancreatic tumors, and the annual prevalence is reported to be less than one per 100,000 individuals. According to the American SEER (Surveillance, Epidemiology, and End Results) database, more than 60% of tumors registered between 1973 and 2004 were gastrointestinal NET in which the ileum and rectum were sites of high incidence; 3.6% of these tumors were PanNET [1]. However, the incidence of NET has been increasing in the West [2, 3]. Epidemiologic surveys for PanNET were also conducted in Japan in 2005 and 2010 [4–6]. It was reported that approximately 2845 Japanese PanNET patients were treated in 2005 whereas 3379 patients were treated in 2010; the number of PanNET patients per 100,000 people was approximately 2.23 in 2005 and 2.69 in 2010. Moreover, the number of new patients per 100,000 people was estimated to be approximately 1.01 in 2005 and 1.27 in 2010. Hence the number of NET patients is definitely rising in Japan also.

## Clinical Symptoms of PanNET

As mentioned, PanNET is broadly categorized into functional and nonfunctional PanNET. The clinical symptoms of functional PanNET are caused by excessively secreted hormones.

### Functional PanNET

Two aspects must be taken into consideration when treating functional PanNET. First, multiple symptoms can be present because of the excessive levels of various hormones autonomously secreted by the tumors (Table 124.1), possibly causing deterioration of the patient's quality of life or development of a life-threatening situation. Therefore, appropriate treatments for alleviating hormone symptoms are critical. Second, malignant NET may grow rapidly and can frequently metastasize to other organs during the course of the disease. Therefore, a multidisciplinary approach, including chemotherapy, is of utmost importance.

#### Insulinoma

Insulinoma is characterized by hypoglycemic symptoms induced by excessive autonomous insulin secretion, and

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

**Table 124.1** Symptomatic gastroenteropancreatic neuroendocrine tumors.

| Tumor | Cause | Site | Incidence of metastases (%) | Symptoms |
|---|---|---|---|---|
| Insulinoma | Insulin | Pancreas | <10 | Hypoglycemia (sweating, tremor, dizziness, unconsciousness, convulsion) |
| Gastrinoma | Gastrin | Pancreas | 100 | Refractory/recurrent ulcers, reflux esophagitis, duodenum |
| Glucagonoma | Glucagon | Pancreas | 80 | Necrolytic migratory erythema, glucose intolerance, hypoaminoacidemia, hypoalbuminemia, weight loss, anemia |
| VIPoma | VIP | Pancreas | 50 | WDHA syndrome (watery diarrhea, hypokalemia, achlorhydria) duodenum |
| Somatostatinoma | Somatostatin | Pancreas | 100 | Diabetes, fatty stool, gallstones, duodenum |

is categorized according to symptoms of the central nervous system (CNS) and those of the autonomous nerve system. CNS symptoms include headache, dizziness, disturbance of consciousness, and convulsions; they are sometimes mistaken for epilepsy or mental disease.

During hypoglycemic conditions, sympathicotonia can occur, followed by autonomic symptoms such as hunger, sweating, and tremors. As hypoglycemia improves upon consumption of food, a patient may tend to overeat, resulting in weight gain or obesity. Persistence of this condition can lead to memory disturbances or the development of intellectual impairment; such cases are sometimes regarded as dementia or cerebrovascular disorders. Some patients may fall into a coma without presenting with any autonomic symptoms beforehand; therefore, a cautious approach is necessary. Meanwhile, fasting hypoglycemic events are not the primary symptoms in some insulinoma patients; instead, excessive insulin secretion is noted after glucose loading (i.e., after eating a meal).

#### Gastrinoma

Gastrinoma is caused by excessive gastric acid secretion due to autonomic excessive gastrin release by the tumor, possibly leading to refractory/recurrent ulcers and reflux esophagitis. These conditions are well known as Zollinger–Ellison syndrome. Abdominal pain, heartburn, nausea/vomiting, gastrointestinal bleeding, and gastrointestinal perforation may occur, and are symptoms of refractory ulcers or excessive gastric acid. Digestion–absorption disorder may also occur because gastric acid is not neutralized in the duodenum, and pancreatic digestive enzymes are inactivated. As a result, fatty diarrhea, weight loss, and other symptoms may be observed.

#### Glucagonoma

Necrolytic migratory erythema, a well-described rash caused by glucagonoma, frequently occurs on the face, perineum, and limbs, causing itchiness and pain and exhibiting chronic healing/recurrence cycles. Excessive secretion of glucagon induces glucose intolerance, hypoaminoacidemia, hypoalbuminemia, weight loss, anemia, glossitis, angular cheilitis, venous thrombosis, mental symptoms, and other conditions.

#### VIPoma

Secretion of electrolytes and water from the intestine is accelerated by autonomic excessive secretion of VIP (vasoactive intestinal polypeptide) from the tumor, resulting in severe watery diarrhea and hypokalemia and also metabolic acidosis induced by massive excretion of bicarbonate ions. Owing to the secretin-like action of VIP, gastric acid becomes hypoacidic or anacidic. Various symptoms occur, including severe dehydration, weight loss, vasodilatation-caused skin flushing, hypercalcemia caused by accelerated bone resorption, and glucose intolerance.

#### Somatostatinoma

In addition to abdominal pain and weight loss, diabetes, gallstones, and fatty stool are also observed. Somatostatinoma is sometimes discovered during detailed examination of these symptoms.

### Nonfunctional PanNET

No specific symptoms are present in patients with nonfunctional PanNET. As the tumor grows, nonspecific symptoms appear that include abdominal distension, abdominal pain, anorexia, and weight loss. Nonfunctional PanNET is often discovered following compression or invasion by the primary tumor or a distant metastasis. In the case of advanced liver metastasis, hepatic dysfunction and jaundice are observed.

According to the results of an epidemiologic study in Japan, approximately 22 months passed between the appearance of PanNET symptoms and disease diagnosis in symptomatic cases, on average [5,6]. Although PanNET is not often encountered in actual clinical practice, it is important to consider it during differential diagnosis.

## Diagnosis of PanNET

When repetitive hypoglycemic events or refractory gastrointestinal ulcers are investigated, differential diagnosis for functional PanNET is required, including insulinoma and gastrinoma. If functional PanNET is suspected on the basis of the clinical symptoms, measurement of basal hormone levels in the blood and various loading tests are required to detect the presence of a hormone-producing tumor. If such a tumor is confirmed, its location should be accurately identified using imaging modalities; this is important for deciding the subsequent therapeutic strategy. Even if the presence of a tumor is first detected via imaging, as in the case of nonfunctional PanNET, the hormone-producing ability of the tumor and also the presence or absence of metastasis should be investigated in detail. PanNET is often associated with multiple endocrine neoplasia type 1; therefore, serum calcium and potassium levels should be determined upon initial examination to rule out excessive parathyroid hormone production.

### Diagnosis of Tumor Presence

#### Insulinoma

In the past, Whipple's triad (i.e., loss of consciousness on fasting combined with blood glucose levels <50 mg/dL, where symptoms improve upon consuming glucose) and Fajan's index for insulinoma (the ratio of plasma insulin concentration to fasting blood glucose >0.3) have been observed; however false-negative findings should be ruled out. For definitive diagnosis, a 72-hour fasting test is recommended.

#### Gastrinoma

Measurement of fasting serum gastrin and gastric acid secretion, and/or a 24-hour gastric pH monitoring test, are essential for diagnosis. It is important to inquire about the patient's medication history, as serum gastrin levels may increase owing to oral administration of proton pump inhibitors or $H_2$ blockers. For definitive diagnosis, a secretin or calcium stimulation test is useful, as gastrin secretion is increased by intravenous injection of secretin or calcium.

### Localization Diagnosis

Many PanNET are plethoric with inner uniformity; therefore, diagnosis is not difficult in typical cases. However, in atypical cases involving oligemia or cyst formation, it may be difficult to distinguish PanNET from a pancreatic ductal cancer or cystic pancreatic tumor on differential diagnosis. Furthermore, insulinoma and gastrinoma are often small in diameter, and accurate localization is important for surgery. Therefore, various imaging modalities are employed during actual examination.

#### Abdominal Ultrasonography (US)

The more uniform the inside of tumor, the more likely the mass can be visualized on US. When the tumor is large, an irregular shape that reflects internal bleeding, necrosis, or cystic degeneration is sometimes observed. Abdominal US is easy to perform, and is the least invasive among imaging modalities. However, its diagnostic accuracy is low (Fig. 124.1a).

#### Abdominal Computed Tomography (CT)

When contrast medium is used, typical PanNET are highly enhanced in the arterial phase (Fig. 124.1b). As contrast enhancement is weak in oligemic pancreatic ductal tumors, a CT image may be critical in distinguishing between PanNET and pancreatic ductal cancer. However, plethoric pancreatic tumors present the same contrast enhancement as PanNET, metastatic pancreatic tumor, and especially renal cancer; therefore, differential diagnosis should be carefully conducted. The diagnostic accuracy of CT is approximately 80% [7, 8].

#### Abdominal Magnetic Resonance Imaging (MRI)

A T1-weighted MRI scan of a PanNET shows low intensity, whereas a T2-weighted scan shows high intensity (Fig. 124.1c and d) [8, 9]. On MRI, a tumor is visualized similarly to CT; however, the diagnostic accuracy of this method is approximately 70%, which is slightly lower than that of CT. On the other hand, for the detection of hepatic metastases from PanNET, enhanced MRI is more sensitive than enhanced CT (Fig. 124.2) [10].

#### Endoscopic Ultrasound-Guided Fine-Needle Aspiration (Fig. 124.3)

PanNET is visualized on endoscopic ultrasonography (EUS) as a hypoechoic mass with border regularity and inner uniformity. EUS can screen the entire pancreas and detect lesions smaller than 1 cm. With a diagnostic accuracy of approximately 80–95%, this method is superior to CT and MRI and is therefore a very useful testing modality [11–13]. Furthermore, concurrent use of endoscopic ultrasound-guided fine-needle aspiration (EUS-FNA) permits histopathologic diagnosis, which is critical for deciding the therapeutic strategy [14–16].

#### Endoscopic Retrograde Cholangiopancreatography

Endoscopic retrograde cholangiopancreatography (ERCP) can determine the position of the tumor in relation to the pancreatic duct. Additionally, ERCP allows pancreatic juice cytology, making it a critical test to employ during diagnosis.

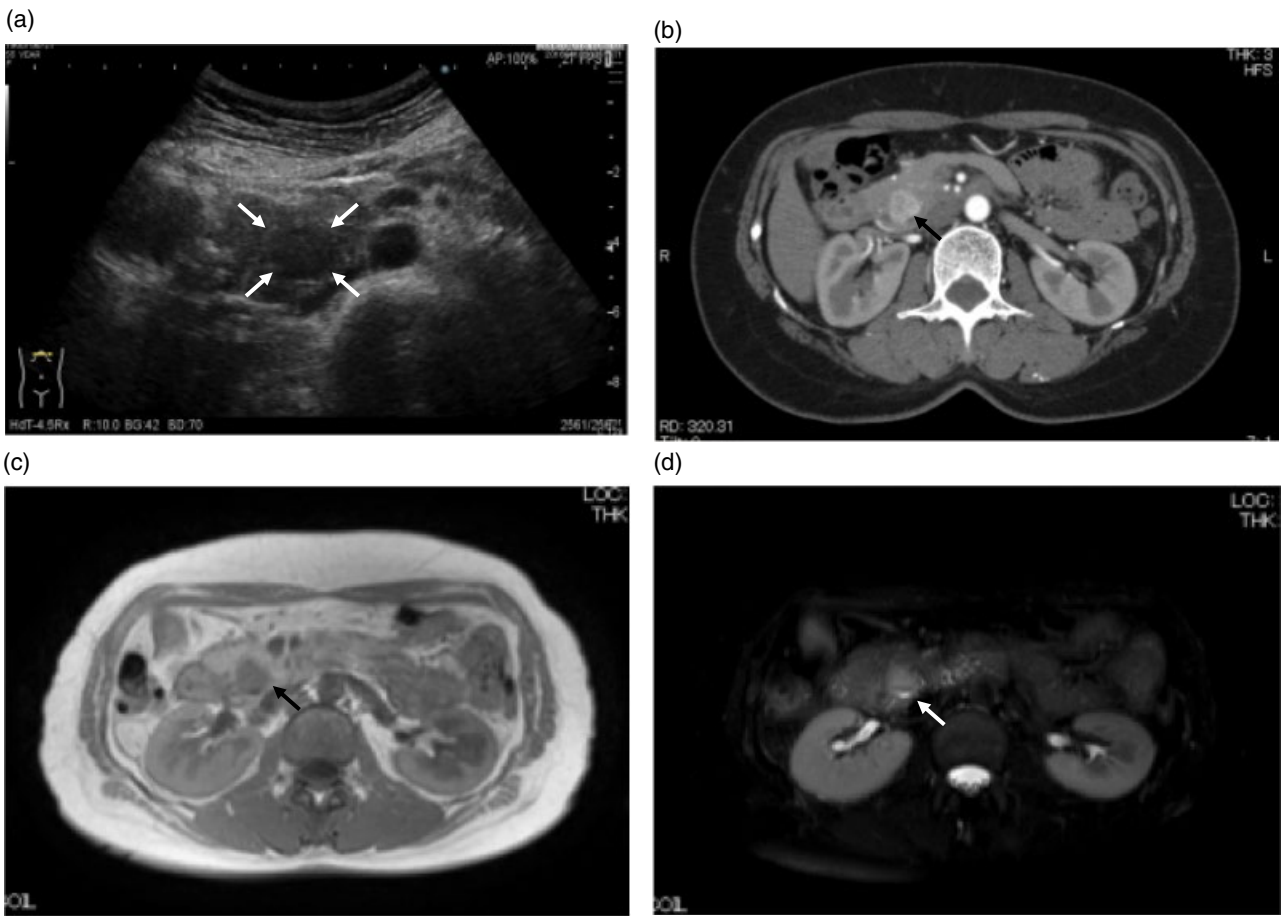

**Figure 124.1** Clinical imaging studies in a 55-year-old female patient with a nonfunctional neuroendocrine G1 tumor (white and black arrows) in the pancreatic head lesion: (a) US; (b) CT; (c) T1-weighted MRI; (d) T2-weighted MRI.

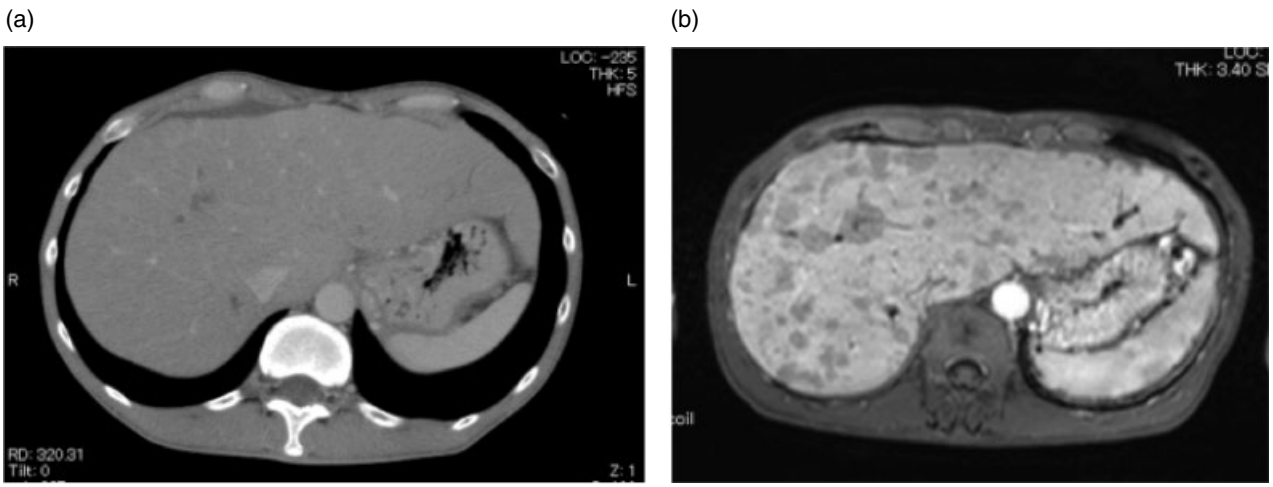

**Figure 124.2** Hepatic screening images in a 43-year-old male patient with pancreatic nonfunctional neuroendocrine tumors. An enhanced CT image shows no obvious metastases (a) whereas an enhanced MRI image clearly shows multiple liver metastases (b).

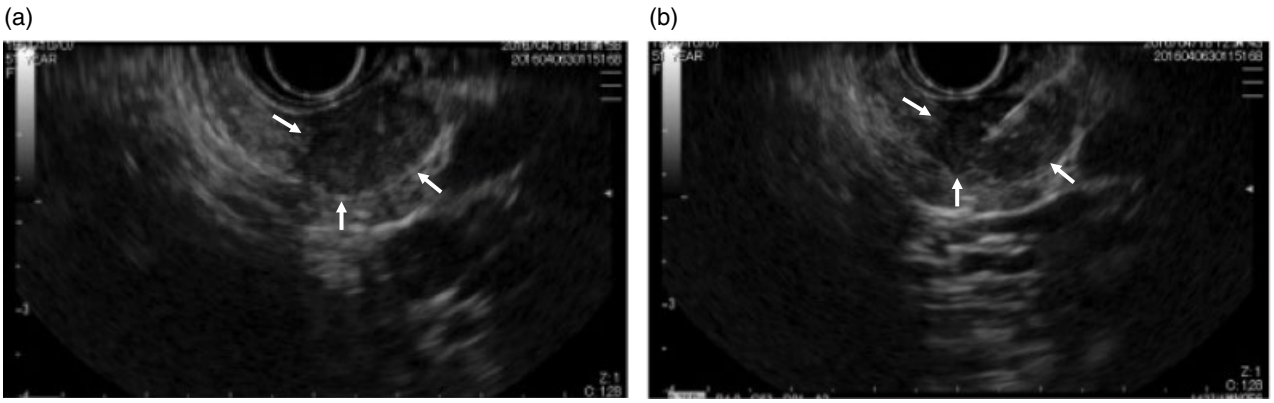

**Figure 124.3** EUS-FNA images in a 51-year-old female patient with a nonfunctional neuroendocrine G2 tumor (white arrows).

#### Selective Arterial Secretin/Calcium Injection Test

At the time of abdominal arteriography, a catheter is placed in the hepatic vein for secretin/calcium infusion into the feeding artery of each pancreatic region. The level of gastrin/insulin in the hepatic venous blood is then measured. The tumor's location is determined based on the increase in gastrin concentration (more than twofold). As the supply vessel for the tumor is identified, localization becomes possible for those tumors that are difficult to visualize by imaging modalities. This technique is especially useful as a preoperative test for gastrinoma and insulinoma [17, 18].

#### Somatostatin Receptor Scintigraphy

In well-differentiated PanNET, somatostatin receptor (SSTR) is highly expressed on the cell membrane. The somatostatin mimetic octreotide, which is metabolically stable and has a strong affinity for SSTR, is labeled with a radioisotope and then injected, whereupon it binds to SSTR and emits a gamma ray. This ray is then detected by single photon emission CT or positron emission tomography. Somatostatin receptor scintigraphy is useful for searching the entire body for PanNET, including metastatic lesions [19].

## Introduction

The term "pancreatic neuroendocrine tumors" (PanNET) covers a variety of heterogeneous pancreatic tumors, originating from neuroendocrine cells. Many synthesize and secrete a variety of unique molecules and overexpress somatostatin receptors (SSTR) on their cell surface. Functional PanNET secrete one, or more than one, active hormone, resulting in classical symptoms and signs (see Chapter 124). Nonfunctional PanNET do not secrete any active hormones. The investigation of PanNET requires specialized biochemical investigations of specific hormones. Serum DNA and serum RNA are emerging as promising investigative tools. However, as PanNET are still rare, there is a lack of standardization of the various investigations and assays. This may cause difficulties in the interpretation of many of the laboratory-based investigations. Imaging with conventional computed tomography (CT), magnetic resonance imaging (MRI), and radionuclide scans is an essential part of the localization and assessment of PanNET. Imaging investigations based on the unique specific expression of cell surface receptors and unique metabolic features are particularly important in the detection of PanNET.

There has been rapid progress in many of the investigations for PanNET, with more serum-based measurements, better dynamic enhanced CT and MRI techniques, and a number of radioisotope-linked ligands and molecules becoming available for nuclear imaging. This chapter describes serum-based laboratory investigations followed by various conventional and more PanNET-specific radionuclide imaging investigations.

## Serum-Based Laboratory Investigations

Pancreatic neuroendocrine tumors often secrete hormones. However, as there may be incomplete or defective processing, the hormones may not be functionally active. Some of these incomplete hormones may still be identified in immunochemistry and be measurable in the serum in many commercial assays, and cause confusion if nonspecific symptoms and signs are present as to whether they are "functional" or not. Measurement of the relevant hormone, functional or not, if elevated, remains useful for diagnostic and prognostic purposes.

In addition to these hormonal secretions, some common molecules are secreted by many PanNET. The most established is chromogranin A (ChA). Many others have been reported, including chromogranin B, human pancreatic polypeptide, and neuron-specific enolase (NSE), but these markers generally have low specificity and sensitivity [1]. Finally, the rapidly advancing field of serum DNA and RNA identification, in particular patterns and clusters ("signatures"), is being studied for its usefulness as diagnostic and prognostic markers in PanNET.

All these serum-based investigations should be carried out with the appropriate precautions because of the difficulty in the interpretation of many of them. Endocrine hormones may be affected by their own dynamic regulation, and also by many commonly prescribed drugs. A recent consensus concluded that all the available biomarkers for neuroendocrine tumors (NET) had significant limitations and suggested a "multianalyte" approach [2].

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

Table 125.1 gives a list of the more common functional PanNET for which specific hormonal and other investigations are useful.

## Insulinomas

Insulinomas are the most frequent functional PanNET. However, insulinomas are unlike other PanNET and rarely secrete ChA or overexpress SSTR. Insulinomas almost always originate from the pancreas, and may be sporadic or be associated with multiple endocrine neoplasia type 1 (MEN1), where they present as multiple tumors (see Chapter 126). Diagnosis of an insulinoma requires the clear demonstration of inappropriately elevated serum insulin concentrations in the presence of venous hypoglycemia, and exclusion of other causes. They are usually benign at the time of diagnosis.

The gold standard for diagnosis is the supervised prolonged fast (72 hours) with regular venous blood sampling every 4–6 hours for glucose, insulin, and C-peptide. The fast is terminated if there is hypoglycemia (glucose <2.5 or 3.0 mmol/L) with symptoms and signs. The presence of inappropriately elevated serum insulin and C-peptide concentrations (even within the normal range) is diagnostic. An elevated insulin level with low C-peptide indicates surreptitious exogenous insulin use. Absolute cut-off values given in some reports [3] have to be interpreted within the context of the laboratory, as both insulin and C-peptide assays are not standardized internationally.

A 48- or 24-hour fast, followed by vigorous exercise, with or without the aid of continuous glucose monitoring, has been reported to be as good in making a conclusive diagnosis [3,4]. An elevated plasma proinsulin-to-insulin ratio may be helpful. Provocative tests with infusion of arginine, calcium, and glucagon are now rarely performed.

In addition, urine or plasma sulfonylurea should be measured, as both insulin and C-peptide are elevated in patients taking these drugs surreptitiously. In East Asians, anti-insulin autoantibodies should also be measured to exclude insulin autoimmune syndrome [5]. Care should also be taken in the interpretation of elevated insulin levels if there has been previous bariatric surgery.

Imaging investigations should proceed after establishing a laboratory diagnosis (see later).

## Gastrinomas

Gastrin-secreting PanNET can occur sporadically and in association with MEN1 (one in four in some series). They are often multiple, malignant, and are present in the duodenum in addition to the pancreas at diagnosis. The hypergastrinemia causes severe gastric hyperacidity, with abdominal pain, increased gut motility, and diarrhea. Fasting serum gastrin is usually markedly elevated. However, there is no standardization of the assays or agreed normal population ranges. Commonly prescribed acid-suppressing drugs will elevate serum gastrin. These have to be stopped (7 days for proton-pump inhibitors [PPI], 2 days for others) and the fasting serum gastrin remeasured. Other causes of elevated fasting serum gastrin are chronic kidney disease, atrophic gastritis, and short bowel syndrome. Finally, several molecular forms of gastrin may be secreted that may or may not be accurately measured by many of the available commercial assays [6]. Therefore, care must be exercised in the preparation of the patient before taking measurements and in the interpretation of the results. Most patients with gastrinomas are *Helicobacter pylori* negative, and the presence of multiple peptic ulcers in such patients should raise the index of suspicion.

The secretin stimulation test has been reported to be useful in some patients, especially when hyperacidity symptoms are too severe to permit withdrawal of acid-suppression drugs. A 2 U/kg bolus of secretin is administered intravenously after an overnight fast and serum gastrin is measured at 0, 2, 5, 10 and 15 min. An increase in serum gastrin of >200 pg/mL is considered as diagnostic. However, false-positive results may still occur and care has to be taken in the interpretation of these tests [7].

Imaging studies should proceed if there is clear suspicion from the presence of severe hyperacidity or if gastroscopy shows the presence of multiple peptic ulcers (see later). SST-based positron emission tomography (PET)/CT may be necessary if other imaging modalities are negative.

## Glucagonomas

Glucagon-secreting PanNET are very rare and originate from the pancreas. They are usually sporadic but may be associated with MEN. The classical clinical syndrome of diarrhea, weight loss, hyperglycemia, and necrolytic migratory erythematous rash is usually recognized late, when the PanNET is large and liver and other metastases are already present (see Chapter 124). Mild anemia and recurrent venous thromboembolism are common. The grossly elevated concentrations of fasting serum glucagon and imaging findings will give a clear diagnosis. However, glucagon measurements in the absence of clinical signs are difficult to interpret. Secretion of glucagon is affected by many factors, and many smaller glucagon-like molecules are present in the blood and may give falsely elevated results [8].

Elevated fasting glucagonemia may be found in liver cirrhosis, chronic kidney disease, acromegaly, and hypercortisolism.

**Table 125.1** Investigation of pancreatic neuroendocrine tumors (see text for details).

| Suspected PanNET | Differential diagnosis | Pancreatic origin (versus other locations) (%) | Confined to pancreas at diagnosis | Laboratory investigations | Imaging investigations | Other special investigations |
|---|---|---|---|---|---|---|
| Insulinoma | Factitious; autoimmune disease | >90 | Often | Prolonged fast with insulin and C-peptide measurements | EUS | Selective intra-arteriolar calcium infusion; other radionuclide imaging (non-SSTR) |
| Gastrinoma | Acid-suppressing medications (proton pump inhibitors) | <50 | Very rarely | Fasting serum gastrin;secretin test; ChA | | SSTR imaging |
| Glucagonoma | | >90 | Very rarely | Serum glucagon<br>ChA | | Conventional CT/MRI usually adequate |
| VIPoma | | <50 | Rarely | Serum VIP;<br>ChA | | SSTR imaging |
| ACTH | Nonpancreatic ectopic ACTH tumor | <10 | If pancreatic, very often | Dexamethasone suppression test, CRH stimulation test | EUS | SSTR imaging |
| Somatostatinoma | | <50 | Very rarely | Serum somatostatin;<br>ChA | | Unknown |
| "Classical carcinoid syndrome" | | <10 | Rarely | 24-hour urine 5HIAA<br>ChA | | SSTR imaging |
| Nonfunctioning PanNET | | | Increasingly as "incidentalomas" | ChA, NSE, human pancreatic polypeptide, serum DNA signatures | Dynamic CT or MRI | SSTR imaging |

For abbreviations, see text.
SSTR imaging: includes PET/CT with [$^{68}$Ga]DOTA-TOC, DOTA-TATE and DOTA-NOC.
Non-SSTR radionuclides are not widely available and include PET/CT with [$^{68}$Ga]DOTA-exendin 4 and PET with [$^{18}$F]dopamine.

### Vasoactive Intestinal Peptide (VIP)

VIPomas are rare, sporadic, and usually occur in the distal pancreas. They are, like gastrinomas and glucagonomas, diagnosed late with established metastatic spread at diagnosis. The classical presentation is that of severe watery diarrhea, hypokalemia, and occasionally facial flushing. Serum VIP is often grossly elevated. However, in the early stages when secretion is episodic, levels may fluctuate and blood samples should be collected when the patient is having diarrhea. It is also important to use a reliable tested assay as elevated VIP may also be found in chronic kidney disease, short bowel syndrome. and radiation enteritis.

Imaging studies with SST analogs may be helpful in this rare PanNET.

### ACTH (and CRH)-Secreting PanNET

The diagnosis of Cushing syndrome due to ectopic adrenocorticotropic hormone (ACTH) secretion is often difficult. The initial screening test for hypercortisolemia is the 1 mg overnight dexamethasone test; wherein an adequate suppression of serum cortisol excludes hypercortisolemia. In the event of uncertainty, hypercortisolemia should be confirmed with a formal 3-day low-dose dexamethasone suppression test. The plasma ACTH should then be measured to distinguish between an adrenal cause or an ACTH-dependent hypercortisolic state. If the ACTH level is inappropriately elevated, then further investigations are necessary to distinguish between a pituitary tumor and an ectopic ACTH tumor. This may include a corticotrophin hormone test and inferior petrosal sinus sampling, or a combination of the two. In patients with ectopic Cushing syndrome, imaging and localization studies for the NET will include the pancreas, lung, and thymus. Imaging of the pancreas with fine-cut CT may reveal an ACTH-secreting PanNET. Rarely, PanNET may secrete corticotropin-releasing hormone (CRH). Measurements for serum CRH are not widely available, and interpretation is difficult.

Imaging with SST analogs is useful if conventional CT or MRI does not reveal a tumor.

### Other Functional PanNET (Somatostatin, Ghrelin, Serotonin)

Other PanNET have been reported to secrete endocrine hormones, including somatostatin (SST), ghrelin, growth hormone (GH), and parathyroid hormone (PTH). Other hormones have been reported, often as single case reports, and will not be discussed further.

SST-secreting PanNET are very rare, sporadic, and usually arise from the pancreas, but are found also in the duodenum. Symptoms are usually mild and nonspecific and include hyperglycemia, weight loss, abdominal pain, gallbladder stasis, and diarrhea. Liver and other metastases are usually present at diagnosis. Elevated SST levels are diagnostic but, like the other rarely measured hormones, available assays vary considerably in characteristics and ranges. Elevated SST may be found in medullary thyroid tumors, small-cell lung tumors, pheochromocytomas, and paragangliomas.

Ghrelin, growth hormone-releasing hormone (GHRH), and GH-secreting PanNET are very rare, and originate in the lung and pancreas. They may be sporadic or, rarely, associated with MEN1. Both ghrelin and GH cause classical acromegaly, which presents to the endocrinologist. There should be suspicion of this rare NET if there is elevated GH in the presence of a generally enlarged pituitary gland without a defined pituitary adenoma. Ghrelin and GHRH assays are not standardized and not widely available.

Serotonin (5-hydroxytryptamine, 5-HT)-secreting PanNET are very rare, as these classical "carcinoid tumors" are more frequent in the hindgut and other locations. When found as a PanNET, they are usually large and malignant, with metastases present at diagnosis. Urinary 5-hydroxyindoleacetic acid (5HIAA) is the investigation of choice and is elevated in most patients with the classical symptoms of facial flushing, diarrhea, and right heart failure.

Other functioning PanNET reported (as case reports) include the following: PTH and PTH-related polypeptide (PTH-rP)-secreting PanNET causing hypercalcemia, renin-secreting PanNET causing hypertension, erythropoietin (EPO)-secreting PanNET causing polycythemia, and calcitonin, cholecystokinin, and neurotensin. It is likely that there will be more reports when more assays become available and our understanding of the various rare hormones improves.

### Nonspecific Biochemical Markers in PanNET

Many PanNET secrete other molecules, which, if present, may be useful as biomarkers for diagnosis and prognosis [9,10]. These are useful in establishing a diagnosis of a PanNET in incidentalomas of the pancreas, or where a nonfunctioning PanNET is suspected. These include ChA, other chromogranins [11], human chorionic gonadotrophin (hCG), synaptophysin, NSE [12], pancreatic polypeptide, and, more recently pancreastatin (a derivative of ChA) [13]. Of these, only ChA has proved consistently useful as a marker for diagnosis and prognostication for most functioning and nonfunctioning PanNET, except for insulinomas. It is important to remember that ChA may also be elevated in other nonpancreatic endocrine tumors and in liver and kidney

disease. NSE is useful mainly in poorly differentiated PanNET, and pancreatic polypeptide may be useful in nonfunctioning PanNET.

Imaging with SST analogs is useful in identifying and distinguishing a PanNET from other tumors (except for insulinomas).

### Serum RNA and DNA Measurements in PanNET

Recent advances in measurements of serum DNA and RNA have led to studies of their usefulness as biomarkers in PanNET. Studies on serum DNA, together with fresh tissue from patients with NET, have been reported to identify similarities in the patterns of DNA expression and secretion into the circulation. Serum RNAs, including microRNAs (miRNA) and long non-coding RNAs (lcRNA) have been measured in various PanNET. Various patterns ('signatures') have been reported as potentially useful in distinguishing NET from other pancreatic tumors [14].

Some groups have reported promising results with serum DNA signatures [15]. Studies with serum RNA signatures are less promising, as RNA degradation in serum is more rapid and variable, and further studies will be necessary to establish their usefulness [2,16]. With the increasing availability of these techniques and the decrease in costs, it is possible that they may be useful in the future as biomarkers for PanNET.

## Instrumental and Invasive Investigations

Conventional ultrasound (US) scans are widely available and inexpensive, but have high operator dependency. Transabdominal US may be sufficient for large PanNET, but is generally less suitable for obese patients.

Insulinomas most frequently require invasive instrumental investigations because the diagnosis is made early with biochemical investigations when the tumor is very small. Insulinomas are almost always confined to the pancreas, rarely secrete ChA, and are not detectable on SST radionuclide imaging. In this context, endoscopic ultrasound (EUS) may be helpful in the localization of a small biochemically proven insulinoma [17]. Selective venous sampling, selective arterial injection of calcium, and intraoperative US (with direct contact with the pancreas during surgery) may all be useful. If all of these fail to reveal the tumor, then progressive partial pancreatectomy may be necessary, and that may find single or multiple tiny insulinomas or diffuse nesidioblastosis. Recent advances in dynamic CT (see later) and radionuclide receptor ligands may reduce the need for such invasive preoperative investigations for insulinomas in the future [18]. Other functioning PanNET are usually detectable as large tumors at diagnosis.

EUS, combined with guided fine-needle aspiration cytology and/or core biopsy, may be useful in diagnosing small nonfunctioning PanNET.

## Imaging

### Conventional CT and MRI

Conventional CT and MRI are useful for most functioning larger PanNET (around 1 cm in diameter or larger). Recent developments in multiphase contrast-enhanced CT and dynamic MRI have reported good results for earlier detection and characterization of smaller and nonfunctioning PanNET [19,20], and even for histologic staging [21]. Pancreatic NET are usually densely hypervascular and therefore appear as well-circumscribed masses with early strong enhancement from the arterial to pancreatic phase. Diffusion-weighted imaging MRI (DWI) has also been reported to be useful, alone or in conjunction with SST-based radionuclide imaging, in some PanNET [22]. Pancreatic NET usually appear as low-intensity images on T1 and high intensity on T2, with clear gadolinium enhancement. These findings may be adequate when sophisticated and expensive specialized radionuclide SST and other PET/CT imaging facilities are unavailable.

### Conventional PET Scans

Conventional scintigraphic scans are not helpful in the investigation of PanNET. The classical PET scan (including single-photon emission computed tomography [SPECT] and PET/CT) uses the uptake of [$^{18}$F]fluoro-2-deoxy-D-glucose (FDG) to identify tumor cells with high glucose utilization, and is useful in identifying aggressive PanNET with higher mitotic rates. More indolent PanNET are not identified using this scan.

To identify slower growing PanNET, other radionuclides have been studied based on the metabolic characteristics of normal pancreatic islet cells. Dopamine-based radionuclide studies have been reported using [$^{18}$F]fluorodopamine ([$^{18}$F]DOPA) and [$^{11}$C]-L-dopamine ([$^{11}$C]-L-DOPA), and [$^{11}$C]-5-hydroxytryptophan ([$^{11}$C]-5-HTP) for insulinomas [23]. However, all of these are available only at specialized centers and have been reported to be of use only in PanNET with negative or minimal SSTR expression (see later).

### Somatostatin and Other Peptide Receptor-Based Radionuclide Imaging

Most differentiated PanNET (except insulinomas), functional and nonfunctional, have the unique property of overexpression of cell-surface SSTR. This has led to the

development of radionuclides linked to SST analogs. Endogenous SST has a very short half-life of a few minutes and the synthetic analog octreotide, with a longer half-life, has been shown to be very useful in NET. Initially this was linked to iodine-123 and subsequently with indium-111 (commercialized as Octreoscan) and technetium-99 m. Detection rates were reportedly good in many PanNET and correlated with prognosis and response to treatment. More recently, these have been superseded by PET/CT scanning with gallium-68-linked octreotide analogs. The chelating molecule DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid) is used and three main DOTA compounds have been extensively studied and compared in large numbers of PanNET in several centers: DOTA-TOC (DOTA-Tyr-octreotide), DOTA-TATE (DOTA-Tyr-octreotate) and DOTA-NOC (DOTA-Nal-octreotide). These have proven much better at identifying both functioning and

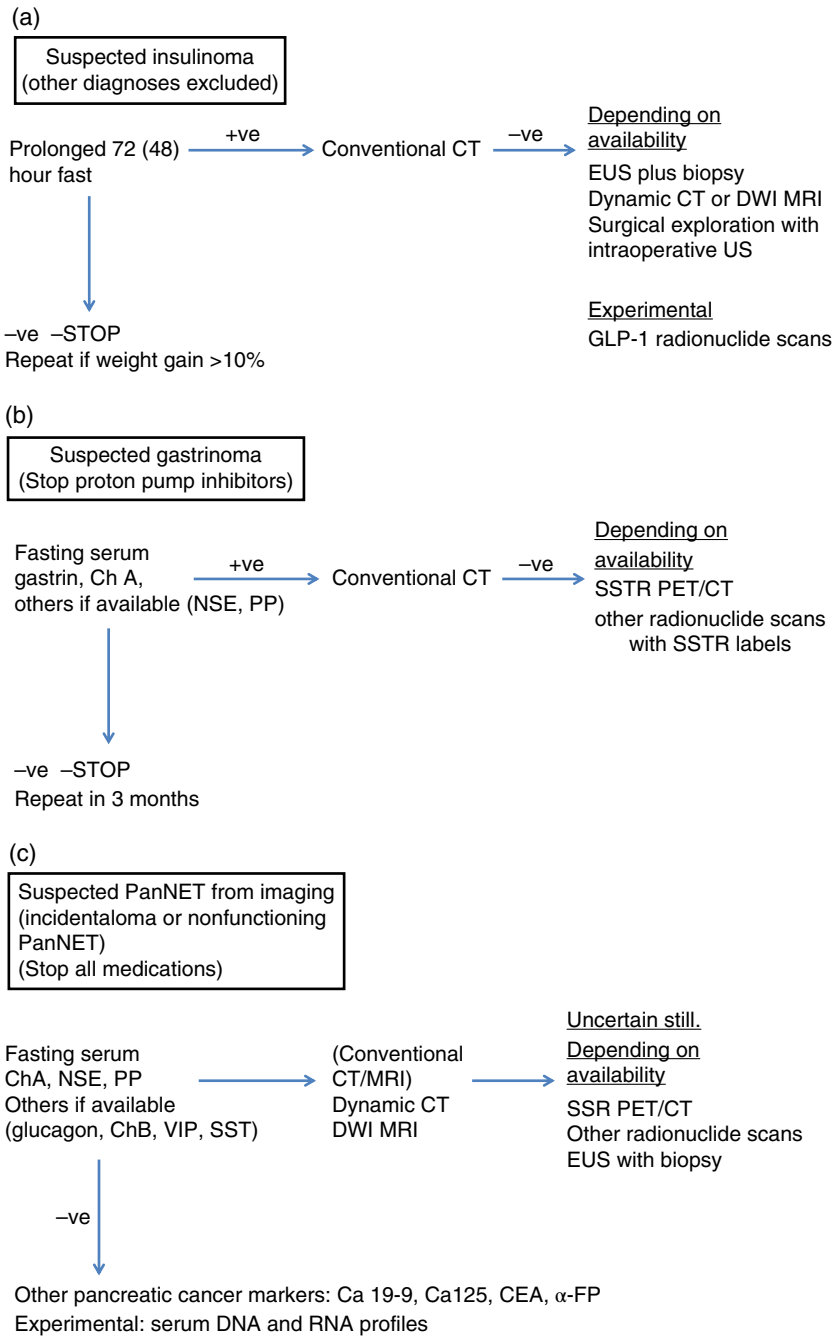

**Figure 125.1** Suggested flow chart for investigations in suspected PanNET.

nonfunctioning PanNET and their metastases. The specificity and sensitivity are high (>80%) and the differences reported in different PanNET of differing histologic stages are minor and may be the result of the different study populations [20].

There are five SSTR subtypes. Octreotide binds strongly only to the SSTR-2, and less to SSTR-5. Recent studies have investigated the newer SSTR analogs lanreotide and pasireotide. Lanreotide has similar binding as octreotide, but pasireotide has higher binding to SSTR-3 and -5 and similar binding to SSTR-2 compared with octreotide. Newer [$^{68}$Ga]DOTA radionuclides linked to pasireotide are being developed and studied actively in PanNET.

Other peptide receptors have been identified in PanNET and attempts have been made to utilize these for imaging (and therapy) in the less common NET with less overexpression of SSTR. These would have the greatest potential in insulinomas where the glucagon-like peptide 1 (GLP-1) receptor and the glucose-dependent insulinotropic peptide (GIP) receptor are abundant. The GLP-1 radioligand [$^{68}$Ga]DOTA-exendin 4 is already available with a promising report [24]. Other peptide receptors are being actively investigated at present and may have potential in pancreatic and other NET, including cholecystokinin-2/gastrin, gastrin-releasing peptide, and neuropeptide-Y [25].

### Combined Multitracer Radionuclide Scans

A recent multitargeted approach, using a cocktail of three different radioligand peptide receptors at the same time, targeting the SSTR, GLP-1, and GIP receptors, suggested better results than with single radioligand imaging [26]. Although this approach would save time, the costs will invariably be much higher. Moreover, interpretation may be difficult as normal tissues have different levels of expression of these peptide receptors, hence false-positive and -negative rates will have to be confirmed in other centers. In addition, in peptide receptor radionuclide therapy (PRRT) (see Chapter 128), information is necessary on the relative abundance of single receptor types, as the therapeutic doses of the therapeutic radioisotope, most commonly lutetium-177 or yttrium-90 (Y90), are bound to single analogs. This information will be lost if a cocktail of radionuclides is utilized for imaging.

## Conclusions

A suggested flow chart for investigations in suspected PanNET is presented in Figure 125.1.

Pancreatic NET are rare and heterogeneous tumors. Biochemical investigations are necessary and essential, but may be difficult to interpret because of the use of nonstandardized assays. However, rapid advances are emerging with an increase in the understanding of their distinguishing properties and behavior. The unique overexpression of SSTR in most PanNET has made this an essential imaging modality for the diagnosis and assessment of most PanNET.

Advances in both serum-based and imaging investigations of PanNET will need to be carefully evaluated for both diagnosis and management.

# Pancreatic Neuroendocrine Tumors in Multiple Neoplasia Syndromes

*Anja Rinke and Thomas Matthias Gress*

*Department of Internal Medicine, Division of Gastroenterology and Endocrinology, Philipps University, Marburg, Germany*

## Introduction

Neuroendocrine tumors, including pancreatic neuroendocrine tumors (PanNET), are on the rise and, probably owing to improved imaging techniques and better awareness, especially localized disease is more often diagnosed [1]. Although most of these tumors are sporadic, in 10–15% of PanNET there is a hereditary background with multiple endocrine neoplasia type 1 (MEN1) being the most relevant family cancer syndrome for PanNET. Early diagnosis of the hereditary syndrome is of diagnostic and therapeutic relevance for the patient and his or her kindreds. Diagnostic procedures, follow-up, and treatment should be managed by a multidisciplinary team with experience in the management of MEN1 [2].

MEN1 should always be suspected in patients with PanNET with multiple lesions, a positive family history, a second MEN1 typical manifestation such as hyperparathyroidism or pituitary tumor, or in cases of gastrinoma/Zollinger–Ellison syndrome (ZES) even in the absence of a positive family history. In addition to the classical "three-P triad" of **p**arathyroid tumor (90–100% of cases), **p**ituitary tumor (20–60%), and **p**ancreatic tumor (60–80%), patients with MEN1 may also develop adrenocortical tumors, lipomas, carcinoid tumors, including thymic, gastric, and lung carcinoids, facial angiofibromas, collagenomas, and meningiomas and may also have an increased risk for other nonendocrine malignant tumors such as lymphoma, myeloma, melanoma, renal cell cancer, ovarian tumors, and sarcoma [3]. This chapter focuses on the management of PanNET in MEN1.

## Epidemiology

With an estimated prevalence of 0.02–0.2 per 1000 inhabitants, MEN1 is one of the most common familial cancer syndromes; in an old autopsy study, the reported incidence was 0.25% [4,5]. Duodenopancreatic neuroendocrine tumors are the second most frequent manifestation of MEN1. Older studies probably underestimated the prevalence of PanNET in MEN1 syndrome and with more sensitive diagnostic tools about 70–80% of patients are found to develop PanNET [2,6]. PanNET have an earlier age of onset in patients with MEN1 than in patients without MEN1. These tumors are typically multiple and can present with hormone syndromes or be nonfunctioning [7]. The most common hormone-active duodenopancreatic tumors are gastrinomas, followed by insulinomas, whereas vasoactive intestinal peptide-releasing tumors (VIPomas) and glucagonomas are rare. Approximately 20–30% of all patients with ZES will have MEN1 [2,8].

## Genetics

MEN1 is an autosomal dominant inherited syndrome with high penetrance; 90% of persons with germline MEN1 mutation will develop symptoms of MEN1 during life. In 1988, the MEN1 gene locus was first mapped to the long arm of chromosome 11 (11q13) [9] and in 1997 the gene was identified and cloned [10]. It acts as a tumor suppressor gene and codes for the 610 amino acid protein

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

menin, which is involved in transcription regulation, genome stability, and proliferation [2,10]. In about 10% of MEN1 cases, the germline mutation arises *de novo* and the family history is negative [2].

More than 1300 inactivating mutations involving all locations of the gene have been identified so far and in about 90% of clinically diagnosed MEN1 cases the mutation in the MEN1 gene can be detected [2]. About 70% of the mutations are non-sense and frame-shift mutations, resulting in truncation of the protein. In contrast to the MEN2 syndrome, there is no clear genotype–phenotype correlation and even in one family the manifestations may vary [11,12]. The diversity of mutations makes mutational analysis in MEN1 difficult and complete sequencing of the whole gene is necessary. In contrast, if the mutation of an index case in the family is known, family members only have to be analyzed to determine whether the known mutation is present or absent.

## Diagnosis

Three diagnostic criteria for MEN1 exist, each individually establishing the diagnosis of MEN1 [2]:

1) identification of a germline MEN1 mutation in the individual, or
2) diagnosis of a MEN-associated tumor in a person who has a first-degree relative with known MEN1, or
3) occurrence of two or more primary MEN1-associated endocrine tumors.

The diagnosis of a PanNET may result either from symptoms (e.g., hypoglcycemia in a patient with insulinoma) or from biochemical (elevated levels of pancreatic polypeptide, gastrin, insulin, glucagon, vasoactive intestinal polypeptide [VIP]) or morphologic screening (identification of pancreatic lesions in computed tomography [CT], magnetic resonance imaging [MRI], endoscopic ultrasound, somatostatin receptor imaging).

In a patient with MEN1 syndrome, at least annual biochemical and morphologic screening for PanNET is recommended [2]. There is no clear recommendation regarding the method of morphologic screening, but endoscopic ultrasound (EUS) is more sensitive for small pancreatic lesions than CT or MRI [13]. It also could be demonstrated that precise documentation of the growth behavior of these small pancreatic lesions can be achieved using EUS [14]. In patients with gastrinoma, upper gastrointestinal endoscopy is indicated. Typically gastrinomas in MEN1 are small, multiple, and located in the duodenum, where the sensitivity of EUS is inferior compared with pancreatic lesions. In recent publications, a role for [$^{68}$Ga]DOTA-TOC (DOTA, 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid; DOTA-TOC, DOTA-Tyr-octreotide) positron emission tomography (PET)/CT or DOTA-TATE (DOTA-Tyr-octreotate) PET/CT for screening and surveillance of patients with MEN1 has been suggested (Fig. 126.1) as this method has a higher sensitivity than somatostatin receptor scintigraphy and CT, especially for detecting small metastases and extra-abdominal disease [15,16]. Insulinomas express the somatostatin receptor subtype 2a in only

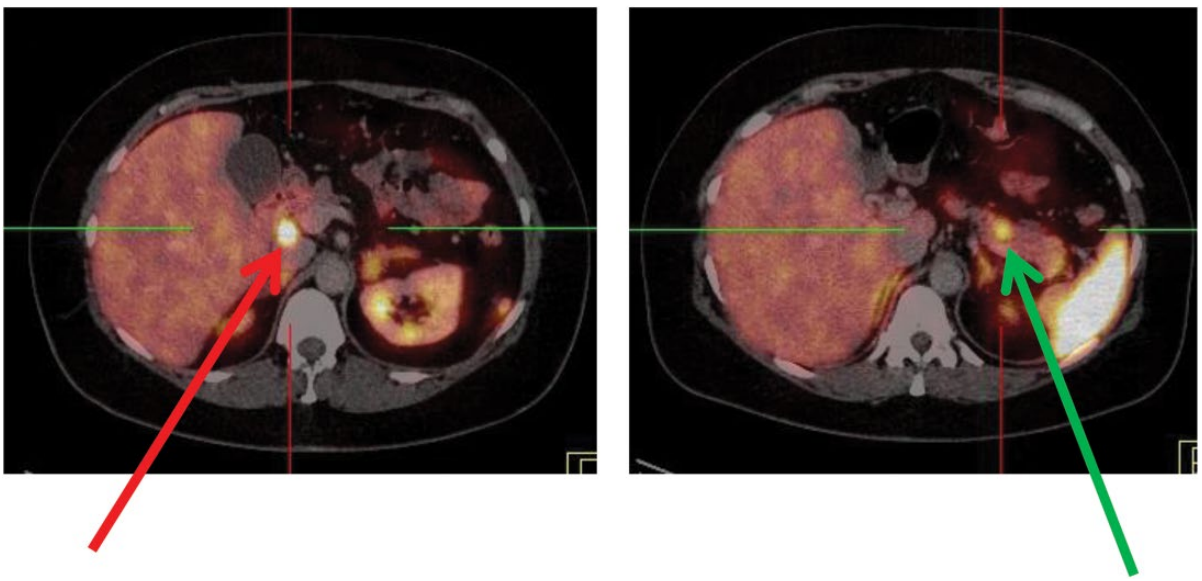

**Figure 126.1** [$^{68}$Ga]DOTA-TOC PET/CT in a 41-year-old patient with known MEN1 syndrome. She had undergone parathyroidectomy because of hyperparathyroidism 10 years earlier. At present she is diagnosed with hypergastrinemia without clinical manifestation of ZES. Red arrow, duodenal lesion. Green arrow, additional pancreatic lesion; no evidence of metastases.

about 50% of cases and therefore are often not detected in somatostatin receptor-based imaging. Recently, glucagon-like peptide 1 (GLP-1)-based scintigraphy or PET/CT has been shown to localize insulinoma with high sensitivity [17,18].

## Clinical Presentation

*Nonfunctioning PanNET* are usually asymptomatic. In cases of advanced disease, they can cause unspecific tumor-associated symptoms such as abdominal or back pain, jaundice, or weight loss.

*Gastrinomas* cause the *Zollinger–Ellison syndrome* (ZES) with a clinical manifestation resulting from gastric acid hypersecretion such as severe peptic disease (peptic ulcerations), gastroesophageal reflux disease, and diarrhea. Peptic ulcer bleeding may be the presenting symptom in some patients. The use of proton-pump inhibitors (PPI), however, may mask the symptoms of ZES and delay diagnosis. Concomitant hyperparathyroidism may enhance hypergastrinemia-associated symptoms. With biochemical screening in patients with a known diagnosis of MEN1, hypergastrinemia can be detected early before a clinically relevant ZES develops. Patients with MEN1 with ZES present at an earlier age (mean 32–35 years) than patients with sporadic gastrinomas.

*Insulinomas* present with symptoms of hypoglycemia (headache, diplopia, confusion, dizziness, abnormal behavior, amnesia, rarely seizures and coma) and symptoms resulting from the counter-regulation of the autonomic nervous system (sweating, weakness, hunger, tremor, anxiety, and palpitations). Patients often gain weight. The presence of a Whipple triad remains useful in suspecting underlying insulinoma [19]. The triad consists of symptoms of hypoglycemia, plasma glucose level <40 mg/dL, and relief of symptoms with administration of glucose. Insulinomas in patients with MEN1 often occur at young age (many <20 years), whereas sporadic cases generally occur in patients aged >40 years [2].

A *glucagonoma syndrome* is found in <5% of patients with MEN1 and is characterized by the presence of a necrolytic migratory erythema (a characteristic skin rash), weight loss, anemia, and glucose intolerance or diabetes. In clinical practice, the glucagnoma syndrome is rare and more often pancreatic lesions stain positive for glucagon with slightly increased glucagon serum levels, although without the clinical syndrome [2].

The *Verner–Morrison syndrome*, also called pancreatic cholera or WDHA syndrome (watery diarrhea, hypokalemia, and achlorhydria) is caused by hypersecretion of VIP. Patients suffer from excessive diarrhea with electrolyte and pH disturbances and dehydration. Less than 1% of patients with MEN1 present with Verner–Morrison syndrome [2].

In a patient with MEN1, more than one hypersecretion syndrome can develop over the years.

## Surgical Treatment

A proven organic hyperinsulinism is an indication for surgical treatment. Whereas in sporadic cases an enucleation is often appropriate, in patients with MEN1 who often have multiple tumors impeding the clear identification of the insulinoma, a left pancreatic resection with enucleation of tumors in the pancreatic head is regarded as the standard procedure by most surgeons. Excision of all macroscopically detectable tumors may be an alternative. Routine lymphadenectomy is not indicated. Intraoperative ultrasound and the determination of the insulin/glucose ratio have been suggested for assessing the success of the removal of the insulinoma [20].

In patients with glucagonomas and VIPomas, the primary tumor is often located in the pancreatic tail and surgical removal with curative intention (left pancreatectomy with lymph node resection) is the treatment of choice. In metastasized cases, interdisciplinary discussion of operative debulking, medical treatment, and hepatic artery embolization or combinations thereof is necessary.

The role of surgery in treating patients with MEN1-associated gastrinomas is controversial. About 90% of patients with MEN1 have multiple tumors in the duodenum and a favorable long-term prognosis if only small tumors (<2 cm) or no tumors are present on preoperative imaging examination [21]. In a French study, gastrinomas >3 cm demonstrated liver metastases in 40% of cases compared with only 4.8% when the tumors were <3 cm. Surgical treatment was associated with a significantly reduced risk for the development of liver metastases compared with medical treatment; however, the only significant prognostic factors for overall survival were the diagnosis of ZES before 1980 and age [22]. Thompson et al. proposed subtotal left pancreatectomy with preservation of the spleen, enucleation of tumors of the pancreatic head, duodenotomy with excision of duodenal tumors, and lymphadenectomy as the standard procedure for surgical treatment of ZES in MEN1 [23]. Most patients can be rendered eugastrinemic with this approach but cure is rare. Therefore, some centers suggest a more aggressive surgical approach with partial pancreaticoduodenotomy to provide a higher rate of cure [24]. The increased likelihood of cure has to be weighed against an increased operative mortality and long-term morbidity in each individual case and the patient's preference must be considered.

Nonfunctioning PanNET also harbor the risk of malignant transformation and there is an ongoing debate

regarding the correct timing and extent for surgical intervention. Thakker et al. suggested in their guidelines that surgery should be considered for tumors larger than 1 cm and/or demonstrating a significant growth over 6–12 months [2]. In the ENETS guidelines [25] and also in the French multicenter trial, a conservative approach is suggested unless the tumor exceeds 2 cm or is rapidly growing [7] because the risk of metastasis is low in this group and surgery may not prevent the development of metastases unless a total pancreatectomy is performed. However, total pancreatectomy is usually not recommended because of the significant long-term morbidity. Most authors suggest left pancreatectomy with enucleation of tumors of the pancreatic head with lympadenectomy, but sole enucleation and also more aggressive approaches have also been proposed.

## Medical Treatment

The principles of medical treatment of PanNET in MEN1 are identical with those in sporadic cases as studies especially for MEN1 are very limited.

### Medical Treatment in Functioning Tumors

In patients with gastrinoma, treatment with PPI is indicated to suppress hyperacidity. The recommended starting dose is equivalent to omeprazole 40–60 mg b.i.d. in MEN1/ZES [21]. Long-acting somatostatin analogs such as octreotide-LAR or lanreotide autogel also control acid secretion and can be added to PPI, which is the basic treatment of choice because of its effectiveness and the ease of oral intake.

In patients with insulinoma, prior to mostly curative surgery, intravenous glucose administration in addition to frequent small carbohydrate meals may be necessary. Additional medical treatment is mainly indicated in the rare metastatic cases and includes diazoxide (in combination with diuretics), somatostatin analogs (which should be started in the hospital to exclude worsening of hypoglycemia, which also has been reported), and the mammalian target of rapamycin (mTOR) inhibitor everolimus [26].

In patients with VIPomas and glucagonomas, long-acting somatostatin analogs can control the hypersecretion syndrome.

### Medical Treatment for Tumor Control

Medical treatment with antiproliferative intention is usually started in patients with nonresectable or metastatic disease. Nevertheless, one recent study suggested that early octreotide treatment in patients with MEN1 syndrome and duodenopancreatic manifestation may delay tumor progression [27].

Long-acting somatostatin analogs can be administered for antiproliferative purposes in patients with metastatic PanNET showing a slow tumor growth. The CLARINET trial has proven the efficacy with respect to progression-free survival (PFS) in somatostatin receptor-positive (sporadic) gastroenteropancreatic neuroendocrine tumors with a proliferation rate Ki-67 not exceeding 10% [28].

In patients with a high tumor load or rapid tumor growth, chemotherapy with streptozotocin and 5-fluorouracil or temozolomide and capecitabine is indicated [29]; in patients with liver-predominant disease, chemoembolization is an alternative. In recent years, two molecular-targeted treatments have become available for metastatic PanNET: the multikinase inhibitor sunitinib and the mTOR inhibitor everolimus. In placebo-controlled trials, both drugs demonstrated a doubling of PFS compared with placebo [30,31] and were approved for progressive metastatic PanNET. Although the studies included mainly non-MEN patients (two patients with MEN1 in the sunitinib trial; in the everolimus trial MEN status was not provided), it seems plausible that the results also apply for PanNET in MEN1 syndrome.

### Follow-up

Patients with MEN1 syndrome or MEN1 gene carriers should be offered a program of combined clinical, biochemical, and radiologic screening and follow-up as summarized in Table 126.1 [2]. The program should be individualized according to clinical judgment of the patient's history and actual situation and also the patient's preferences. A critical assessment of the screening program at our center demonstrated that most tumors were found at initial staging and concluded that an extension of the screening interval to 3 years may be appropriate [32], whereas others recommend CT or MRI every 1–2 years, especially to detect thymic, bronchial, and pancreatic NET early as these tumors are the leading cause of death in patients with MEN1 [3].

## Prognosis

Despite the fact that life expectancy in patients with MEN1 has increased in recent decades, still 50–70% of patients with MEN1 will die of causes directly related to MEN1 [33,34]. The mean age at death is 55–60 years [3]. Whereas in early series patients often died as a result of complications of hormonal effects of the tumors such as upper gastrointestinal bleeding resulting from ZES or renal complications as a consequence of hyperparathyroidism, today there is a shift toward death from

**Table 126.1** Suggested program of combined clinical, biochemical, and radiologic screening and follow-up.

| Examination | Interval | Extent |
|---|---|---|
| Clinical evaluation | Annually | Extensive history of symptoms of tumor manifestations and physical examination |
| Biochemical screening | Annually | Ca, parathyroid hormone, gastrin, fasting glucose, insulin, ChA, glucagon, VIP, prolactin, IGF-1 |
| Functional testing | No routine investigation, suspicion of gastrinoma | Gastric pH, secretin test, or Ca infusion test |
| | Suspicion of insulinoma | Fasting test |
| Abdominal imaging | Annually | EUS, MRI, or CT (or [$^{8}$Ga]DOTA-TOC PET/CT) |
| Imaging of the chest | Every 1–2 years | CT or MRI (or [$^{68}$Ga]DOTA-TOC PET/CT) |
| Imaging of the pituitary gland | Every 3 years | MRI |

ChA, chromogranin A; IGF-1, insulin-like growth factor 1; for other abbreviations, see text.

malignancy. PanNET and especially the more aggressive thymic carcinoid tumors are associated with an increased risk of death [34] and the risk of dying from a malignant nonendocrine tumor is also elevated [3]. Early diagnosis and surgical resection in cases with significant growth or diameter >2 cm to prevent metastatic spread provide a more favorable outcome in patients with MEN1 with nonfunctioning PanNET compared with sporadic cases. In patients with ZES, prognosis in patients with MEN1 is also better than in patients with sporadic ZES: the 15-year survival in patients with MEN-1 was 93% compared with 68% in sporadic patients [35].

# Nonfunctioning Pancreatic Neuroendocrine Tumors: Diagnosis and Management Principles

*Takao Ohtsuka, Hideyo Kimura, and Masafumi Nakamura*

*Department of Surgery and Oncology, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan*

## Definition

Among pancreatic neuroendocrine tumors (PanNET), nonfunctioning PanNET (NF-PanNET) are defined as tumors exhibiting no specific symptoms arising from an excess of hormonal secretion. Therefore, PanNET exhibiting a high level of serum hormone or a positive result for a specific hormone on immunohistochemical assessment, while no specific symptoms are observed, are managed as NF-PanNET.

## Pathology

According to the World Health Organization (WHO) classification 2010 [1], neuroendocrine tumors (NET), including PanNET, are graded as G1, G2, and G3 using the mitotic count and/or the Ki67 labeling index. G1 (mitotic count <2 per 10 high-power fields [HPF] and/or ≤2% Ki-67 index) and G2 (mitotic count 2–20 per 10 HPF and/or 3–20% Ki-67 index) are compatible with well-differentiated NET, and G3 (mitotic count >20 HPF and/or >20% Ki-67 index) is compatible with poorly differentiated neuroendocrine carcinomas (NEC). Positive staining for specific neuroendocrine markers, such as chromogranin A and/or synaptophysin, is necessary to make a definitive diagnosis of the NET. Of note, there are some NF-PanNET that show positive staining for several specific hormones, including glucagon, pancreatic polypeptide, or serotonin, on immunohistochemical assessment.

## Mechanism of Tumorigenicity

Neoplastic cells of PanNET are considered to originate from neuroendocrine stem cells in the islet of Langerhans or pancreatic ductal epithelium; however, the mechanism of the progression to a PanNET has not been well documented. Several genetic alterations, which may be associated with the tumorigenicity of PanNET, have been reported. Jiao et al. [2] showed that alterations of *DAXX/ATR*, *MEN1*, and mammalian target of rapamycin (mTOR) pathway genes are frequently observed in well-differentiated PanNET. It is well known that NF-PanNET are often accompanied by hereditary diseases, including multiple endocrine neoplasia type 1 (MEN1), von Hippel–Lindau disease, von Recklinghausen disease, and tuberous sclerosis. However, poorly differentiated pancreatic NEC (PanNEC) are reported to have alterations in *p53*, *Rb*, and *bcl-2* and therefore are considered to have a different mechanism in terms of tumorigenicity from well-differentiated PanNET [3].

## Clinical Findings

PanNET account for about 2% of all pancreatic neoplasms, and NF-PanNET are the most common PanNET (40–60%), followed by insulinomas (~20%) and gastrinomas (~10%). In a recent Japanese nationwide survey [4], the estimated prevalence of PanNET in 2010 was 2.69/100,000 with an annual onset incidence of 1.27/100,000, including 65.5% of NF-PanNET. Most of

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

the NF-PanNET are solitary, and sometimes multiple, especially in hereditary diseases. Well-differentiated NF-PanNET grow slowly; however, owing to the large size of NF-PanNET, they have the potential to metastasize to lymph nodes and the liver. Of note, NF-PanNET sometimes acquire hormonal production and the relevant symptoms with their progression [1]. However, poorly differentiated PanNEC show a fairly high malignant behavior, and most of the PanNEC are determined as unresectable because of distant metastases at the time of diagnosis. The frequency of PanNEC among NF-PanNET was 2–10%, and the associated MEN1 was observed in 4–30% of NF-PanNET. These distributions differ among races [4].

## Symptoms

Most of the patients with NF-PanNET do not have any specific symptoms, and the number of the patients who are diagnosed as having an asymptomatic small NF-PanNET at the time of medical examination or during surveillance for other diseases has recently been increasing. The patients with a large NF-PanNET often present with symptoms such as abdominal pain, discomfort, distension, weight loss, nausea, or a palpable mass. Involvement of the bile duct or pancreatic duct leads to jaundice, obstructive pancreatitis, or diabetes mellitus.

## Diagnosis

Typical radiologic findings in well-differentiated NF-PanNET are a well-demarcated homogeneous hypoechoic lesion from ultrasonography, a well-demarcated enhanced solid tumor from the early phase of enhanced computed tomography (CT) (Fig. 127.1a), and a low-intensity tumor in the T1-weighted image and a high-intensity lesion in the T2-weighted image from magnetic resonance imaging (MRI). The large-sized NF-PanNET often exhibit cystic changes or calcification, which are reflected in the radiologic findings (Fig. 127.1b and c). The lesions, which should be discriminated from well-differentiated PanNET because of the similarity of these radiologic findings, include acinar cell carcinoma, solid and pseudopapillary neoplasm, solid-type serous cystic neoplasm, metastatic pancreatic tumor from renal cell carcinoma, and accessory spleen. Somatostatin receptor scintigraphy is applied for the detection of metastatic lesions, and enhanced MRI is also useful for detecting small hepatic metastases. The serum chromogranin A concentration is used to assess the disease control during chemoradiotherapy or to detect recurrence after curative resection.

However, a pancreatic PanNEC has various radiologic findings and sometimes shows an irregular low-density solid lesion from the enhanced CT (Fig. 127.1d), which is similar to the findings for a pancreatic ductal adenocarcinoma.

For a definitive diagnosis, cytologic assessment under endoscopic ultrasound-guided fine-needle aspiration (EUS-FNA) is mandatory, and histologic grading can also be evaluated if a sufficient amount of neoplastic cells (usually over 2000 cells) can be obtained [5].

Table 127.1 presents a brief summary of the diagnostic issues.

## Surgical Treatment for Localized Lesions

Curative resection should be considered as the first treatment in all cases of localized well-differentiated NF-PanNET. However, the National Comprehensive Cancer Network (NCCN) guidelines [6] recommend that asymptomatic small-sized well-differentiated NF-PanNET (<10 mm in diameter), which are occasionally observed by imaging, can be determined without resection depending on consideration of the patient's general condition and the expected invasiveness of the operation. Operations for localized well-differentiated NF-PanNET range from enucleation to organ-preserving pancreatectomy, and standard pancreatectomy with regional lymph node dissection, and the surgical treatment strategy is determined based on the tumor size, the invasiveness, and the presence of regional lymph node metastases from imaging studies. Histologic grading by EUS-FNA is not usually included for these strategies in the guidelines [6–8], because this technique cannot always be performed in every institution worldwide, and a high sensitivity to determine accurately the histologic grade in the resected specimen has only been reported by a high-volume center. The rate of lymph node metastases in a small well-differentiated NF-PanNET remains unclear, hence sampling of the regional lymph node is always necessary even in enucleation or organ-preserving pancreatectomy for small NF-PanNET. In several guidelines [6–8], small NF-PanNET are considered as those with a tumor size of <2 cm and with no sign of invasiveness or lymph node metastasis. There is no evidence showing a benefit of neoadjuvant therapy before operation or adjuvant therapy after curative resection for well-differentiated NF-PanNET, therefore such adjuvant therapies are not recommended.

The surgical treatment for resectable PanNEC is standard pancreatectomy with regional lymph node dissection, and adjuvant therapy using platinum-based chemotherapy, in proportion to the regimen for small-cell carcinomas of the lung, is recommended [6].

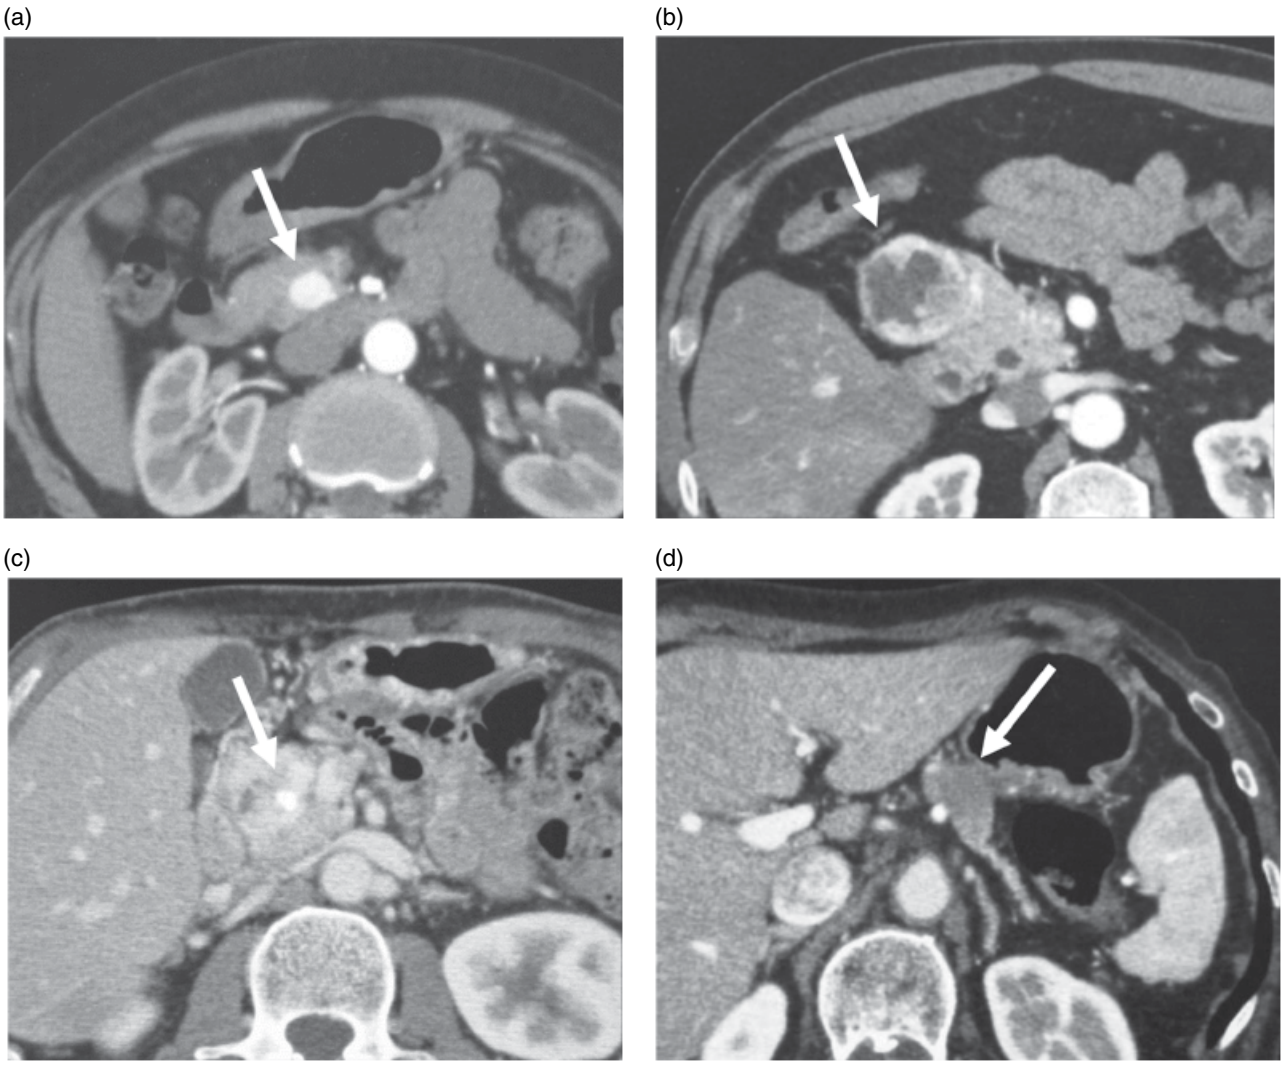

**Figure 127.1** Computed tomography of NF-PanNET. (a) Well-demarcated enhanced lesion in the pancreas head (arrow, 15 mm, G1); (b) enhanced lesion with cystic change in the pancreas head (arrow, 45 mm, G2); (c) enhanced lesion with calcification in the pancreas head (arrow, 35 mm, G2); (d) low-density lesion in the pancreas body with atrophy of the distal part of the pancreas (arrow, 25 mm, G3). *Source:* Parts (a)–(c) provided by Dr Tetsuhide Ito, Department of Medicine and Bioregulatory Science, Graduate School of Medical Sciences, Kyushu University.

PanNET are clinically observed in 50–60% of patients with MEN1, and all autopsy cases of MEN1 have PanNET, although they are microlesions [9]. Most cases involve multiple lesions, and the most frequent type is NF-PanNET. The presence of a PanNET is an important prognostic factor in patients with MEN1 [10]. Surgical treatment for multiple NF-PanNET in patients with MEN1 is complicated. Several guidelines [6–8] recommend removing only functioning PanNET and high-risk NF-PanNET (>1–2 cm in diameter) to avoid total pancreatectomy, for example, using distal pancreatectomy with enucleation of the PanNET in the proximal part of the pancreas, or pancreatoduodenectomy with enucleation of the PanNET in the distal part of the pancreas.

Prognosis of NF-PanNET after resection depends on the histologic grade, and 5-year survival rates are 80–100% in G1, 50–70% in G2, and 0–30% in G3 [11]. Some patients experience recurrences more than 10 years after operation, and therefore postoperative surveillance over a long duration is necessary.

## Multidisciplinary Treatment for Metastatic Lesions

The most frequent site for the distant metastases of PanNET is the liver, and 70% of hepatic metastases are diagnosed as multiple lesions at the time of initial

assessment [7]. In the recurrent cases after resection, some patients experienced hepatic metastasis more than 10 years after curative operation, as described above. Hepatic metastases are usually classified as simple (unilobar or limited), complex (bilobar), and diffuse pattern, according to the European Neuroendocrine Tumor Society (ENETS) guidelines [7]. Simple and complex patterns without extrahepatic metastases are usually treated by operation with or without regional ablation therapies such as radiofrequency ablation and transarterial chemoembolization. A diffuse pattern is basically a contraindication for surgical treatment; however, aggressive multidisciplinary treatment, including surgical debulking, might lead to a 5-year survival rate of over 50% if over 90% of the lesions can be removed [12–14]. Asymptomatic and slow-growing unresectable small-volume metastatic NF-PanNET can be observed without any treatment until the signs of growth or symptoms are apparent [1]. Liver transplantation for unresectable hepatic metastases from PanNET is not recommended because of unsatisfactory outcomes [15].

The necessity for resection of primary lesions in cases of synchronous unresectable hepatic metastases remains controversial. One report [8] claimed that the resection of the primary lesion would lead to a definitive diagnosis of PanNET with accurate histologic grade and also subsequent application of specific therapies for hepatic metastases such as transarterial chemoembolization and radiofrequency ablation. However, another report [16] showed that there were no differences in survival

**Table 127.1** Summary of diagnosis and treatment principles for nonfunctioning pancreatic neuroendocrine tumors.

1) Well-differentiated PanNET (G1, G2)
   a) Diagnosis
      Typical radiologic findings of primary lesion
         Ultrsonography; well-demarcated, homogeneous, hypoechoic lesion
         Computed tomography; well-demarcated enhanced lesion in early phase
         Magnetic resonance imaging; T1 low intensity, T2 high intensity
         Other findings: cystic change, calcification, etc.
      Differential diagnosis
         Acinar cell carcinoma, solid-pseudopapillary neoplasm, accessory spleen, etc.
      Definitive diagnosis
         Endoscopic ultrasound-guided fine-needle aspiration
      Detection of metastatic lesion
         Systemic; computed tomography, somatostatin receptor scintigraphy
         Liver; enhanced magnetic resonance imaging
   b) Treatment
      Primary
         <2 cm: enucleation or organ-preserving pancreatectomy (positive-node sampling)
         ≥2 cm: standard pancreatectomy with node dissection
         In multiple tumors of MEN1, remove only functioning tumor and high-risk
         nonfunctioning tumor (>1–2 cm in diameter) to avoid total pancreatectomy
      Metastases
         Resection, if possible, or multidisciplinary treatment including debulking surgery,
         regional ablation therapy, systemic chemotherapy, molecular-targeted therapy, somatostatin receptor agonist, etc.
2) Poorly differentiated PanNEC (G3)
   a) Diagnosis
      Radiologic findings of primary lesion
         Ultrasonography; irregular hypoechoic
         Computed tomography; irregular low density
         Magnetic resonance imaging; T1 low intensity, T2 high intensity
      Differential diagnosis
         Pancreatic ductal adenocarcinoma, etc.
      Definitive diagnosis
         Endoscopic ultrasound-guided fine-needle aspiration
      Detection of metastatic lesion
         Computed tomography, magnetic resonance imaging
   b) Treatment
      Resectable primary
         Resection + adjuvant chemotherapy using platinum-based regimen
      Unresectable primary or metastases
         Chemotherapy using platinum-based regimen

between patients with synchronous unresectable hepatic metastases who underwent resection of primary PanNET and those without primary resection. Owing to recent advances in the EUS-FNA technique for the definitive diagnosis of PanNET with histologic grade, and the development of new drugs, including molecular-targeted drugs, various types of somatostatin receptor analog, and radionuclide-labeled peptide targeting the somatostatin receptor, resection of the primary tumor is not always necessary in cases with synchronous unresectable hepatic metastases of PanNET.

Surgical indication for extrahepatic metastases is limited, because most of these cases also have hepatic metastases, and indication depends on the status of the hepatic metastases.

Treatment principles for NF-PanNET are summarized in Table 127.1. Medical treatment for PanNET includes chemotherapy (streptozocin, dacarbazine), molecular-targeted therapy (everolimus, sunitinib), and somatostatin receptor analog therapy, including radionuclide therapy, and details of these therapies are described elsewhere.

## Introduction

Pancreatic neuroendocrine tumors (PanNET), although relatively rare, are increasingly being diagnosed following the introduction of newer sensitive imaging techniques. Although a number of PanNET are capable of synthesizing and secreting biochemically active substances leading to distinct clinical syndromes (functioning tumors), the great majority are nonfunctioning [1] (Table 128.1). Surgical resection is the best means of removing the tumorous tissue, but this is not always feasible as a significant number of patients with PanNET present with unresectable disease. Even in such instances, surgery may be of benefit in cases of difficult-to-control secretory syndromes or when a substantial proportion of the tumor load can be removed [1]. However, for a significant number of patients, additional medical treatment will be required to deal with the symptoms related to secretory syndromes and existing tumor load and also prevent further tumor growth.

Before treatment initiation, a number of parameters need to be considered in order to choose the most appropriate treatment for each patient (Table 128.2). In the past, chemotherapy has been the main therapeutic approach substantiated by few well-controlled but mostly retrospective studies [2,3]. Similarly, long-acting somatostatin (SST) analogs have been used for the control of symptoms secondary to clinical syndromes, also achieving a mainly stabilizing effect on tumor growth [1]. Recent Phase III studies have introduced new therapeutic approaches and a number of retrospective studies have provided good-quality data on the efficacy of new and previously utilized treatments. Several international societies have established guidelines to aid in dealing with PanNET, but there are still some unresolved issues regarding the choice of first-line therapy, estimation of response, and selection of further treatment options following disease progression [4–6].

As every distinct clinical syndrome attributable to a specific functioning PanNET may require more complex and specific treatment, the syndromes will be discussed separately first, followed by a discussion of treatment against tumor growth, which will be similar for both functioning and nonfunctioning PanNET.

## Nonsurgical Treatment of the Secretory Syndromes

Treatment of common and relatively rare secretory syndromes secondary to functioning PanNET is shown in Table 128.1.

### Insulinoma

The most appropriate treatment for insulinomas is surgical resection, which is associated with a greater than 95% success rate. Medical treatment may be necessary in patients with unresectable disease who remain symptomatic despite administration of frequent meals. The use of medications, such as diazoxide, which exerts a direct inhibitory effect on insulin secretion, has been shown to be efficacious in approximately 60% of cases [5]. Diazoxide is usually well tolerated and can be given in doses of 3–8 mg/kg divided throughout the day; however, almost half of the patients on diazoxide therapy may develop fluid retention, hirsutism, and gastrointestinal upset [5]. As the majority of PanNET express on

SRS, somatostatin receptor scintigraphy.

their surface somatostatin receptors (SSTR), the administration of long-acting synthetic SST analogs exerts an inhibitory effect on the secretory components of most functioning PanNET [1]. However, as more than half of insulinomas do not express enough SSTR (particularly SSTR2), the administration of long-acting SST analogs should be treated with caution, as it may worsen hypoglycemia owing to the inhibition of counter-regulatory hormone secretion [5]. This can be avoided by prior demonstration of avidity of the tumor to SSTR using somatostatin receptor scintigraphy (SRS) or by administering short-acting octreotide demonstrating that it is not associated with hypoglycemia [5]. Long-acting SST analogs are effective in approximately 35–50% of patients. For unresectable and metastatic cases, the mammalian target of rapamycin (mTOR) inhibitor everolimus has been shown to exhibit a specific capability to increase blood glucose levels [7]. Pasireotide, a long-acting somatostatin analog that binds to all SSTR except SSTR4, and can be associated with high glucose levels, could also be an additional option, but has not been specifically evaluated in insulinomas. In cases of extensive disease not responding to medical treatment, cytoreductive techniques, such as (chemo)embolization therapy using radiolabeled somatostatin analogs or surgical debulking, are employed, aiming at decreasing the tumor load and thus the amount of insulin secreted.

## Gastrinoma

Medical treatment of gastrinoma is directed against the gastric acid hypersecretory state, and also at the treatment of various endocrinopathies that may develop in patients with gastrinomas associated with multiple endocrine neoplasia type 1 (MEN1) syndrome (which accounts for approximately 25% of all gastrinomas). Proton-pump

inhibitors (PPI) are the drugs of choice because of their potency and long duration of action, and also their ability to be administered intravenously in the acute state. Histamine H2 antagonists (H2-R blockers) are also effective but need to be administered more frequently and at higher doses. Patients with difficult-to-control Zollinger–Ellison syndrome (ZES) may require higher doses of PPI, more frequent administration of PPI, or a combination of PPI with H2-R blockers. Long-term treatment with PPI has been shown to be safe. The potential side-effects are PPI-induced achlorhydria, which may lead to vitamin B12 deficiency, and there is a suggestion of an increased incidence of bone fractures [5].

### Other Functioning PanNET

In patients with vasoactive intestinal peptide-releasing tumors (VIPomas), meticulous control of high-volume fluid loss is mandatory, as these tumors may lead to severe electrolyte abnormalities and dehydration. Long-acting SST analogs achieve control of the diarrhea in the majority of such patients; medications such as glucocorticoids, clonidine, and loperamide, which were previously used, have now been surpassed by SST analogs. Similarly to VIPomas, SST analogs can control necrolytic erythema in 50–90% of patients with glucagonomas, although diabetes mellitus may not improve substantially; parenteral nutrition is required to help improve concomitant cachexia, hypoaminoacidemia, and weight loss [5]. SST analogs have also been shown to be efficacious in the few cases of apparent somatostatinomas described in the literature. Higher doses of SST analogs can be used in patients with suboptimal control of the secretory syndromes using conventional doses of the drugs. Patients who experience exacerbation of symptoms toward the final week of each treatment cycle may benefit from an increased frequency of administration. Supplemental doses of short-acting octreotide may also be used, offering an additive effect in such cases. Rarer syndromes related to the unique ability of these tumors to synthesize and secrete compounds that traditionally originate from different tissues, leading to so-called paraneoplastic syndromes, necessitate the administration of additional more specific treatment [8].

## Nonsurgical Treatment Directed Against Tumor Growth

### Treatment of PanNET with Somatostatin Analogs

The majority of PanNET (with the exception of insulinomas) express on their surface SSTR2 and -5, which aids in their diagnosis by use of SRS and in treatment with use of long-acting SST analogs (octreotide and lanreotide). SST and its synthetic analogs not only exert an inhibitory effect on the secretory components of most functioning PanNET (except insulinomas) but also show an antiproliferative activity mainly manifested as disease stabilization [1]. Following the findings of an earlier prospective Phase III study, which demonstrated that octreotide long-acting release (LAR) improves the median time to progression in patients with carcinoid tumors compared with placebo, a subsequent Phase III study, CLARINET, evaluated the efficacy of the other SST analog, lanreotide, in a variety of nonfunctioning gastrointestinal (GI)-NET, including PanNET [9,10]. In that study, 91 patients with nonfunctioning PanNET, who had no tumor progression in the 3–6 months before randomization, were studied. All patients had grade 1 or grade 2 tumors and a Ki-67 value of up to 10%, whereas a significant number of them had a hepatic tumor load of >25%. Patients were randomized to receive either lanreotide 120 mg monthly (without dose adjustment) or placebo, and were followed for 96 weeks [10]. After a median follow-up period of 14 months, the progression-free survival (PFS) in the lanreotide-treated patients was not reached (the predefined 50% progression rate among patients treated with lanreotide was not obtained) whereas that of the placebo group was 12.1 months, resulting in a hazard ratio of 0.58 (CI 0.32–1.04, $P = 0.0657$) [10]. This finding implies that patients treated with lanreotide had an almost 50% chance of remaining stable in respect of tumor progression compared with those treated with placebo, who experienced disease progression. Tolerance to treatment was consistent with that in previous studies [10]. The beneficial effect of lanreotide in respect of PFS was documented even in patients with a >25% hepatic involvement by the tumor and in those with grade 2 tumors (Ki-67 values up to 10%) [10]. CLARINET was the first study to provide good-quality data on the antiproliferative effect of SST analogs on PanNET; however, the data on the effect of this treatment on overall survival (OS) are still emerging. Recent preclinical and clinical studies have evaluated the effect of the more potent SST analog pasireotide, which binds to all SSTR except SSTR4, in PanNET. In a Phase II study, 28 patients with GI-NET were treated (including six with PanNET) and the most favorable effect was observed in patients with low hepatic tumor burden, normal baseline chromogranin A levels, and high tumorous SSTR5 expression; the best radiographic response was stable disease in 17 patients (60%). However, pasireotide was associated with a 79% rate of hyperglycemia, including 14% hyperglycemia of grade 3, raising concerns regarding its suitability as a first-line systemic agent [11].

Based on these findings, it has been suggested that patients with grade 1 and grade 2 tumors with a Ki-67

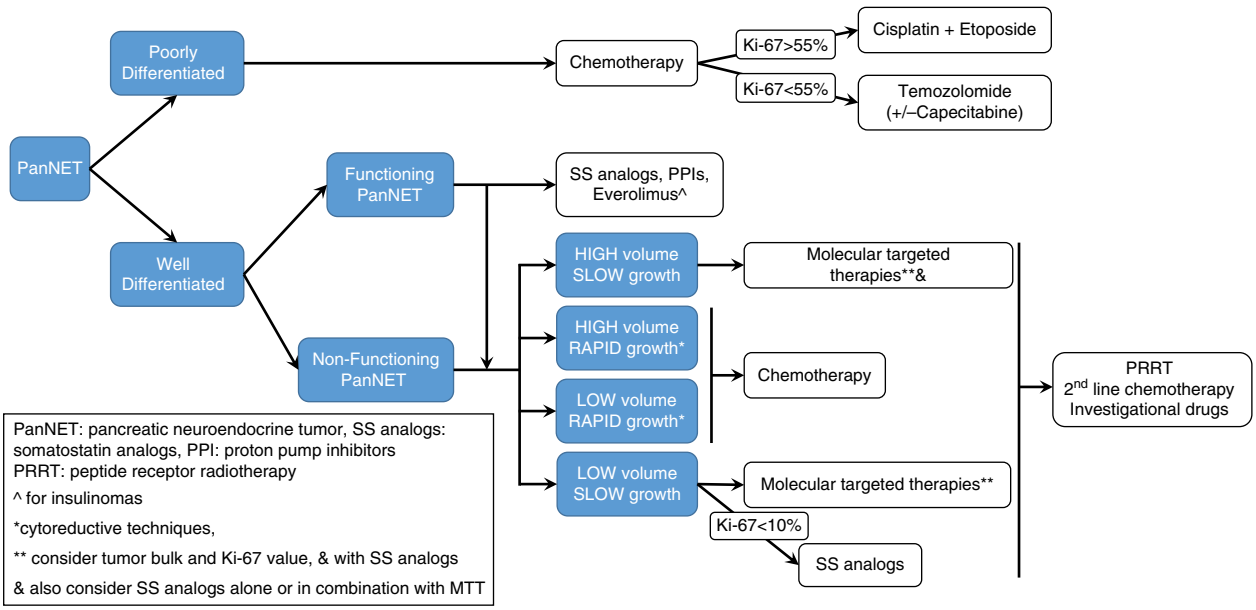

**Figure 128.1** Suggested algorithm for the nonsurgical management of PanNET.

value of up to 10% could be treated with SST analogs [10;11]. However, there are still a number of unresolved issues as to whether treatment should be initiated immediately following diagnosis or after a period of monitoring to access tumor growth rate, the effect that lower doses of SST analogs could exert, should treatment be intermittently discontinued, and data regarding their effect on OS are still pending [6]. In the presence of extensive disease involving the majority of the liver or in the presence of extrahepatic disease, other therapies should also be considered aimed at effectively reducing the tumor load (Fig. 128.1).

## Treatment with Chemotherapeutic Agents

In contrast to other GI-NET that are typically chemoresistant, well-differentiated (grade 1/2) PanNET appear to be sensitive to alkylating agents, including streptozotocin, dacarbazine, and temozolomide, and also fluoropyrimidines. Previous studies have shown that the combination of streptozotocin and fluorouracil (5FU) resulted in a response rate of 63% compared with streptozotocin monotherapy [2]. Furthermore, the combination of streptozotocin and doxorubicin appeared to be more efficacious than that of streptozotocin and 5FU, exhibiting a response rate and time to progression of 69% and 20 months compared with 45% and 6.9 months, respectively [2]. However, a more recent retrospective study of 84 patients with PanNET, which evaluated the response rate of the combination of streptozotocin, 5FU, and doxorubicin, demonstrated a 39% response rate whereas the median response duration was 9.3 months [12]. These later findings most probably represent more realistic figures, as the evaluation of response to therapy was performed with modern and more robust radiologic means compared with the earlier studies. Because streptozotocin has a relatively high toxicity profile and can cause myelosuppression and renal impairment, alternative chemotherapeutic regimens have recently emerged. Following the findings of a Phase II study that showed a 45% response rate for the combination of temozolomide and thalidomide in a small cohort of 11 patients with PanNET, a subsequent retrospective study evaluated the combination of temozolomide (oral derivative of dacarbazine) and capecitabine (oral derivative of 5FU) in 30 chemonaïve patients with PanNET and found a 70% radiologic response whereas the median PFS was 18 months [13–15]. Another antiangiogenic-based combination, temozolomide (given at 150–200 mg/m$^2$ for 14 days or as a metronomic daily dose) and bevazicumab, exhibited response rates ranging from 33 to 64% in 49 treated patients, 22 of whom had a PanNET. Temozolomide has also been coadministered with everolimus, exhibiting increased response rates [13]. The majority of these studies have limitations, including relatively small numbers of patients studied, differences in regimens used, and variable response rates obtained. However, temozolomide has gained popularity owing to its convenient mode of administration and favorable side-effect profile. Currently, chemotherapy is recommended in patients with a high tumor burden when tumor shrinkage is required, a rapidly progressive tumor

in subsequent follow-up suggestive of a more aggressive course, and when the Ki-67 labeling index is relatively high (>10%).

The role of chemotherapy is also well established in patients with pancreatic neuroendocrine carcinomas (PanNEC). These high-grade malignancies are locally advanced or metastatic at presentation, only rarely express SSTR, and are not associated with secretory syndromes. First-line systemic chemotherapy with a platinum-based agent (cisplatin or carboplatin) and etoposide is recommended for most patients with metastatic-stage disease, whereas sequential or concurrent chemoradiation is recommended for patients with locoregional disease [16]. Response rates ranging from 42 to 67% have been described but are usually of short duration; the median survival ranges from 15 to 19 months [16]. Based on the response, usually 3–4 cycles of chemotherapy are administered but, following relapse or nonresponse, second-line options are limited [16]. A recent retrospective study suggested that patients with PanNEC and Ki-67 values of less than 55% may respond better to temozolomide-based regimens than cisplatin combinations [17].

## Treatment with Molecular-Targeted Agents and Angiogenesis Inhibitors

Targeting a number of pathways thought to be involved in the pathogenesis and/or progression of PanNET has recently resulted in the availability of further therapeutic options. The tyrosine inhibitor sunitinib, which targets vascular endothelial growth factor receptor (VEGFR) 1, 2, and 3, platelet-derived growth factor receptor (PDGFR), and tyrosine protein kinase Kit (c-Kit), was evaluated in a Phase III study at a dose of 37.5 mg versus placebo in 171 patients with grade 1/2 PanNET. A statistically significant improvement in PFS was found in the sunitinib arm (11.1 versus 5.5 months), with a response rate of 9.3%; however, data on its effect on OS are lacking. Sunitinib is currently approved for the treatment of metastatic PanNET; common toxicities include gastrointestinal, hypertension, palmar–plantar erythrodysesthesia, and cytopenias [18]. The mTOR inhibitor everolimus has also been evaluated in PanNET in a Phase III study (RADIANT 3) in which 410 patients with grade 1/2 PanNET were assigned to either 10 mg of everolimus or placebo. The median PFS was 11.0 months with everolimus compared with 4.6 months with placebo, representing a 65% reduction in the estimated risk of progression or death. Drug-related adverse events were mostly grade 1 or 2, including stomatitis, rash, diarrhea, fatigue, atypical infections, and rarely pneumonitis. Grade 3 or 4 events encountered more frequently with everolimus than placebo included anemia (6 versus 0%) and hyperglycemia (5 versus 2%). Everolimus is also currently approved for the treatment of PanNET, and it has been suggested that it should be widely used as its efficacy is not affected by previously administered therapies such as chemotherapy [19]. Although there have been no comparative studies between these two agents, they are usually the preferred second-line therapeutic options following progression after treatment with SST analogs (Table 128.3). Bevacizumab, a monoclonal antibody against vascular endothelial growth factor A (VEGF-A), has also been used in combination with temozolomide and biological treatments exhibiting clinically useful responses [13]. Recently, combinations of molecular-targeted therapies with chemotherapeutic agents or bevacizumab have also been employed in small series and observational studies, the findings of which require further validation.

**Table 128.3** Comparison of the findings of Phase III trials of molecular-targeted therapies.

| Study | Patients | Active treatment (mg/day) | PD at entry | ORR | PFS (months) | Safety |
|---|---|---|---|---|---|---|
| Sunitinib | 171 (86 sunitinib, 85 placebo) PanNET | 37.5 | Yes | Sunitinib: CR 2.3%, PR 7%, SD 62.8%<br>Placebo: CR 0%, PR 0%, SD 60% | Sunitinib: 11.4<br>Placebo: 5.5 | Most common adverse effects >30%: diarrhea, nausea, asthenia, vomiting, fatigue<br>Grade 3–4 neutropenia and hypertension 10–12% |
| Everolimus | 410 (207 everolimus, 203 placebo) PanNET | 10 | Yes | Everolimus: PR 5%, SD 73%, PD 14%<br>Placebo: PR 2%, SD 51%, PD 42% | Everolimus: 11.04<br>Placebo: 4.6 | Most common adverse effects: stomatitis 64%, rash 49%, diarrhea 34%, fatigue 31%, infections 23%<br>Severe side-effects: pneumonitis 12%, interstitial lung disease 2% |

CR, complete response; ORR, overall response rate; PD, progressive disease; PFS, progression-free survival; PR, partial response; SD, stable disease.

### Treatment with Radionuclides

Radiolabeled SST analog therapy (peptide receptor radionuclide therapy [PRRT]), aims at delivering potentially toxic radioactivity through radionuclides that bind to PanNET bearing SSTR. As the majority of PanNET are grade 1/2 tumors, they express on their surface somatostatin receptors, and can therefore be selected for treatment with PRRT on the basis of the intensity of tumorous tissue uptake during SRS. Treatment is restricted to tumors showing considerable uptake, and tumors demonstrating uptake higher than that of the liver are the ones that exhibit the best therapeutic response. Two radionuclides, namely $^{90}$Y-DOTA-TOC (DOTA-Tyr-octreotide) and $^{177}$Lu-DOTA-TATE (DOTA-Tyr-octreotate), have been extensively used in the treatment of functioning and nonfunctioning PanNET. A large nonrandomized study, which included 310 patients with GI-NET (91 PanNET) showed an overall 30% radiologic response that was more pronounced in patients with PanNET; the median time to progression was 40 months [20]. A similar study evaluated more than 1000 patients with NET (342 PanNET) treated with $^{90}$Y-DOTA-TOC; 34.1% of them experienced a radiologic response, 15.5% a biochemical response (a >50% reduction in tumor markers), and 29.7% a clinical response (improvement of symptoms of either a clinical syndrome in the case of a functioning tumor or of symptoms of mass effect to surrounding structures in the case of a nonfunctioning tumor). Patients who experienced any response had a much better survival than nonresponders after a median follow-up of 23 months [21]. In a recent analysis of 810 patients with various NET treated with these radionuclides, either singly or in combination, permanent nephrotoxicity occurred in 1.5% (mostly with $^{90}$Y), whereas myelodysplasia and leukemia occurred in 2.35 and 1.1%, respectively [22].

Studies combining different forms of medical treatments are currently emerging in an attempt to increase their efficacy and reduce potential side-effects.

## Conclusions

Treatment of PanNET has evolved significantly over the last decade following the introduction of newer therapeutic agents and the accumulation of good-quality information regarding the efficacy and safety of a number of therapies. As the majority of symptoms related to functioning PanNET are responsive to SST analogs, attention has mainly focused on control of tumor growth. SST analogs can be used for tumor growth control, mainly resulting in disease stabilization. For progressive tumors, or tumors with a relatively high Ki-67 labeling index (>10%), molecular-targeted agents can result in disease stabilization, but without achieving significant tumor shrinkage. Temozolomide- or streptozotocin-based chemotherapy is used in patients with rapidly progressive tumors and/or significant tumor bulk. PRRT can also be applied to tumors exhibiting significant uptake to SRS. High proliferative grade 3 PanNEC are treated with cisplatin-based chemotherapy but exhibit an overall worse prognosis. There is a clear need for the development of tumor markers that could help in individualization of treatment. Several societies have proposed therapeutic algorithms based on the findings of recent studies and acquired cumulative experience, as the one suggested (Fig. 128.1). However, several issues still remain unresolved, and it is hoped that these will be addressed by the findings of a number of ongoing prospective multicenter studies.

# Interventional Radiology in the Treatment of Pancreatic Neuroendocrine Tumors

*Takao Ohtsuka, Hideyo Kimura, and Masafumi Nakamura*

*Department of Surgery and Oncology, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan*

## Type of Interventional Radiology Treatment

Interventional radiologic therapy is indicated as a treatment for hepatic metastases only from a well-differentiated pancreatic neuroendocrine tumor (PanNET). This is compatible for grade 1 and 2 tumors, according to the World Health Organization classification [1], but not for those from poorly differentiated pancreatic neuroendocrine carcinomas (grade 3). The reasons for this preference are that well-differentiated PanNETs show morphologically well-demarcated lesions and are relatively slow growing, even in the metastatic sites, and over 90% of the blood supply to the metastatic lesions in the liver is reported to be provided by the hepatic artery [2] (Fig. 129.1). Therefore, as is the case for hepatocellular carcinomas, transarterial embolization (TAE), transarterial chemoembolization (TACE), and radiofrequency ablation (RFA) are applied for metastatic PanNET in the liver. Microwave coagulation therapy, laser interstitial thermotherapy, and cryotherapy have recently been incorporated as potential advances in the various effective treatment options for unresectable PanNET.

Hepatic metastases from PanNET are morphologically classified into three patterns according to the European Neuroendocrine Tumor Society (ENETS) guidelines [3]: simple (unilobar or limited), complex (bilobar), and diffuse pattern. Simple and complex patterns without extrahepatic metastases are usually treated by curative resection, and the diffuse pattern is treated by multidisciplinary treatment including systemic medication and surgical debulking with regional ablation therapies such as TAE/TACE and RFA. Owing to recent advances in surgical techniques and the development of systemic medication using anticancer agents, molecular-targeted drugs, and peptide receptor analogs, the roles of TAE/TACE and RFA have been limited to providing relief of the hormonal symptoms caused by the rapid growth of the tumor or the adjuvant therapy during or after operation [3–7].

## TAE/TACE

TAE/TACE are involved in the multidisciplinary treatment of unresectable hepatic metastases from well-differentiated PanNET. Therefore, the effects of TAE/TACE alone on survival remain unclear; however, TAE/TACE are reported to provide a decrease of 50–90% in the symptoms caused by hormonal hypersecretion, with a prolonged effect of 6–53 months, and a time to progression of 10–19 months [2]. The reported 5-year survival rate of patients treated with TAE/TACE ranges widely from 0 to 80%, because the conditions, such as the range of tumor spread, timing of the TAE/TACE during multidisciplinary treatment, and other treatments subsequently performed after TAE/TACE, differ among the reports [2].

In TAE, histoacryl, in conjugation with lipiodol, forms particles with or without lipiodol, poly(vinyl alcohol) foam, and microspheres using glass or resin, which are used as embolic agents [2]. Several chemotherapeutic drugs, such as doxorubicin, streptozocin, dacarbazine, adriamycin, cisplatin, and mitomycin C, are used in conjugation with lipiodol during TACE [2,7]. A recent trend in transarterial techniques is radioembolization using a

radioconjugated somatostatin analog. Radioembolization using [$^{90}$Y]lanreotide provides a radiologic response of 22.5–63% and median survival times of 22–70 months [7]. The regional concentration of chemotherapeutic drugs by TACE is reported to be 10–20 times higher than that by systemic chemotherapy; however, the additional effect of chemotherapeutic drugs on TAE alone remains unclear [2]. Repeat TAE/TACE would lead to the disruption of the arterial endothelium and then acceleration of the collateral formation, resulting in difficulties with further TAE/TACE.

Morbidity and mortality after TAE/TACE are reported to be 0–28% and 0–5.6%, respectively [2]. Complications in relation to TAE/TACE include hepatic abscess, hepatic dysfunction (sometimes hepatic failure arising from infarction), pleural effusion, and gastric ulcer. Many patients experience post-TAE/TACE syndrome symptoms, including transient fever elevation, leukocytosis, and increase in hepatic enzymes, most of which are improved within a few days after TAE/TACE. Regional chronic infection in the biliary tree is a risk factor for hepatic abscess after TAE/TACE because the biliary system has a blood supply exclusively from a hepatic artery, and TAE/TACE would lead to biliary ischemia. Therefore, this technique should be avoided in patients who have a history of biliary intervention, including those after pancreatoduodenectomy or endoscopic sphincterotomy. In addition, patients who have portal neoplastic thrombus or hepatic ascites are also contraindications for TAE/TACE because of the high risk of post-TAE/TACE hepatic failure.

## RFA

RFA can be performed during open surgery and also laparoscopic operation, or by computed tomography or ultrasound-guided percutaneous techniques. One report [8] demonstrated that RFA alone for hepatic metastases from well-differentiated PanNET can provide a favorable prognosis comparable to that with hepatic resection; however, the indicated cases were limited to patients who had a relatively small size and small number of metastatic lesions. At present, RFA is being performed for persistent viable lesions as an adjuvant therapy during or after hepatic resection, or after TAE/TACE [3–7] (Fig. 129.2). Adverse events related to RFA include pneumothorax, hepatic abscess, perforation of the gastrointestinal tract, and skin burn; however, major and fatal complications are rarely observed [7]. RFA for patients who have a history of biliary intervention should be avoided for the same reason as mentioned for TAE/TACE, where there is a risk of fatal hepatic abscess.

Use of RFA for primary PanNET has recently been reported. An Italian group [9] described their experience with 10 patients, seven patients having their tumor in the proximal part of the pancreas and three in the distal part of the pancreas, with a mean tumor diameter of 16 mm (range, 9–29 mm). All the lesions were completely ablated by the percutaneous route in seven cases, under laparotomy in two cases, and under laparoscopy in one case. Mild pancreatitis occurred in three patients, all of whom were cured within 2 days. No recurrence was observed during the median surveillance period of

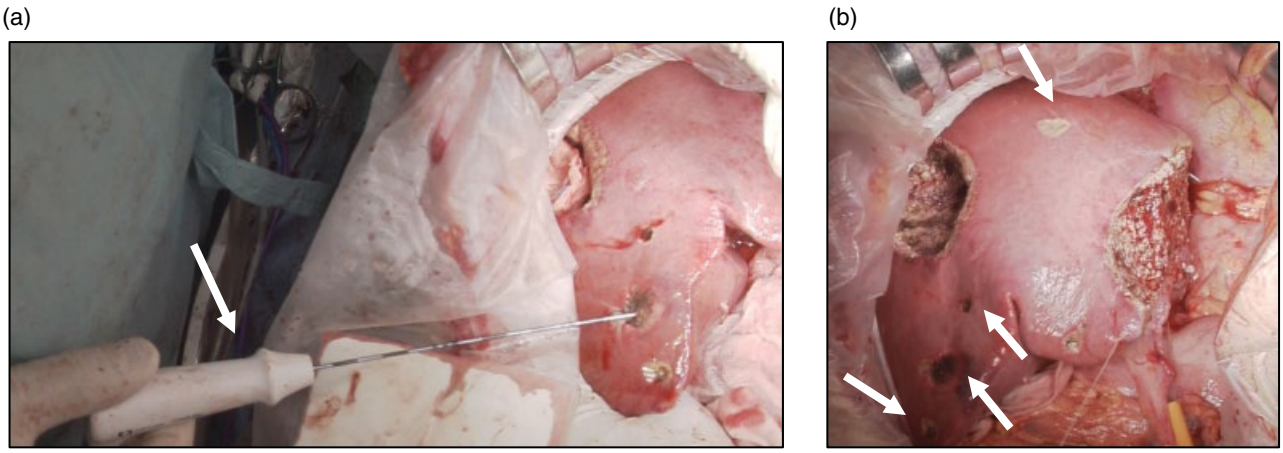

**Figure 129.2** Surgical debulking using radiofrequency ablation for hepatic metastases from pancreatic neuroendocrine tumors. (a) Radiofrequency ablation using a tip device (arrow). (b) Completion of the debulking operation. Arrows indicate the trace of the tip device for radiofrequency ablation. The patients are the same as those in Fig. 129.1.

30 months (range, 12–60 months). Although this intervention can be applicable for relatively small-sized primary PanNET in patients who are in generally poor condition, further investigations using a larger study population and with long-term surveillance are needed to determine the adequacy of this procedure.

### Introduction

The history of pancreatic surgery is closely connected to pancreatic neuroendocrine tumors (PanNET), namely surgery for malignant and benign insulinoma [1,2]. Although not evidence based at the time, enucleation used to be preferred over resection because the endocrine tumor was almost always cured and the patient developed few and mostly minor surgical complications [3]. Some 90 years of surgical experience with small, clinically benign PanNET later, the important role of enucleation is still uncontroversial. However, the growing number of pancreatic incidentaloma, unearthed by advanced imaging techniques [4–10], has multiplied the challenge of managing these tumors appropriately. Risk stratification, using proliferation markers such as frequency of mitosis and the Ki-67 index in the tumor [11–14], informs clinical treatment plans such that the therapy selected is commensurate with the risk profile of the tumor at hand. Interventions range from expectant observation in the absence of hormone excess to enucleation, and ultimately to pancreatic resection.

### Observation Versus Surgery for Small Sporadic, Benign-Appearing, Nonfunctioning Pancreatic Neuroendocrine Tumors

Incidental small, nonfunctioning PanNET feature less aggressive growth patterns on histopathology compared with symptomatic PanNET [15]. Primary tumor size, reflecting a biological continuum, positively correlates with tumor grade [16], Ki-67 index [17], and the presence of lymph node and distant metastases [17–19]. The smallest tumors with lymph node metastases measured 12–19 mm in greatest dimension [17,18]. For PanNET smaller than 2 cm, disease-related mortality in most studies was close to zero [17,19–21]. Without surgical intervention, 13% [20] and 16% [17] of these sporadic nonfunctioning PanNET enlarged by more than 20%, yielding an estimated tumor growth of 0.12 mm per year [20]. In carefully selected groups of patients with nonfunctioning PanNET who were managed without surgery, no disease progression was seen after 18 [20], 45 [21], and even 283 months [17]. Provided that there is no clinical evidence of metastases and tumor growth, sporadic, incidentally detected nonfunctioning PanNET smaller than 15 mm are good candidates for expectant observation.

### Preoperative Imaging and Assessment of Proliferative Tumor Activity

In patients with small PanNET, preoperative imaging using endoscopic ultrasonography [22–25], cross-sectional (computed tomography [CT]; magnetic resonance imaging [MRI]) or functional (octreoscan; [$^{18}$F]fluoro-2-deoxy-D-glucose positron emission tomography [FDG-PET]/CT) imaging [26–30] informs the approach to the surgical target (laparoscopic versus conventional open surgery) and the method of tumor clearance (enucleation versus pancreatic resection). Unlike nonfunctioning PanNET, some functioning tumors, specifically very

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

**Table 130.1** Indications for enucleation of PanNET.

Small nonfunctioning PanNET 1–2 cm, or insulinomas up to 2 cm in greatest dimension and

- benign appearing and low grade, based on standard and functional imaging, and, if performed, Ki-67 immunocytology
- without suspicious lymph node enlargement or distant metastases
- without wide and deep involvement of the pancreas
- without attachment to the main pancreatic duct on intraoperative ultrasonography.

Enucleation can be performed as a standalone procedure, or in combination with pancreatic resection for multiple MEN1-associated PanNET.

For PanNET located in the posterior head of the pancreas, both enucleation and head dorsal pancreatectomy may be considered.

Pancreatic gastrinomas should be treated preferentially by standard pancreatic resection irrespective of size because as many as 80–90% may be malignant and node-positive.

small insulinomas, may evade standard imaging. In this scenario, selective arterial stimulation is indicated to narrow down the location of the hormone-producing pancreatic tumor [31]. Small tumors residing in the anterior pancreatic head and the pancreatic body and tail usually qualify for enucleation unless they are situated deep down inside the pancreas and involve the main pancreatic duct (Table 130.1; Figs 130.1, 130.2, and 130.3). Conversely, deep-seated pancreatic tumors and tumors adherent to, or invading, the main pancreatic duct (Figs 130.1 and 130.3) necessitate pancreatic resection, with partial or complete resection of the pancreatic head, body, or tail depending on the situation. Preoperative imaging, whatever technique is being used, cannot exclude tumor involvement of the main pancreatic duct. It is crucial in this setting that intraoperative ultrasonography be used to identify the pancreatic duct and to rule out multifocal lesions before deciding on whether to embark on enucleation or pancreatic resection [32].

Preoperative risk stratification is performed by endoscopic ultrasound-guided fine-needle aspiration cytology to establish the diagnosis and allow tumor grading, supported by Ki-67 immunocytology to determine the proliferative tumor activity [32–35]. To make that determination correctly, the cytopathologist must be sufficiently experienced and cognizant of the methodologic limitations [33]. There is also a paucity of data about the prognostic significance of preoperative grading and Ki-67 immunocytology for small pancreatic tumors so that the benefits of enucleation versus pancreatic resection based on these findings remain unclear.

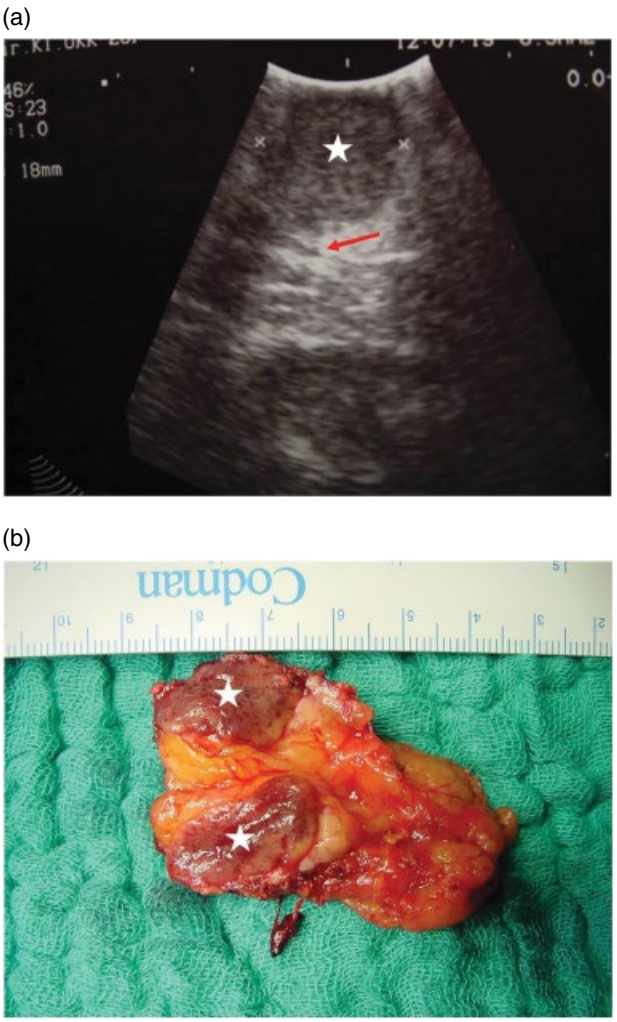

**Figure 130.1** Adherence of a pancreatic body insulinoma (asterisk) to the main pancreatic duct (arrow) (a) that was laparoscopically resected, instead of enucleated, because of this fact (b).

## Surgical Technique of Enucleation

Enucleation is the surgical technique of choice for small, benign-appearing or low-grade functioning and nonfunctioning PanNET without clinical evidence of metastases or involvement of the main pancreatic duct [36–46]. Unless the tumor is situated in the posterior part of the pancreatic head [47], enucleation of tumors from the head, body, and tail of the pancreas is technically feasible. The key advantage of enucleation is reduced surgical trauma, with better postoperative endocrine and exocrine pancreatic function. Major disadvantages include the considerable risk of pancreatic fistula and the fairly low risk of late recurrence and metastases if pancreatic tumors should turn out to be malignant and no lymph node dissection was carried out at the time.

Enucleation of the PanNET is performed after ultrasonographic evidence that the main pancreatic duct is

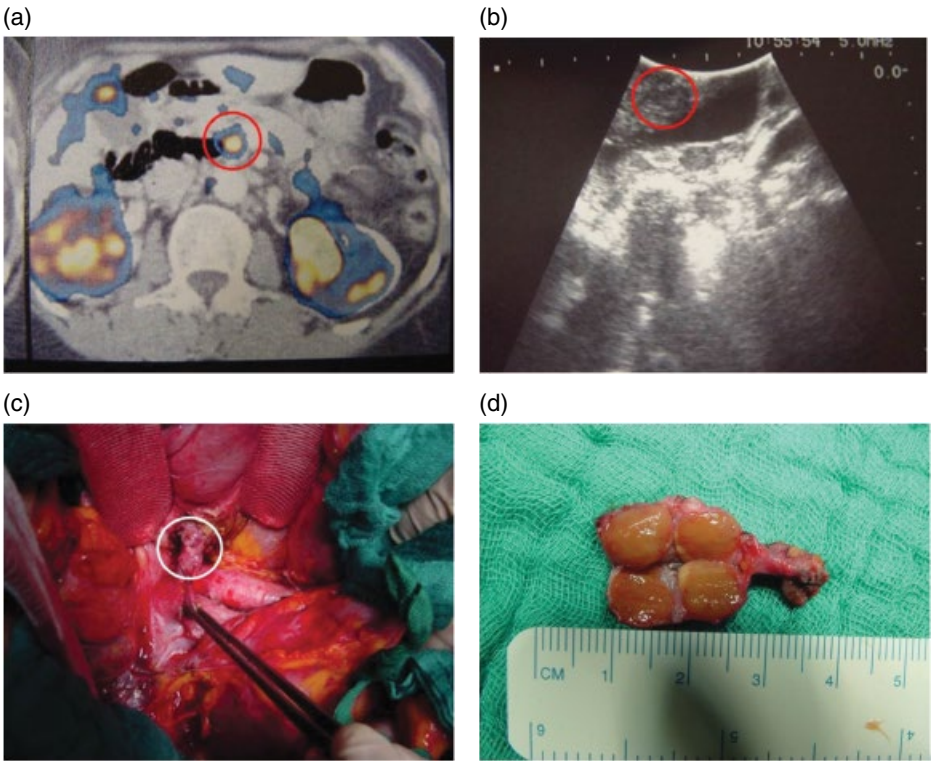

**Figure 130.2** Enucleation of a multiple endocrine neoplasia type 1 (MEN1)-associated insulinoma (encircled) in the uncinate process of the pancreas enucleated via open relaparotomy. (a) Preoperative [$^{18}$F]DOPA PET/CT; (b) intraoperative ultrasonography; (c) intraoperative view showing tumor enucleation; (d) surgical specimen.

clear. Particular care must be taken to dissect the pancreatic parenchyma around the tumor capsule meticulously, without opening it or resecting adjacent pancreatic tissue (Figs 130.2 and 130.3). Great emphasis is laid on closing small pancreatic ducts and vessels using fine sutures or clips. Upon confirmation that the surgical margins of the enucleated tumor specimen are clear on frozen section, the pancreatic capsule is closed using atraumatic absorbable single or running 5-0 or 6-0 sutures. Surgical drains are routinely placed and subsequently removed depending on the amount of, and the enzyme concentrations in, the fluid drained. When the main pancreatic duct has been inadvertently opened, it may be safer not to attempt to over-sew the leak but to convert the planned enucleation into a segmental (pancreatic body) or distal (pancreatic tail) resection or fashion a Roux-en-Y jejunal loop onto the pancreatic defect to drain the leak [46].

## Short- and Long-Term Outcomes After Enucleation

In a recent systematic review and meta-analysis of enucleation versus standard pancreatic resection for small, mainly (69%) neuroendocrine tumors [48], enucleation was performed laparoscopically in 9% of operations. Enucleation was superior to standard pancreatic resection, leading to shorter operations ($P < 0.001$) with fewer blood loss incidents ($P < 0.001$), inferior regarding the overall fistula rate (33 versus 20%) and comparable in the length of hospitalization, postoperative mortality, and the percentage of reoperation. Grade B/C fistula, as defined by the International Study Group [49], was slightly less frequent after enucleation than after standard pancreatic resection (44 versus 50%). Major contributors to postoperative pancreatic fistula included deep enucleations [38] and enucleation of PanNET from the head and uncinate process of the pancreas [36,37], but not surgical (laparoscopic versus open) approach [38].

With respect to long-term oncologic outcome, enucleation was not inferior to standard pancreatic resection when the tumor was low grade, surgical margins were clear on definitive histopathology, and locoregional or distant metastases were absent [48,50,51].

After enucleation of <2 cm nonfunctioning PanNET, late recurrences and metastases were found in 8% of patients [52]. The need to dissect regional lymph nodes in addition to clearing these tumors from the pancreas has sparked a lot of debate [53–59] because lymph node metastasis may have a negative prognostic impact on survival [53–57]. Lymph node metastases can be present in up to 25% of patients with nonfunctioning

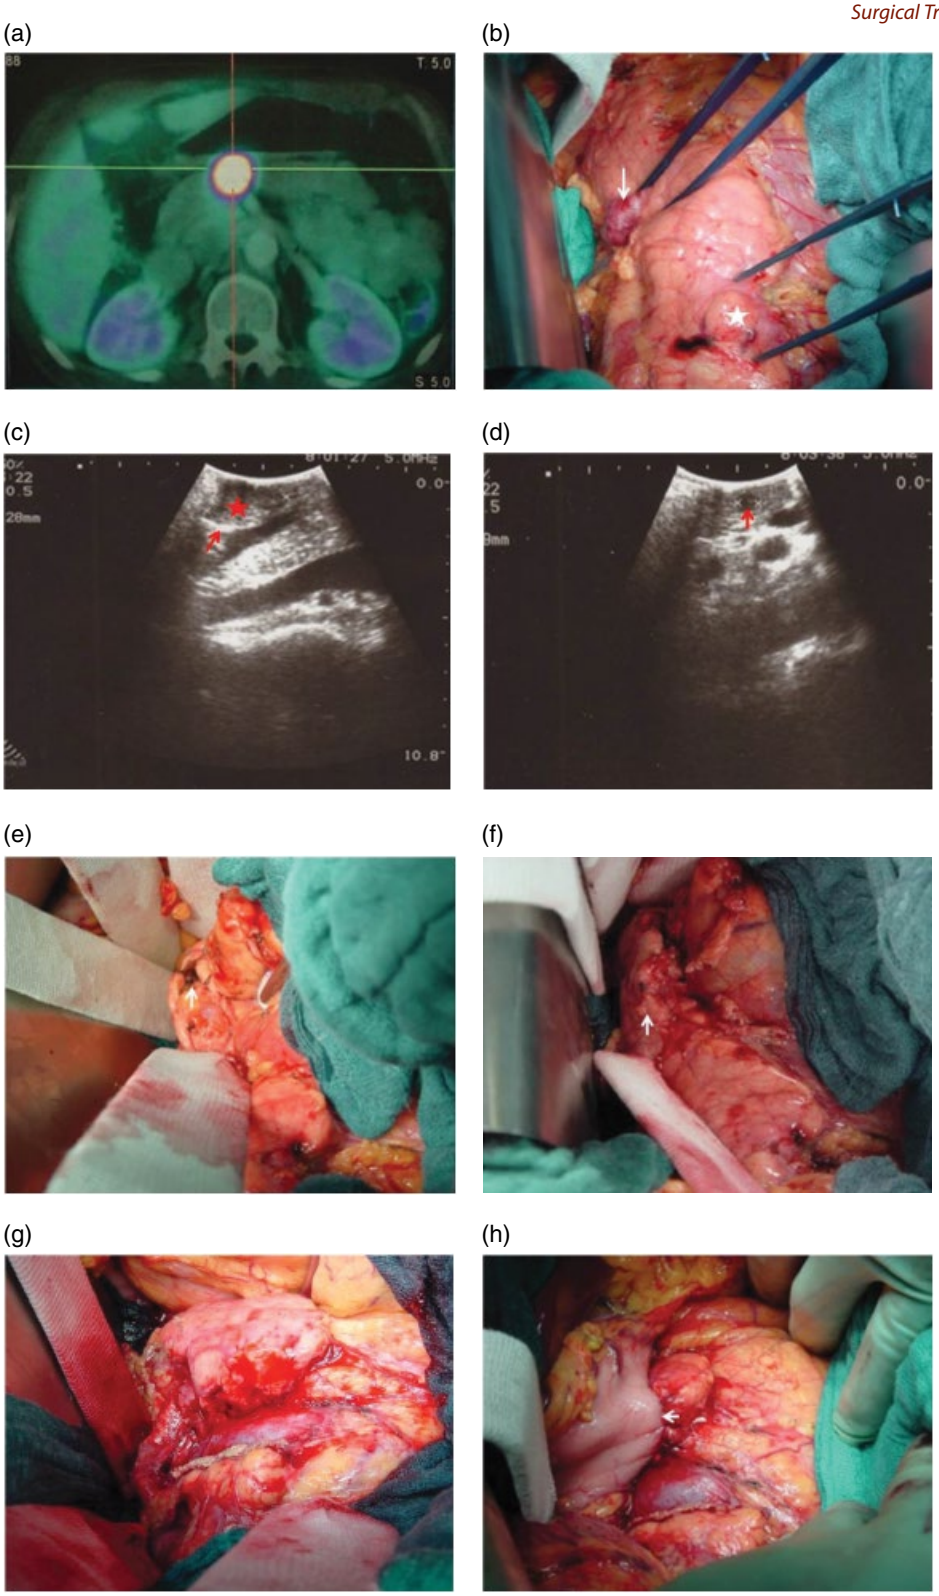

**Figure 130.3** Combined pancreatic tail enucleation and central pancreatectomy for multiple MEN1-associated nonfunctioning neuroendocrine pancreatic tumors. (a) Preoperative [$^{68}$Ga]DOTA-NOC (DOTA-Nal-octreotide) PET/CT showing a PanNET in the body of the pancreas adjoining the posterior pancreatic vascular axis; (b) intraoperative view picturing a PanNET at the body (asterisk) and another PanNET at the tail of the pancreas (arrow); (c) intraoperative ultrasonography revealing close proximity of the 25 mm pancreatic body PanNET (asterisk) to the mesenterico-portal vein and the main pancreatic duct (arrow); (d) intraoperative ultrasonography delineating the 6 mm PanNET in the pancreatic tail (arrow); (e) intraoperative situs of the pancreatic tail after enucleation (arrow); (f) intraoperative view of the closed pancreatic defect (arrow); (g) Intraoperative situs after central pancreatectomy; (h) intraoperative view of the pancreas reconstructed by pancreatogastrostomy (arrow).

PanNET no larger than 2 cm [53–55]. Preoperative identification of involved lymph nodes continues to be challenging [58], and concomitant lymph node dissection can drive up surgical morbidity. Balancing the benefits against the risks, it becomes immediately apparent that the recommendation for or against lymph node dissection must be individualized considering the circumstances of the case. There is evidence to suggest that patients with small non-grade 1 grade tumors and clinically suspicious lymph nodes [56] benefit more from standard pancreatic resection and lymph node dissection than from enucleation alone. Otherwise, enucleation, preserving more pancreatic parenchyma, caused fewer endocrine (1 versus 11%) and exocrine (0 versus 25%) pancreatic failures than standard pancreatic resection [48].

## Outcome After Laparoscopic Enucleation

The technical feasibility of laparoscopic enucleation of PanNET, alone or in conjunction with lymph node dissection, is widely recognized [60–66]. Prospective randomized controlled trials comparing laparoscopic with open enucleation have not been performed [60]. Retrospective studies hint at a higher risk of pancreatic fistula after laparoscopic enucleation than laparoscopic resection [64]. Enucleations of tumors from the pancreatic head are associated with more pancreatic leaks than left-sided enucleations [63], regardless of whether laparoscopic or conventional open enucleation has been carried out [65]. There is a dire need for more research to clarify the long-term oncologic and functional outcome after laparoscopic enucleation.

[2] *First Department of Surgery, Faculty of Medicine, Yamagata University, Yamagata, Japan*

## Background

Pancreatic neuroendocrine tumors (PanNETs) are increasingly more frequent, accounting for 10% of all benign tumorous lesions of the pancreas and 2% of all pancreatic neoplasms [1]. Hormonally active and inactive PanNETs develop from the islet cell parenchymal compartment, which constitutes 2–10% of the pancreatic tissue. owing to the systematic use of sensitive imaging modalities, the incidence of nonfunctional pancreatic neuroendocrine adenomas has increased more than twofold in the last 16 years and of small nonfunctional PanNETs (<2 cm) more than sevenfold [2]. The natural history of asymptomatic nonfunctioning adenomas of <2 cm is poorly understood. In contrast to most hormonally active PanNETs, functionally inactive endocrine tumors produce signs only late in the clinical course, which are mostly unspecific. In addition to well-established radiologic and endoscopic ultrasound (EUS) investigations, the measurement of specific hormones in the peripheral blood, somatostatin-receptor scintigraphy, and positron emission tomography (PET) are diagnostic measures that establish in most patients the diagnosis, type, and location of the tumor. Multifocality of PanNETs is well known, particularly in hereditary syndromes, including multiple endocrine neoplasia type 1 (MEN1) and von Hippel–Lindau syndrome. Neoplasms of ≤5 mm have been defined as microadenomas. These are mostly nonfunctioning, rarely grow, and are reported in autopsy studies in up to 10% of cases [3]. Two major staging systems have been proposed. In 2006, the European Neuroendocrine Tumor Society (ENETS) developed a tumor–node–metastasis (TNM) classification [4]. In 2010, the American Joint Commission on Cancer (AJCC) introduced a new classification of endocrine pancreatic tumors with adapted criteria from the staging of exocrine pancreatic adenocarcinoma [5]. Low-risk neuroendocrine carcinomas (NECs) are classified as T1N0, tumor grade 1/2, mitotic rate <20, and Ki-67 > 5% [3–5].

## Surveillance or Treatment of Neuroendocrine Tumors of the Pancreas?

Neuroendocrine neoplasms of the pancreas are a heterogeneous entity and display an unpredictable biological behavior [6]. The progress in diagnostic accuracy of small neoplastic lesions of the pancreas has led to a challenging setting of whether to observe or to operate. All gastroenteropancreatic neuroendocrine tumors are considered to be potentially malignant [7,8]. Only surgical treatment of benign PanNETs and low-risk NECs offers the chance of a cure. Up to 70% of all PanNETs are insulinomas, which most frequently display functional activity. Insulinomas are benign in approximately 90% of cases, independently of the symptoms. Functionally inactive adenomas account for 30–50% of all PanNETs, usually detected late in the clinical course. The risk evaluation focuses on signs of proliferative activities of the lesion. A mitotic count <2, 2–20, >20, Ki-67 index <2, 3–20, >20%, tumor growth, presence of enlarged lymph nodes, and distant metastases are established criteria of malignant transformation [7,8]. Lymph node metastases have been observed in up to 25% of patients with nonfunctioning PanNETs with a tumor diameter of <2 cm [9]. Tumor growth in small, nonfunctioning PanNETs was measured as 0.12 mm/year [10]. Long-term observation of patients with nonfunctioning PanNETs exhibited no disease progression after 45 and 283 months [9,10].

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

After a median follow-up of 34 months, the mean tumor growth of small, sporadic, nonfunctioning PanNETs has been estimated to be 0.01 mm/year [9]. Nonfunctional PanNETs of <10 mm without clinical signs of tumor growth have a low risk of cancerous transformation; an annual monitoring protocol is recommended [11]. A risk–benefit analysis for surveillance or surgical management is recommended for each individual patient. For local advanced and metastatic NECs, an oncologic resection, balanced with cytoreductive and/or antihormonal medication and/or ablative treatment, is suggested.

## Indication for Surgical Treatment of PanNETs

Approximately 50–60% of PanNETs are located in the pancreatic head and neck, being predominantly nonfunctional PanNETs [12], and 40% in the body and tail. Pathomorphologically, endocrine tumors of the pancreas occasionally demonstrate cystic changes, calcification, and intralesional bleeding. The most import criteria for surgical decision making are clinical symptoms, tumor size >2 cm, and a risk calculation for malignancy. A neoplasm of >2 cm, positive nodule status, and a grading of mitoses >20 and Ki-67 index >3% are considered criteria for surgical management [13] (Table 131.1). Of prognostic significance are local infiltration and a neoplasm size >4 cm. For nonfunctional PanNETs, irrespective of tumor size, the Japanese National Comprehensive Cancer Network Guidelines recommend surgical resection, including that of regional lymph nodes. Lymph node metastases have been observed in patients with PanNETs of a maximal size <20 mm [9,14,15]. However, PanNETs with tumor size <2 cm with a histologic grading of G3 and a Ki-67 index >20% have a high probability of developing a neuroendocrine cancer. Sporadic gastrinoma, glucagonoma, and VIPoma of the pancreas display malignancy in >60–80% of cases, irrespective of tumor size. Approximately 10% of sporadic hormone-active insulinomas are malignant. MEN1-associated insulinoma infrequently shows signs of malignancy.

## Parenchyma-Sparing Local Resection of Neuroendocrine Tumors of the Pancreatic Head

A pancreatoduodenectomy (PD) of the Kausch–Whipple type is currently the surgical standard for neuroendocrine tumors of the pancreatic head. However, this multiorgan resection is associated with a considerable risk for early procedure-related complications and late outcome reduction of endocrine and exocrine pancreatic functions [16,17]. To maintain the quality of life of the patients, in recent years, local, parenchyma-sparing tumor extirpation techniques for benign neoplasm of the pancreas have been increasingly used. For small PanNETs up to a maximum diameter of 2 cm, a tumor enucleation is the favored option (see Chapter 130). However, deep enucleation of pancreatic head lesions is associated with increased morbidity regarding postoperative pancreatic fistula (POPF) grades B + C [18]. The limitations of enucleation of neuroendocrine neoplasms are a tumor size >3 cm, close proximity of the lesion to the pancreatic main ducts (PMD), and a high frequency of risk of POPF grades B + C [19].

## Duodenum-Preserving Total or Partial Pancreatic Head Resection

For benign tumors of the pancreatic head, parenchyma-sparing, local head resections are increasingly applied to avoid a classical Kausch–Whipple resection. Duodenum-preserving total or subtotal pancreatic head resection have the potential for a local tumor extirpation associated with a low procedure-related postoperative morbidity

**Table 131.1** Surveillance or local, parenchyma-sparing pancreatic resection of benign PanNETs and low-risk NECs.

| Diagnosis | Symptoms | Treatment |
|---|---|---|
| PanNETs | Clinical symptomatic adenomas | Surgery |
| | Functional adenomas | Surgery |
| | Hormone-active tumors >2 cm | Surgery |
| | Tumors with signs of growth and/or Ki-67 > 3% | Surgery |
| | Small non-G1 adenomas <2 cm and enlarged lymph nodes | Surgery |
| | Nonfunctioning adenomas <10–15 mm | Surveillance |

and preservation of the exocrine and endocrine pancreatic functions compared with the preoperative status [16]. The advantages of duodenum-preserving total head resection (DPPHR) are underlined by randomized clinical trials comparing duodenum-preserving local resection with PD in patients with inflammatory head tumor (see Chapter 58). The size and location determine the application of a partial or total head resection. Of 431 patients who underwent a local tumor resection applying a DPPHR, 11% suffered a PanNET [17] (Table 131.2). The mean tumor size was 3.1 cm. In a subtotal pancreatic-head resection for tumors located in the pancreatic head but remote from the duodenal wall and the intrapancreatic CBD, a careful dissection of the pancreatic tissue from the portal vein is surgically demanding (Fig. 131.1a). When a PanNET is located in the uncinate process, a partial pancreatic-head resection resecting the anatomical uncinate process is recommended, using a jejunal loop for reconstruction (Fig. 131.1b). The surgical technique of total head resection with dissection of the pancreatic tissue from the peripapillary duodenum and preservation of nutritive arterial arcades is well established (Figs 131.2 and 131.3). Dissection of regional lymph nodes is standardized and readily executable. The low frequency of surgery-related complications of 12% and a POPF grades B + C rate of 13% compares favorably with the published figures for early postoperative morbidity after a PD. DPPHR was associated with a very low 90-day mortality of 0.5% [16] (Table 131.3). The major advantage of duodenum-preserving total and subtotal pancreatic head resection in the long-term outcome is the preservation of the exocrine and endocrine pancreatic functions. Long-term measurements showed an almost complete preservation of the exocrine and endocrine pancreatic functions after DPPHR for neoplastic tumors. Recurrence after DPPHR was low.

## Pancreatic Middle-Segment Resection

Pancreatic middle-segment resection of 912 patients was applied to 31% of patients suffering a neuroendocrine tumor [20] (Table 131.2). The mean tumor size was 2.9 ± 0.98 cm. Pancreatic middle-segment resection is an alternative to a pancreatic left resection for benign lesions of the pancreas. Pancreatic left resection results in a significant reduction in insulin production, leading to a deficit in insulin secretion, and thus to new-onset diabetes mellitus

**Table 131.2** Local surgical treatment of neuroendocrine pancreatic tumors and other neoplasms: frequency of extirpation procedures DPPHR and pancreatic middle segment resection (PMSR) for PanNETs.

| Treatment | Patients | PanNETs | Cystic neoplasms | Others | Tumor size (cm) |

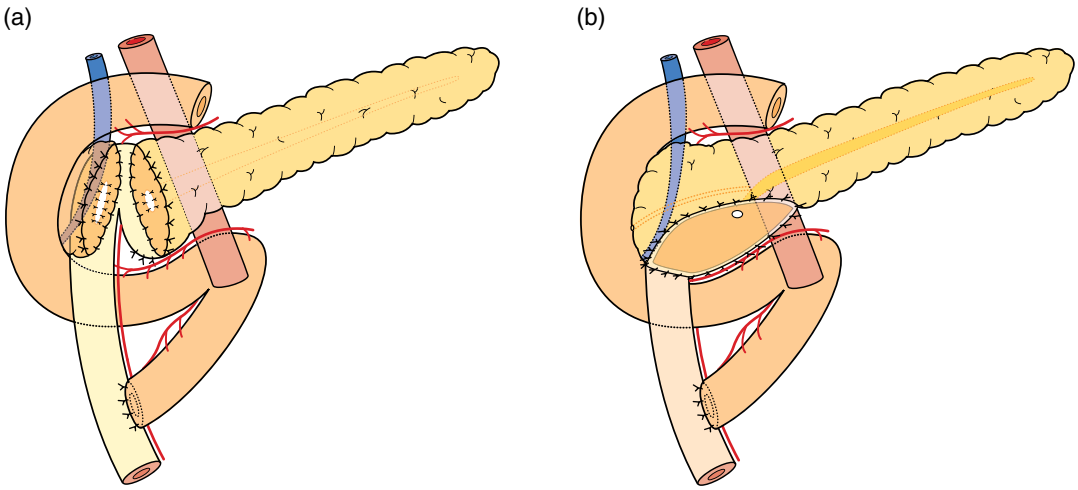

**Figure 131.1** (a) Partial, segmental pancreatic head resection for neuroendocrine tumor; (b) resection of the uncinate process for benign neuroendocrine tumor.

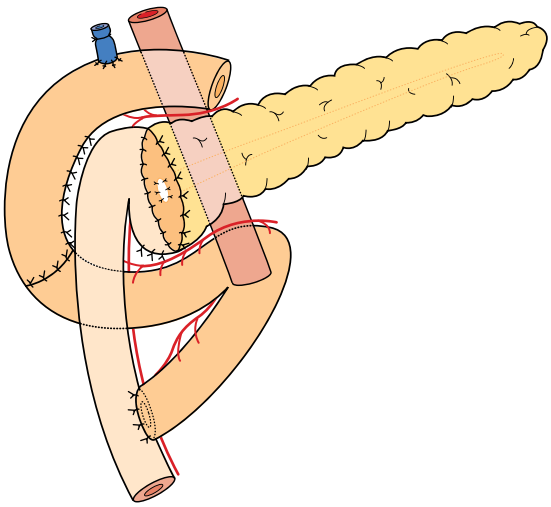

**Figure 131.2** Total pancreatic head resection preserving the duodenum and intrapancreatic common bile duct.

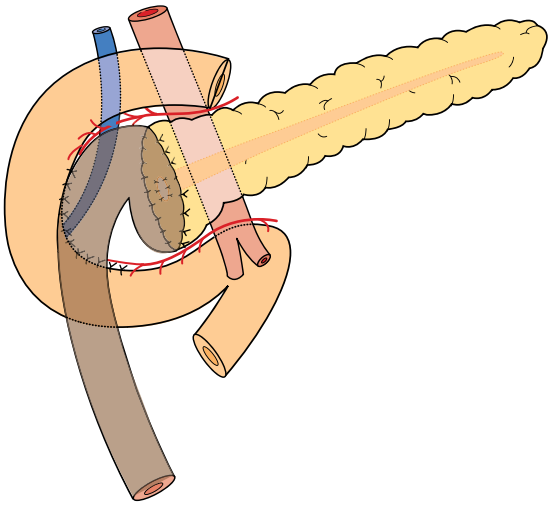

**Figure 131.3** Duodenum-preserving total pancreatic head resection for large PanNETs and low-risk NECs with segment resection of the peripapillary duodenum and the intrapancreatic common bile duct.

in 20–40% of cases and in 50% of the patients to a persistent exocrine insufficiency. The frequency of severe postoperative procedure-related complications was 16%. In 35% of cases, a fistula developed, of which 66% were of grades B + C and 5% displayed local hemorrhage, which required reoperation, involving reintervention and blood transfusion (Table 131.3). The crucial point of pancreatic middle-segment resection is surgical handling of the proximal pancreatic stump. Whereas the left pancreas is secured by a pancreaticojejunostomosis or an anastomosis with the stomach, the proximal pancreatic stump is mostly handled by a simple closure. The frequency of postoperative hemorrhage is caused by a surgical lesion of the splenic artery or vein during the resection process. After an extended middle-segment resection of a large pancreatic segment, the risk increases for a permanent endocrine and exocrine insufficiency in the long-term outcome.

## Conclusion

Neuroendocrine neoplasms of the pancreas are an increasingly more frequent entity of benign pancreatic tumors. Surgical extirpation is the only treatment modality to cure the patients with symptomatic adenoma and tumors at risk for malignancy. Local, parenchyma-sparing tumor resection is associated with a low level of postoperative complications, very low hospital mortality, and preservation of pancreatic functions. Duodenum-preserving pancreatic head resection for tumorous lesions in the pancreatic head and pancreatic middle-segment resection for body and tail tumors are recommended.

## Introduction

Over the past two decades, pancreatic neuroendocrine tumors (PanNET) in general, not just small tumors <2 cm in greatest dimension, have become more frequent at the population level worldwide [1–6]. Among large PanNET, 90% of tumors are nonfunctioning [2], and about 20% have spread to distant organs at the time of diagnosis [1]. Whereas patient age is by and large comparable in patients with small and large sporadic tumors, greater primary tumor size correlates positively with lymph node and distant metastases, lower histopathologic grading, and extrapancreatic extension [1,5–7]. Although resection of the primary tumor, even when metastases are present, may prolong survival, the considerable morbidity inherent in major pancreatic resection limits the net benefit of extended surgery for locally advanced and metastasized PanNET [8–10].

## Clinical Workup of Advanced PanNET for Major Oncologic Resection

Unlike functional PanNET that present with signs and symptoms of hormone excess, such as insulinoma, gastrinoma, and the rare glucagonoma, vasoactive intestinal peptide-releasing tumor (VIPoma), or somatostatinoma, nonfunctioning PanNET rather manifest with symptoms caused by tumor expansion, invasion, or metastatic disease. Nonfunctioning PanNET often reside in the pancreatic head, mimicking pancreatic adenocarcinoma, and compress adjacent organs, giving rise to jaundice, abdominal pain, weight loss, nausea and vomiting, back pain, and occasionally pancreatitis [2]. About 10% of PanNET are inherited in the context of multiple endocrine neoplasia type 1 (MEN 1), von Hippel–Lindau syndrome (VHL), neurofibromatosis type 1 (NF1), and the tuberous sclerosis complex (TSC). Patients with hereditary PanNET typically are younger than patients with sporadic PanNET, have multiple lesions scattered throughout the pancreas, and often yield a positive family history. MEN1-associated PanNET often comprises functioning and nonfunctioning tumors [11,12], necessitating more customized treatment plans than are required for solitary sporadic PanNET (Fig. 132.1) [13,14].

Diagnosis and extent of PanNET are established by cross-sectional (computed tomography [CT]; magnetic resonance imaging [MRI]) [15–17] and functional imaging (somatostatin receptor scintigraphy) in conjunction with [$^{18}$F]fluoro-2-deoxy-D-glucose positron emission tomography (FDG-PET) [18,19] and percutaneous or endoscopic ultrasound (EUS)-guided biopsy [20–23]. Because treatment concepts for metastatic exocrine and endocrine cancers differ tremendously, biopsy of the primary tumor or its metastasis takes center stage in differentiating pancreatic adenocarcinoma from PanNET. Clinical staging and grading of the PanNET afford stratification of patients into prognostic subgroups and facilitate individualized treatment concepts [24–26]. Ki-67 immunocytology, using World Health Organization (WHO)-defined categories of 0–3% (grade 1), 3–20% (grade 2), and >20% (grade 3) [27], helps estimate the patient's risk of recurrence and survival [28–30]. For WHO grades 1, 2, and 3, 5-year overall survival has been estimated at 85, 78, and 9%, respectively [28]. With a Ki-67 score of <2%, the likelihood is remote that the cancer extends beyond the pancreas, invades great

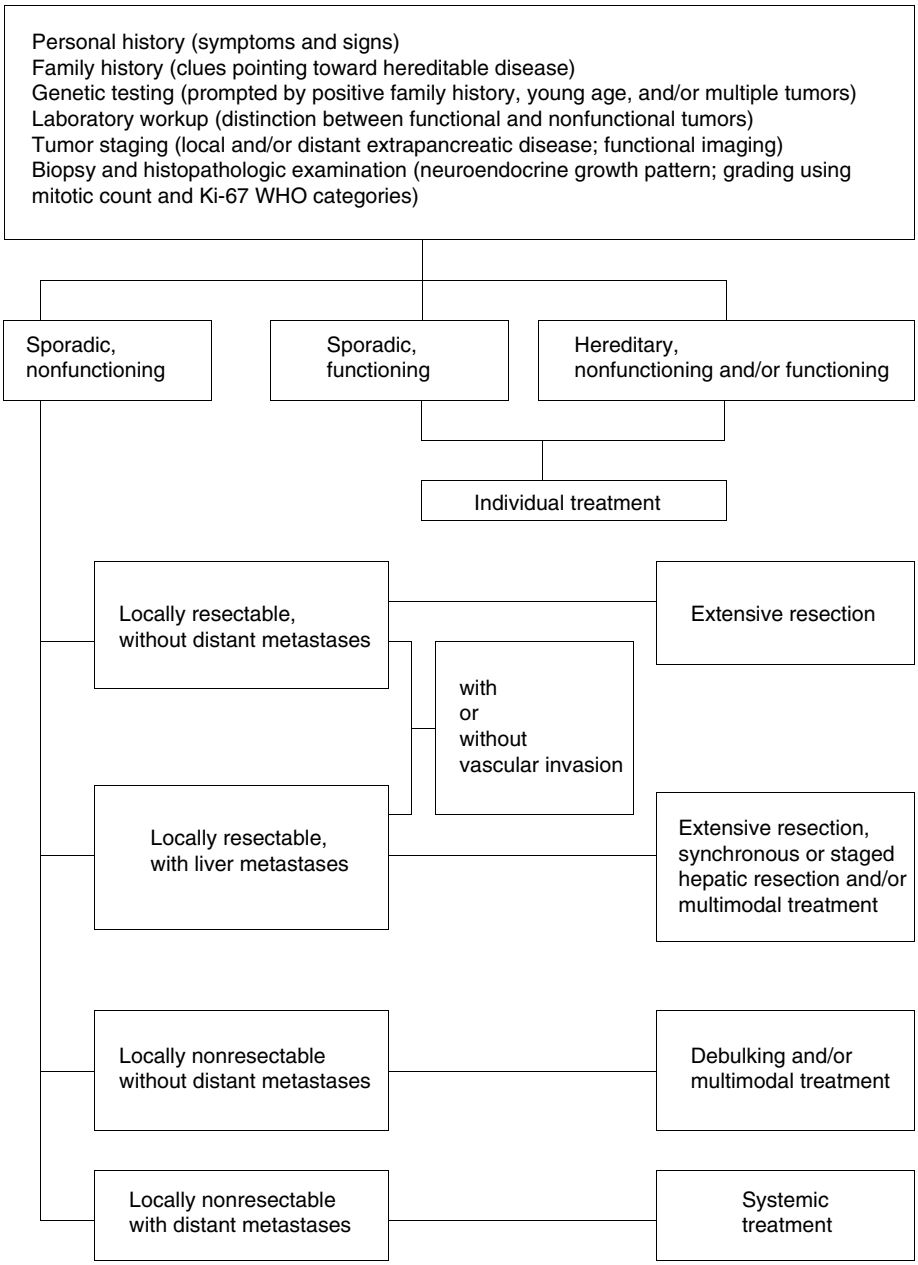

**Figure 132.1** Algorithm for clinical workup and surgical treatment of advanced PanNET.

vessels, is metastatic, or will recur [28]. Most studies support the notion that poor tumor differentiation, WHO grade 3, and distant metastases are closely connected to PanNET-specific mortality [28,31–35].

## Surgical Approach to Locally Advanced Nonfunctioning PanNET Without Clinical Evidence of Distant Metastases

Based on preoperative imaging and intraoperative exploration, locally advanced nonfunctioning PanNET are defined as large tumors frequently invading parapancreatic organs such as the stomach, spleen, colon, kidney, or adrenal gland, and/or great vessels, namely the mesentericoportal vein, superior mesenteric artery, or celiac trunk. Lymph node metastases may evade imaging [36,37], but if clinically apparent often herald systemic disease. Although lymph node metastasis is not a prognostic factor for survival in its own right [38], regional lymph node dissection has become an integral element of surgery for advanced disease reducing the risk of local recurrence.

Given the unavailability of equally effective nonsurgical treatment options, resection of a locally advanced nonfunctioning PanNET at institutions experienced in

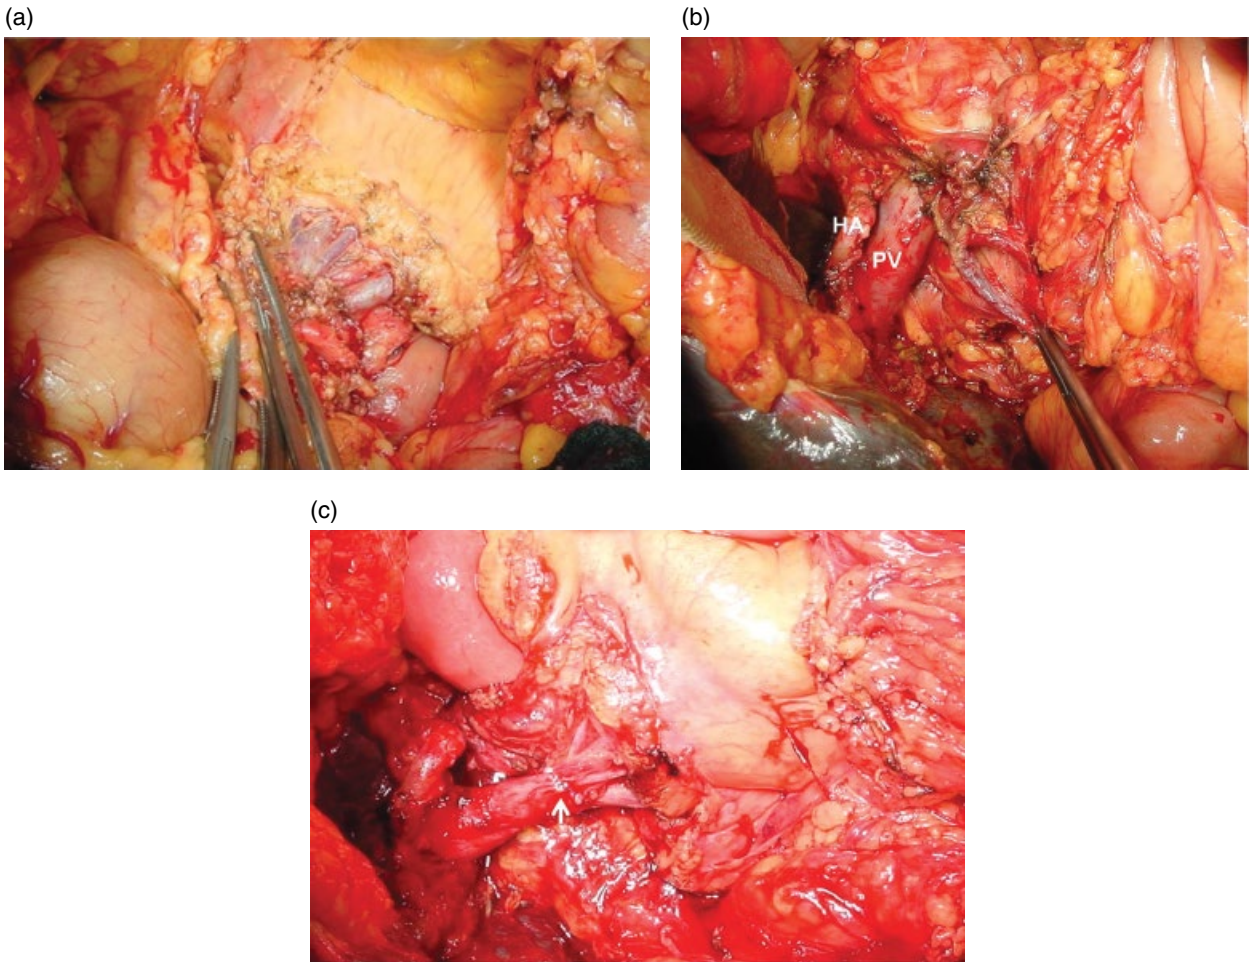

**Figure 132.2** Neuroendocrine carcinoma of the pancreatic uncinate process invading the mesentericoportal vein. (a) Infrapancreatic clamping of the superior mesenteric vein; (b) dissection of the portal vein (PV) and hepatic artery (HA); (c) end-to-end anastomosis of the mesentericoportal vein (arrow).

pancreatic surgery is the method of choice [29,36,39]. Provided that clear surgical margins are achievable, resection of neighboring organs and great vessels seems worthwhile [36,39]. Resection of the mesentericoportal axis is almost always feasible (Fig. 132.2) and requires only rarely the use of an autologous vein, or prosthetic material for reconstruction [40–46]. Conversely, arterial resection and reconstruction (Figs 132.3, 132.4, and 132.5) is much more complex [47–51] and associated with incremental surgical morbidity and mortality [52,53]. The decision to embark on the resection of great arteries needs to be pondered carefully, jointly taking into account patient age and comorbidity, stage and grade of the PanNET, extent of invasion of the artery by the tumor (celiac/hepatic artery and/or superior mesenteric artery without or with invasion of the mesentericoportal vein), and the condition of the artery itself (presence or absence of arteriosclerosis). However, systematic clinical outcome studies after resection and reconstruction of one, two, or more major vessels invaded by PanNET (Fig. 132.5) are unavailable because of the rarity of the condition [47,49]. In the absence of evidence-based information, best judgment should be exercised to determine, on a highly selective basis, whether to resect major arteries invaded by nonfunctioning locally advanced PanNET.

To clarify resectability, the greatest tumor extension outside the pancreas needs to be explored first. For invasion of the mesentericoportal axis below the pancreas, the infrapancreatic/infracolonic approach (Fig. 132.6) is a natural choice. When major branches of the superior mesenteric vein are invaded, complete resection of the tumor is unfeasible and should not be attempted. Major arteries invaded by tumor, such as the superior mesenteric or hepatic artery, are best resected toward the end of pancreatic surgery to allow immediate arterial reconstruction, keeping ischemia time to a minimum. Arterial reconstruction is accomplished directly, or with the use

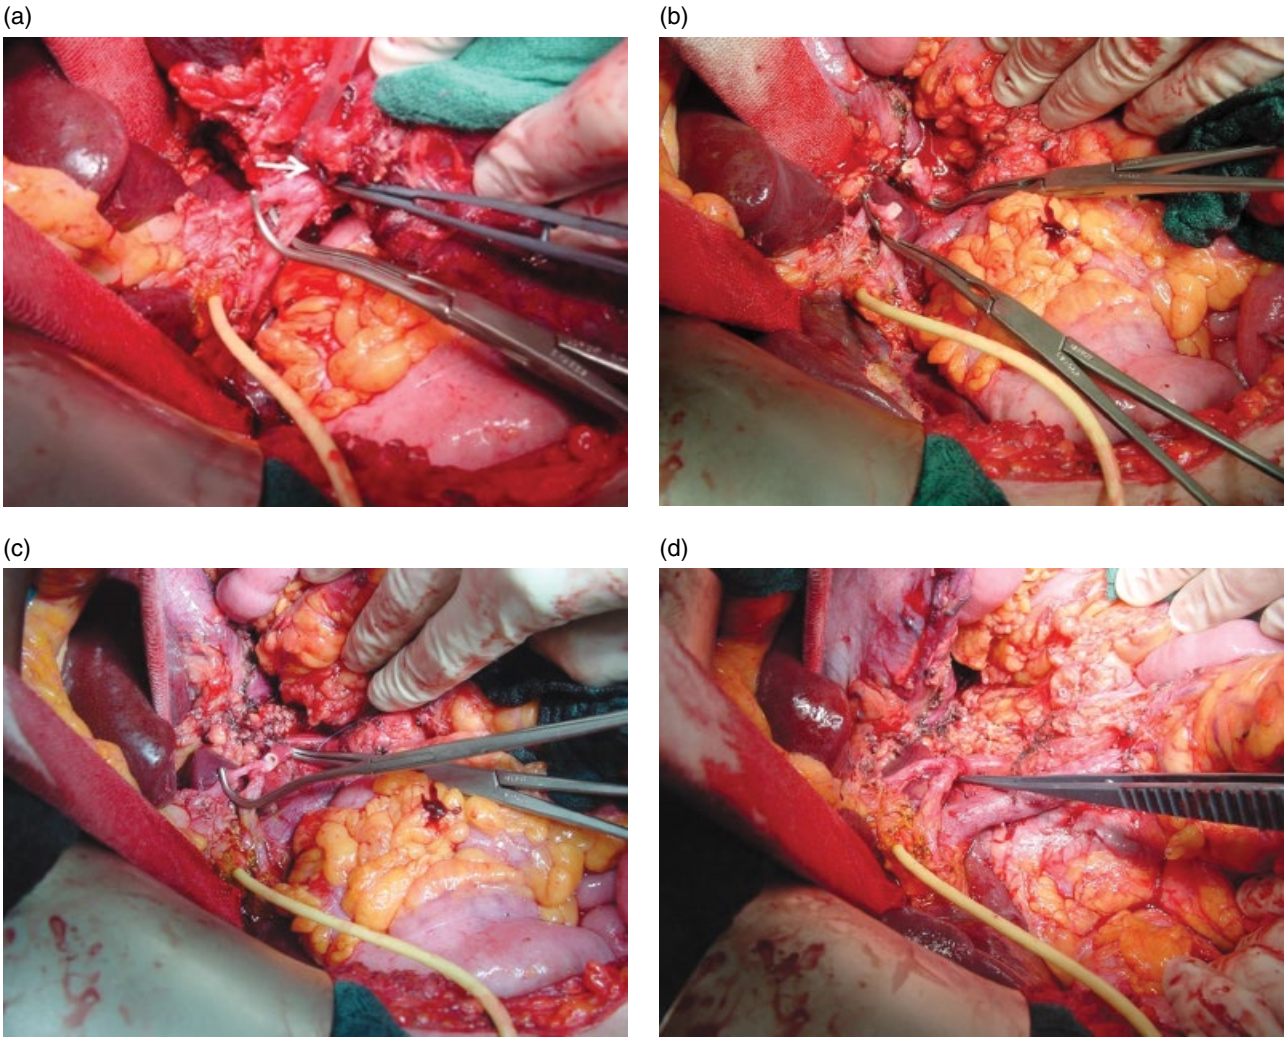

**Figure 132.3** Neuroendocrine carcinoma of the pancreatic head invading the hepatic artery. (a) Operative view of the invaded hepatic artery (arrow); (b)–(d) resection of the invaded hepatic artery segment and reconstruction by end-to-end anastomosis.

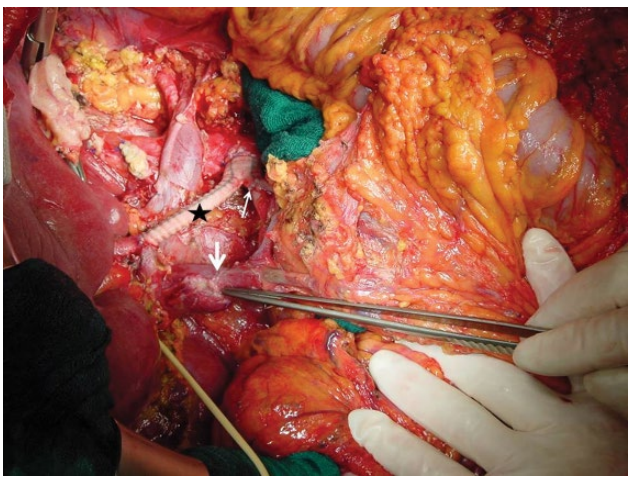

**Figure 132.5** Neuroendocrine carcinoma of the pancreatic body encroaching onto pancreatic head and tail and invading the superior mesenteric artery, superior mesenteric vein and the hepatic artery: operative situs after total pancreatectomy, three-vessel resection, end-to-end-reconstruction of the superior mesenteric vein (thick arrow) and arterial reconstruction using a Y-shaped prosthesis connecting the hepatic (asterisk) and superior mesenteric (thin arrow) arteries with the aorta.

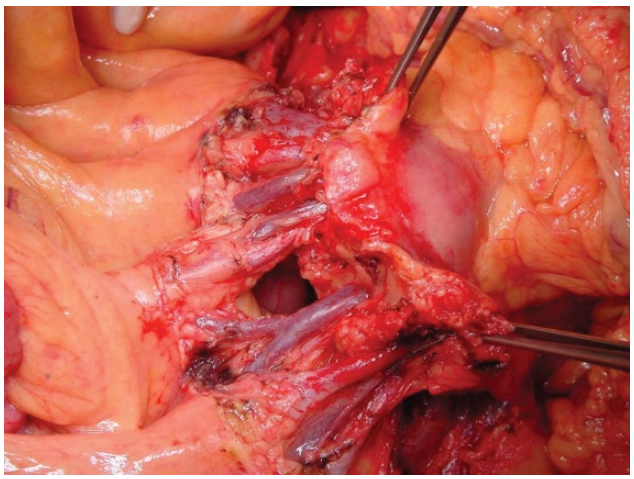

**Figure 132.6** Infracolonic dissection of the superior mesenteric vein and its branches, fenestrating the transverse mesocolon to gain access to a locally advanced PanNET of the pancreatic head.

of autologous or prosthetic material. Resection of the splenic vein alone does not warrant reconstruction [54]. In one study, segmental portal hypertension was not associated with increased mortality or severe morbidity after surgery for advanced PanNET [55].

## Locally Advanced Nonfunctioning PanNET with Clinical Evidence of Distant Metastases

Larger primary PanNET are often associated not only with invasion of adjacent organs and major vessels and more frequent lymph node metastasis, but also with liver metastases [7]. Extensive surgery for locally advanced PanNET with liver metastases, even though it may prolong survival, is controversial regardless of whether the metastases are resectable or not [56–63]. Clinically, PanNET present in more than 50% of patients with liver metastases as the only systemic manifestation, which are unresectable in 80% of patients [56].

For locally advanced PanNET without or with liver metastasis alone, or with liver metastasis as only one manifestation of systemic disease, there are no systematic outcome studies regarding the benefit of resection of the primary tumor so that the role of surgery remains to be defined for a wide range of clinical settings: symptomatic versus asymptomatic PanNET, with or without liver or other remote resectable or unresectable metastases; number and size of liver metastases; location of the primary tumor within the pancreas (head versus body or tail); and tumor grade and differentiation.

In light of the current literature, and subject to interdisciplinary consensus taking into account the circumstances of the case, it may be reasonable to suggest the following courses of action:

- For patients with *locally advanced PanNET with resectable liver metastases*, resection of the primary tumor should be considered, especially when the tumor is symptomatic. The issue of whether liver resection should take place in the same surgical session or whether a staged approach should rather be pursued depends on the extent of resection and the patient's condition [57,59,61]. A recent meta-analysis found that liver resection improved symptom relief and survival compared with nonsurgical therapy [63].
- Patients with *unresectable liver metastases of locally advanced PanNET* also may benefit from resection of the primary tumor. In a single-center study of 43 patients with PanNET and unresectable liver metastasis, the 5-year disease-specific survival was 82% in the operative group compared with 50% in the nonsurgical group ($P = 0.027$). On multivariate analysis, not only removal of the primary tumor but also younger patient age, a lower Ki-67 index, and a liver tumor burden <25% were associated with better disease-specific survival [56].
- Patients with *locally advanced PanNET and liver metastases as only one manifestation of systemic disease* are candidates for surgery only in exceptional circumstances, even when the liver metastases should be resectable. In these highly selected patients, the limited clinical effects of resection need to be carefully balanced with the benefits of nonsurgical treatment options [39,64,65].

## Introduction

Insulinomas are neuroendocrine neoplasms (NEN) originating from the pancreatic Langerhans β cells [1–5]. As symptoms of hyperinsulinemic hypoglycemia are varied and nonspecific, diagnosis of insulinoma is sometimes difficult. Therefore, a cautious diagnostic approach is taken to detect the presence of insulinoma and to localize the tumors [1,2,5]. Most insulinomas are benign, and surgical resection can bring about complete cure. However, in incurable cases, hormonal symptoms are difficult to control, requiring multidisciplinary therapy tailored to each patient [1,4,5].

## Clinical Features of Insulinomas

Insulinoma is a very rare disease, developing in 1–4 individuals per 1 million population per year [1–5]. Insulinoma presents characteristically in the fifth decade of life, and has a predilection for women (41% male, 59% female) [1–4]. Among functional NEN, insulinomas occur most frequently. Over 99% of insulinomas occur in the pancreas [1–3] and the majority of these tumors are sporadic, solitary, and small in size (≤2.0 cm) [1–3,6]. About 4–12% of cases are associated with multiple endocrine neoplasia type 1 (MEN1), and MEN1-associated insulinomas are often multiple [6–9]. About 90% of insulinoma are benign, and surgical resection can bring about complete cure [2,3,6]. The remaining 10% are malignant insulinomas with distant metastasis at the time of diagnosis; prognosis is poor, with a median survival of less than 2 years [1,3,5]. Hypoglycemic symptoms in insulinomas are divided into two major categories: neuroglycopenic symptoms, such as confusion, visual changes, amnesia, and coma, and adrenergic symptoms, such as sweating, weakness, and tremors (Table 133.1) [4,9–11]. Hypoglycemic symptoms occur most frequently in the fasting state; however, they may occur in both the fasting and postprandial states in 21% of patients, and only in the postprandial state in 6% of patients [12]. Classical diagnosis of insulinoma is the Whipple triad (presence of hypoglycemic symptoms, blood glucose level under 50 mg/dL at the time of symptom onset, improvement of symptoms after glucose intake) [1–5]. Although insulinoma is the most frequent cause of adult hypoglycemia, there are other various hypoglycemia-causing diseases that require differentiation and, therefore, cautious diagnosis is important [1–4,7–9].

## Diagnosis of Insulinomas

When excessive endogenous insulin secretion is observed during hypoglycemia, insulinoma is suspected [1–4,10,13]. When spontaneous hypoglycemia is observed, the blood is drawn to measure plasma glucose (PG), serum levels of immunoreactive insulin (IRI), proinsulin, C-peptide, and β-hydroxybutyrate (BHOB) [12–18]. According to the guidelines of the European Neuroendocrine Tumor Society (ENETS), the diagnosis of insulinoma is confirmed by hypoglycemic symptoms and the following six diagnostic criteria [1]: (1) documented blood glucose levels ≤2.2 mmol/L (≤40 mg/dL), (2) concomitant insulin levels ≥6 U/mL (≥36 pmol/L; ≥3 U/L by immunochemiluminometric assay), (3) C-peptide levels ≥200 pmol/L, (4) proinsulin levels ≥5 pmol/L, (5) BHOB levels ≤2.7 mmol/L, and (6) absence of sulfonylurea (metabolites) in the plasma and/or urine. When spontaneous hypoglycemia is not observed, the

**Table 133.1** Clinical symptoms and frequencies in patients with insulinoma.

| Symptoms | | Frequency (%) |
|---|---|---|
| Neuroglycopenic symptoms | | |
| | Confusion | 67–80 |
| | Visual changes | 42–59 |
| | Amnesia or coma | 47 |
| | Altered consciousness | 16–38 |
| | Seizures | 16–17 |
| | Headache | 7 |
| Adrenergic symptoms | | |
| | Sweating | 30–69 |
| | Weakness | 28–56 |
| | Tremors | 12–24 |
| | Hyperphasia | 14 |
| | Palpitations | 5–12 |
| | Anxiety | 12 |
| Obesity | | <50 |

following tolerance tests are conducted to induce hypoglycemia, and the above parameters are measured.

### Fasting Test

The 72-hour fasting test (Table 133.2) is the gold standard for the diagnosis of insulinoma [1–4,7,9,12,19]. In recent years, various insulin surrogates have become measurable, and some reports have indicated that the fasting period can be shortened to 48 hours [16,20]. For the fasting test, a patient needs to be hospitalized for blood collection every 4–8 hours under close medical supervision, for measurement of PG, IRI, proinsulin, and C-peptide [1,2,17–21]. PG ≤45 mg/dL with hypoglycemic symptoms is considered a positive response. Positive results are obtained within 12 hours in 33–42.5%, within 24 hours in 65–66.9%, within 48 hours in 93–94.5%, and within 72 hours in 98.4–99% of cases [16,19]. As hypoglycemic symptoms are often unnoticeable in patients with insulinoma, those symptoms should not be overlooked [16,22]. After the fasting test, serum levels of BHOB and free fatty acids are measured as supplementary data [12–16]. In rare insulinoma cases, positive results are not produced in the fasting test, and insulin is excessively secreted in response to glucagon or glucose loading, according to previous reports [21,23,24]. After the fasting test, glucagon 1.0 mg is injected intravenously and PG is measured at 10, 20, and 30 minutes. When ΔPG, defined as the difference between the maximum and baseline levels, is ≥25 mg/dL, insulinoma may be considered [2,14,21].

**Table 133.2** Fasting test instructions.

1) Meal is eaten at 18:00 and the fasting test is started:
   - Medication is minimized, and unnecessary medicines are suspended. No-calorie decaffeinated drinks can be taken. The patient is instructed to engage in daily activities.
2) Blood is drawn every 6 hours:
   - Blood tests include plasma glucose (PG), immunoreactive insulin, and C-peptide.
   - After PG is lowered to 60 mg/dL or below, blood is drawn every 1–2 hours.
3) Judgment is made as to whether the fasting test should be terminated:
   - PG ≤45 mg/dL and emergence of hypoglycemic symptoms are taken as a positive result for the fasting test, and the test is terminated.
   - When the result is negative, the test is terminated at 72 hours.
   - As PG ≤45 mg/dL may occur during fasting in healthy people (females in particular), the test should not be terminated only with PG decrease.
   - Even if PG ≤45 mg/dL is not achieved, the test can be terminated if hypoglycemic symptoms are severe. In such cases, the succeeding blood tests are carried out.
4) The following blood examinations are conducted at the end of the fasting test:
   - β-Hydroxybutyrate and free fatty acids are measured. Glucagon 1.0 mg is injected intravenously and PG measurements are taken at 10, 20, and 30 minutes. ΔPG = PG(max.) − PG (baseline) is calculated to determine the response to glucagon.
   - When insulin autoantibody syndrome is suspected, anti-insulin antibody and anti-insulin receptor antibody levels are measured.
5) Blood glucose level is promptly corrected after the test.

### Mixed-Meal Tolerance Test

There are some patients with insulinoma who present with hypoglycemic symptoms only in the postprandial state and not during fasting [12]. Furthermore, it is important to differentiate noninsulinoma pancreatogenous hypoglycemia syndrome (NIPHS) from insulinoma. As hypoglycemia often occurs after meal intake in NIPHS, it is important to carry out a mixed meal tolerance test [17,25]. In this test, fasting starts the night before the test, and the mixed-meal tolerance test begins at breakfast. The meal consists of the items that are likely to induce hypoglycemia, or the commercially available mixed meal is used. Since reactive hypoglycemia often occurs over 5 hours after meal intake, observation is continued until 5 hours after the start of the test [17,26].

## Localization of Insulinomas

In typical cases of insulinoma, the tumor is well vascularized and has a well-defined border. Its image is most enhanced in the arterial phase in dynamic computed

tomography (CT) imaging (Fig. 133.1) [1,3,27,28]. On magnetic resonance imaging (MRI), insulinomas generally show low signal intensity on fat-suppressed T1-weighted images and high signal intensity on T2-weighted images [27,28]. As the size of the insulinoma is small (<2.0 cm) in 80% of cases, and MEN1-associated insulinoma often occurs at multiple sites, it is difficult to identify all tumors with conventional imaging [1,2,7–9]. owing to the recent advances in imaging technology, the sensitivity of various conventional imaging methods has improved. Comparing the periods 1983–1993 and 1994–2007, applications of transabdominal ultrasound increased from 0 to 33%, CT from 24 to 80%, and MRI from 43 to 70%, according to Nikfarjam et al. [11].

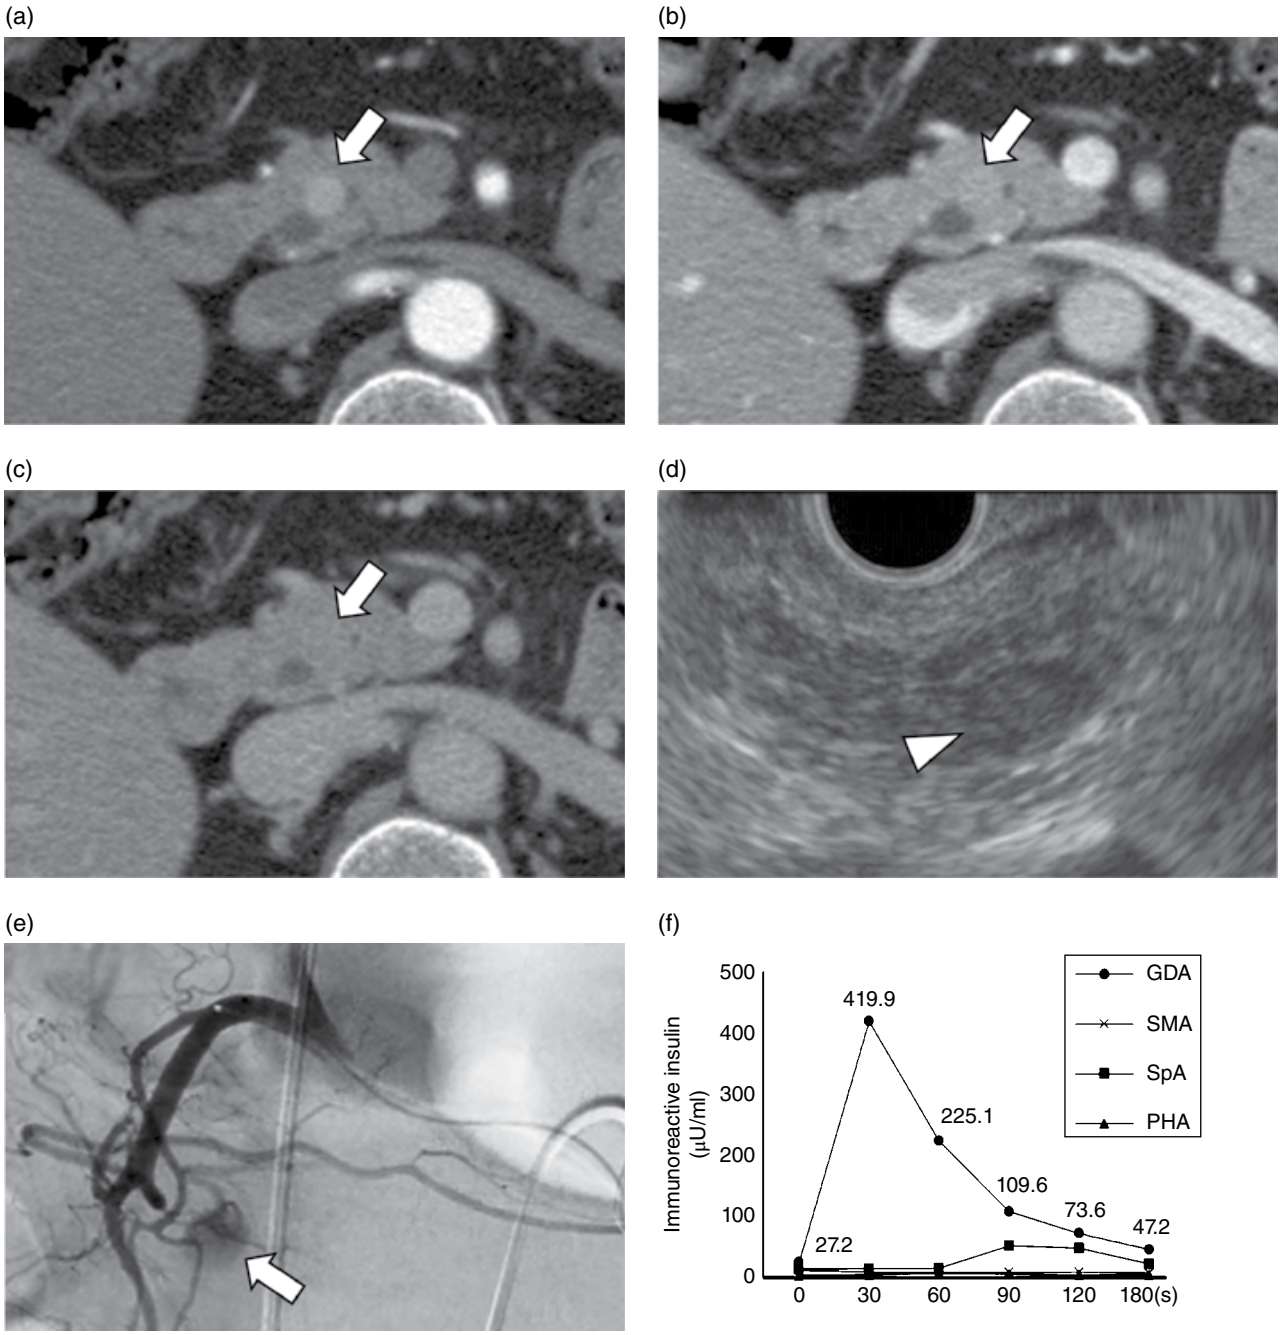

**Figure 133.1** A 68-year-old woman with insulinoma at the pancreatic head. Abdominal CT imaging (a–c) shows an oval lesion with regular margins and well-defined borders, which is most enhanced in the early phase. The lesion cannot be identified in the portal phase/late phase (arrow). EUS (d) shows an oval hypoechoic mass with regular margins and well-defined borders (arrow head). In the SACI test (e, f), a tumor is shown by gastroduodenal artery imaging, and the insulin level is markedly stepped up by glucose disposal agents. The tumor localization by the SACI test coincided with imaging findings.

Nevertheless, the diagnostic ability of these tests is not sufficient, hence these modalities are combined with endoscopic ultrasonography (EUS), the selective arterial calcium injection test (SACI test), and nuclear imaging [1–4,13].

### Endoscopic Ultrasonography

On EUS, insulinoma is revealed as an oval hypoechoic mass with a well-defined border, and a hypervascular pattern on color/power Doppler imaging (Fig. 133.1) [2,3,29,30]. Owing to its high sensitivity (80–93.8%), EUS is more useful for localization of the tumors compared with CT or MRI [2,29,30]. EUS is especially effective for the detection of small insulinomas, and when the size of the insulinoma is 12 mm or smaller, EUS is significantly superior to CT imaging [29]. It has been reported that the combination of CT and EUS permits localization of insulinoma with 100% sensitivity [30].

### Selective Arterial Calcium Injection (SACI) Test

The SACI test is useful when a tumor cannot be confirmed by other modalities (occult insulinoma). It is also useful in identifying insulinomas from among multiple pancreatic tumor masses in MEN1-associated cases [1–4,7,31–33]. For abdominal arterial angiography, calcium gluconate (0.025 mEq/kg) is injected from the feeding artery for each pancreatic region (gastroduodenal artery, superior mesenteric artery, splenic artery, etc.), and then IRI in hepatic venous blood is measured. Based on the increase in IRI, the location of insulinoma is determined (Fig. 133.1) [31–33]. IRI is measured at baseline and 30, 60, 90 and 120 seconds, and a twofold or higher increase in IRI over the baseline is considered to be positive. The sensitivity of the SACI test for insulinoma is 82.2–100%, and the method produces excellent results [2,31–33].

### Nuclear Imaging (Scintigraphy, SPECT, PET/CT)

As the proliferative ability of insulinoma is low, [$^{18}$F] fluoro-2-deoxy-D-glucose positron emission tomography (FDG-PET)/CT imaging of insulinomas is disappointing [1,3,34,35]. While [$^{68}$Ga]DOTA-TOC-PET/CT, [$^{111}$In]pentetreotide scintigraphy, and single-photon emission computed tomography (SPECT) are carried out for somatostatin receptor imaging, the expression rate of somatostatin receptor 2a is low in benign insulinomas, with a low positivity rate and sensitivity below 50% [13,34–36]. Meanwhile, the glucose-like peptide 1 (GLP-1) receptor is known to be highly expressed in more than 90% of insulinoma cases, therefore GLP-1 receptor imaging is considered useful [34–36]. GLP-1 receptor scintigraphy using [$^{111}$In]DOTA-exendin-4 has 100% sensitivity, according to a report with a small sample size [35].

## Treatment of Insulinomas

Treatment of insulinomas can be divided into two aspects: treatment of symptomatic hypoglycemia caused by excessive insulin secretion and treatment of the tumor itself. Therefore, in treating insulinomas, hormone symptoms should be well controlled, while the tumor is simultaneously treated.

### Treatment of Symptomatic Hypoglycemia

First, small, frequent meals or oral/intravenous glucose supplementation are given [1,3,37]. As for medical therapy, diazoxide (50–300 mg/day; can be increased up to 600 mg/day) is most useful [1,3–5,9]. Diazoxide acts directly on pancreatic β cells, suppressing insulin secretion, thus improving hypoglycemic symptoms. Several days are required for stabilizing blood glucose, and edema, weight increase, deterioration of renal function, and hirsutism may occur as adverse reactions [1,3,4,13]. Other drugs such as glucocorticoids, verapamil, and diphenylhydantoin are effective, according to some reports [1,3–5,13]. Somatostatin analogs, such as octreotide and lanreotide, were found to be effective for improving hypoglycemic symptoms in 35–50% of cases of insulinoma. The effects of somatostatin analogs depend on the expression of somatostatin receptor subtypes 2, 3, and 5. Therefore, in cases of no or low expression of somatostatin receptor, hypoglycemia may exacerbate by inhibiting the secretion of competitive hormones, such as glucagon [1,5,37,38]. In malignant insulinoma, the mammalian target of rapamycin (mTOR) inhibitor everolimus is effective for control of excessive insulin secretion and hypoglycemic symptoms [37,39,40].

### Treatment of Resectable Insulinoma (Surgical Treatment)

Surgical resection is a radical treatment for insulinoma. Surgical procedures are different depending upon the size and number of tumors, the tumor location, and whether MEN1 is present or not [1–5]. During surgery, palpation and intraoperative ultrasonography are conducted to examine the pancreas. Blind resection is not recommended for the occult insulinoma that cannot be localized preoperatively [2,41–44]. In general, enucleation is possible if the insulinoma is 2 cm or smaller and its distance from the main pancreatic duct is about 2–3 mm. In the case of damage to the main pancreatic

duct, pancreatic partial excision, segmental resection, pancreaticoduodenectomy, or distal pancreatectomy is carried out [1–5,41–43]. When enucleation or distal pancreatectomy is chosen for the insulinoma localized in the body or tail of the pancreas, laparoscopic surgery can be selected [1,2,42–44].

### Treatment of Unresectable Insulinoma

The therapeutic objectives in unresectable insulinoma cases are hormone symptom control and prolongation of prognosis [3–5,9,13,37]. Systemic chemotherapy for well-differentiated NEN (neuroendocrine tumor [NET] grade 1/2) generally consists of a combination of streptozotocin and doxorubicin or fluorouracil. In recent years, dacarbazine- or temozolomide-based chemotherapy has also been used as the standard chemotherapy for insulinoma [1,3,13,37,45]. In 6–70% of patients with well-differentiated NEN (insulinoma included), improvement of hormone symptoms or objective tumor response was demonstrated [37]. Among molecular target drugs, the already mentioned everolimus is considered effective against hormone oversecretion, and its antitumor effect has also been demonstrated. Therefore, everolimus is recommended [39,40,46]. Sunitinib is not thought to be capable of controlling symptomatic hypoglycemia [37]. Although cisplatin plus irinotecan or cisplatin plus etoposide is generally used to treat poorly differentiated NEN (neuroendocrine carcinoma [NEC]), the incidence of NEC is low in insulinoma, and therefore, sufficient investigations have not been conducted in this field [3,6,9,45]. If medical therapy cannot control hormone symptoms sufficiently, tumor debulking surgery is sometimes conducted even in unresectable cases, targeting the removal of at least 90% of the tumor volume, with the objective of alleviating the symptoms [2,3,5,45,47]. Other therapies for unresectable NEN including insulinoma are liver-directed therapies (embolization, chemoembolization, radiofrequency ablation), laser-induced thermotherapy (LITT), selective internal radiotherapy (SIRT) using yttrium-90 microspheres, peptide receptor radionuclide therapy (PRRT) using [$^{177}$Lu]DOTA$^{0}$-Tyr$^{3}$octreotate, and also liver transplant; alleviation of hormonal symptoms and improvement of prognosis have been reported [1,3–5,45,47–52].

# Evidence of Medical and Surgical Treatment of Gastrinoma

*Ryuichiro Doi*

*Kyoto University Hospital, Kyoto, Japan*

## Treatment Strategy

The goals of gastrinoma treatment are to manage gastric acid hypersecretion and to remove the risk of distant metastasis and ultimately death of the patient by resecting tumors that are usually malignant.

Treatment for gastrinoma has changed significantly since the syndrome was originally described in 1955 [1]. Initially, most patients developed severe symptoms and underwent emergency surgery for complications such as massive hemorrhage or perforation. Partial gastrectomy with or without vagotomy was insufficient treatment, hence total gastrectomy became the standard operation for patients with gastrinoma [2].

The development of effective antisecretory drugs has drastically changed the management of gastrinoma [3]. In most patients, gastric acid hypersecretion can be controlled with antisecretory agents such as $H_2$-receptor antagonists and proton-pump inhibitors. Because those agents are so effective, surgery for the control of gastric acid hypersecretion such as total gastrectomy is no longer required. About 60% of gastrinomas are malignant and those are the major cause of death during long-term follow-up, although they are relatively slow growing. Now, the roles of surgery are to remove the responsible tumor or tumors and to prevent tumor progression and ultimately death.

Along with the increasing recognition of the duodenum as the most common site for gastrinomas, and with improved localization methods, at least 50% of patients with sporadic gastrinoma can be cured by tumor resection [1,4]. Therefore, an aggressive approach to tumor localization is strongly recommended in selecting patients for operative treatment.

## Tumor Localization

Before surgical treatment, tumor localization studies are required in all patients with gastrinomas. Imaging techniques such as computed tomography (CT), ultrasonography (US), endoscopic ultrasonography (EUS), and intraoperative ultrasonography (IOU) have been useful for the localization of most neuroendocrine tumors greater than 2 cm in diameter [5]. However, imaging techniques have difficulty in visualizing neuroendocrine tumors smaller than 5 mm [5]. As gastrinoma shows characteristic symptoms even when smaller than 5 mm, the selective arterial secretagogue injection (SASI) test is useful for preoperative localization of gastrinoma leading to curative resection surgery [6–8]. Somatostatin receptor scintigraphy (SRS) is indispensable for localization of ectopic gastrinoma and the metastatic lesions of gastrinoma throughout the body [9].

### Selective Arterial Secretagogue Injection (SASI) Test with Secretin or Calcium

The SASI test was first described for localization of gastrinoma, and has gradually proved useful for the localization of other symptomatic pancreatic neuroendocrine tumors (PanNET) [6–8,10]. At the time of abdominal arteriography, secretagogue is injected into the splenic artery, the gastroduodenal artery, and the superior mesenteric artery (Fig. 134.1). Then 2 mL blood samples are drawn from the hepatic vein through a catheter inserted via the femoral vein before and 20, 40, and 60 seconds after the injection of secretagogue to detect the change in gastrin levels in hepatic venous blood. When the rise in gastrin levels at 40 seconds after injection is

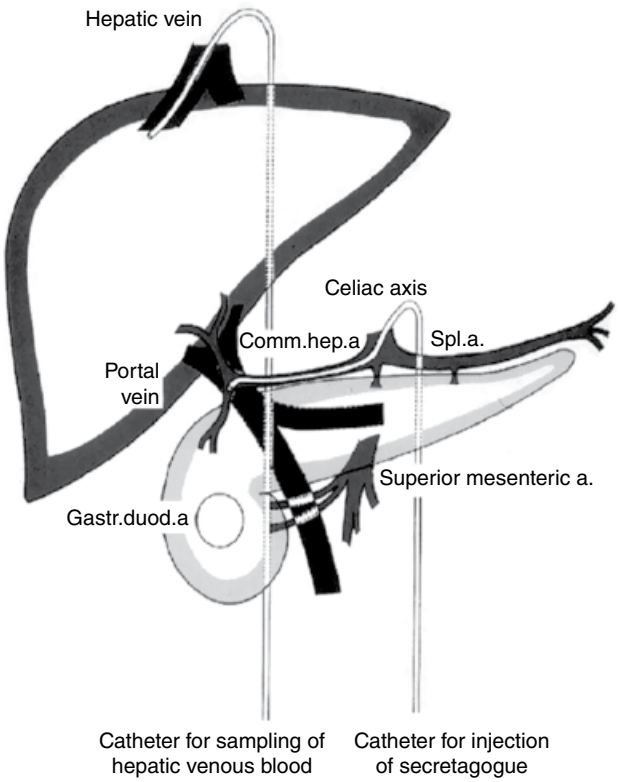

**Figure 134.1** Scheme of the selective arterial secretagogue injection test. Results of the selective arterial secretagogue injection (SASI) test in a patient with Zollinger–Ellison syndrome. In this patient, serum immunoreactive gastrin at 40 s after the injection of 30 units of secretin rose only after injection into the gastroduodenal artery. Hence it was diagnosed that the gastrinoma(s) was located in the upper part of the pancreas and/or the duodenum. Gastr.duod.a, gastroduodenal artery; Spl.a., splenic artery; Superior mesenteric a., superior mesenteric artery.

significantly higher than the measurement errors, the artery is diagnosed as a feeding artery of gastrinoma. Functioning gastrinoma is then located in the feeding area of the identified feeding artery.

More precise localization is possible by injecting secretagogue into a branch of the identified artery. Both the sensitivity and specificity of the SASI test for gastrinoma have been shown to be more than 90% [7].

### Somatostatin Receptor Scintigraphy (SRS)

SRS is clearly able to visualize PanNET larger than 2 cm in diameter in the body, and has contributed to the staging of PanNET [11–13]. SRS can visualize 100% of gastrinomas larger than 3 cm in diameter, but only 20% of gastrinomas are smaller than 5 mm and 30% are smaller than 1 cm [12]. SRS visualized 73% of gastrinomas, depending both on the extent of the presence and the differences in subtypes of somatostatin receptors and on the size of the tumor [13]. For the localization of ectopic gastrinoma, SRS is indispensable [14].

### Intraoperative Ultrasonography (IOU)

IOU is useful in estimating the character of a tumor and in measuring the distance between gastrinoma and the main pancreatic duct. In addition, the form and size of the gastrinoma can be measured more correctly with IOU than any other preoperative imaging technique [15].

## Surgery

Surgery for gastrinoma needs a thorough exploration and careful technique. The omentum is widely opened, and the entire pancreas from head to tail is mobilized. This allows careful bimanual palpation of the gland.

IOU should be performed in any patient undergoing exploration for gastrinoma to identify tumors that are difficult to palpate. It may also detect signs suggestive of malignancy in addition to the relationship of the tumor to the main pancreatic duct and major blood vessels. IOU is not particularly useful in identifying duodenal wall gastrinomas; however, intraoperative endoscopy with transillumination of the duodenum is capable of locating duodenal wall gastrinomas.

The most accurate method of detecting duodenal wall gastrinomas is duodenotomy with careful palpation, a technique employed by experienced surgeons during surgical exploration for gastrinoma. Duodenotomy has been shown to increase the gastrinoma detection rate to 98% compared with 76% without duodenotomy, and also the short-term cure rate (65 versus 44%) and long-term cure rate (52 versus 26%) [16].

Because primary duodenal gastrinomas are associated with lymph node metastases in 60% of patients, a more aggressive lymph node dissection has been recommended. Major vascular involvement is not a contraindication to attempt a resection. A study of 273 patients showed that 46 (17%) had evidence of major vascular involvement on preoperative imaging, and 42 of these 46 patients underwent successful resection [17].

The use of endoscopic and/or laparoscopic approaches for the management of neuroendocrine tumors, including gastrinomas, has been reported in small numbers of patients. However, the role for such an approach in patients with gastrinomas appears to be limited owing to a variety of technical issues, including the multiplicity of lesions, the small size of duodenal tumors, the frequent presence of lymph node metastases, and the presence of critical structures in the usual gastrinoma location in the pancreatic head region. These difficulties tend to favor an open surgical approach.

## Treatment of Hepatic Metastases

A very aggressive management approach has been advocated for advanced and metastatic gastrinomas because of the poor outcome of patients and the overall disappointing results with systemic therapy. It was reported that aggressive resectional procedures were associated with no operative deaths and a 5-year actuarial survival of 80% in 20 patients with locally advanced and metastatic neuroendocrine tumors including 10 gastrinomas [18]. Another study in 85 patients with liver metastases suggested that chemoembolization may be preferred unless a curative resection is possible or 90% of the tumor volume can be removed [19]. Bilobar disease and patients with more than 75% liver involvement were least likely to benefit from surgery.

The role of liver transplantation in patients with liver metastasis remains controversial. The UNOS database showed that 150 liver transplantations were carried out for patients with liver metastasis from neuroendocrine tumors out of 87,280 performed. Among them, 11 cases of gastrinoma (7.3%) were included. Overall survival rates were similar to those for patients who underwent transplantation for hepatocellular carcinoma [20].

Other liver-directed therapies include chemoembolization, radioembolization, and percutaneous radiofrequency ablation. These therapies continue to play a role in the management of neuroendrocrine tumors metastatic to the liver, including gastrinomas. In general, transarterial chemoembolization (TACE) has been shown to be a relatively safe procedure with improvements in symptom control, time to progression, and survival.

## Systemic Chemotherapy

Streptozotocin appears to be the most active single agent in patients with metastatic gastrinoma with objective response rates reported in up to 50% of patients [21]. There is no evidence that the addition of 5-fluorouracil (5FU) with or without doxorubicin improves the outcome compared with streptozotocin alone [21].

A study using a combination of 5FU, cisplatin, and streptozocin for metastatic or locally advanced neuroendocrine tumors of a variety of sites in 79 patients showed that the overall results are not superior to those with streptozocin alone [22].

Octreotide, either alone or combined with interferon, appears to have a role in the management of patients. The development of a long-acting somatostatin analog has greatly facilitated management, and is effective in reducing symptoms.

A randomized multi-institutional double-blind placebo-controlled trial studying the vascular endothelial growth factor (VEGF) inhibitor sunitinib was reported in 171 advanced well-differentiated neuroendocrine tumors, including 19 patients with gastrinoma. Progression-free survival (PFS) was 11.4 months in the sunitinib group compared with 5.5 months in the placebo group. The objective response rate was 9.3% in the sunitinib group versus 0% in the placebo group. Nine deaths were reported in the sunitinib group (10%) versus 21 in the placebo group (25%).

The use of mTOR inhibitors, either alone or combined with octreotide therapy, has recently been studied in patients with pancreatic neuroendocrine tumors. The RADIANT 1 trial, a multinational Phase II study, studied the efficacy of everolimus alone and in combination with octreotide in patients with metastatic PanNET who had progressed on chemotherapy [23]. Treatment with everolimus alone resulted in stable disease in 67.8% of patients and partial response in 9.6%. Combination therapy with everolimus and octreotide LAR resulted in stable disease in 80% of patients and partial response in 4.4%.

In the RADIANT III trial, 410 patients with radiologic progression of disease were randomized to everolimus 10 mg daily or usual therapy, which could include somatostatin [24]. The median PFS was 11 months with everolimus compared with 4.6 months with usual therapy. The proportion of patients alive and progression free at 18 months was 34% with everolimus compared with 9% with placebo.

# Rare Neuroendocrine Tumors of the Pancreas: Management and Evidence of Surgical Treatment

*Ryuichiro Doi*

*Kyoto University Hospital, Kyoto, Japan*

## Introduction

As pancreatic neuroendocrine tumors (PanNET) are rarely encountered in hospitals, standardization of diagnosis and/or the treatment strategy have not progressed until recently. However, recent advances in localization techniques such as the selective arterial secretagogue injection (SASI) test and somatostatin receptor scintigraphy (SRS) have promoted curative resection surgery of PanNET [1,2]. As the number of resections has rapidly increased, a few important characteristic pathologic features of PanNET have been revealed year by year.

PanNET include both PanNET associated with a functional syndrome (functional PanNET) or those associated with no distinct clinical syndrome (nonfunctional PanNET) [3–6]. Nonfunctional PanNET are the most common but they do not usually produce specific symptoms and are therefore considered clinically to be nonfunctional tumors, but they produce and frequently even secrete small amounts of pancreatic polypeptide, chromogranin A, neuron-specific enolase, calcitonin, neurotensin, and other peptides [4,5,7–9]. Gastrinoma and insulinoma are the two most common functional PanNET, but there are also various kinds of rare functional PanNET (rare PanNET) [3–6], including glucagonomas, vasoactive intestinal peptide-releasing tumors (VIPomas) (Verner–Morrison syndrome, pancreatic cholera, watery diarrhea, hypokalemia, and achlorhydria [WDHA] syndrome) and somatostatinomas (Table 135.1) [3–7,9]. Each of the established rare PanNET syndromes is associated with a distinct clinical syndrome reflecting the actions of the secreted excess hormone.

## Clinical Features

Gastrinoma, insulinoma, and nonfunctional PanNET represent over 90% and other rare PanNET less than 10% of all PanNET [4,7]. Rare but well-known PanNET include glucagonomas, VIPomas, and somatostatinomas whose syndromes are established. Rare and lesser-known tumors include PanNET that secrete calcitonin, renin, luteinizing hormone, erythropoietin, and insulin-like growth factor II whose status is unclear as to whether they represent a specific syndrome because of the small numbers of cases (Table 135.1) [3–5,7,9–11].

The majority of patients with rare PanNET have liver metastases at initial diagnosis (40–90%). Somatostatinomas can occur in the pancreas or upper small intestine; however, the duodenal somatostatinomas are rarely associated with a functional clinical syndrome [4,10,12]. In addition to somatostatinomas, a number of the other rare PanNET also occur in extrapancreatic locations (Table 135.1).

The average age at diagnosis is estimated to be 50–55 years, with equal gender distribution. Patients with malignant tumors may present with mixed syndromes or tumors may change clinically over time. The most frequent familial condition associated with rare PanNET is multiple endocrine neoplasia type 1 (MEN1). Glucagonomas occur in 3% of MEN1 patients, VIPomas in 3%, and GRHomas (secreting growth hormone-releasing hormone) and somatostatinomas in less than 1% [13,14]. Somatostatinomas are seen in up to 10% of patients with von Recklinghausen disease (neurofibromatosis type 1) but in almost all cases they are not associated with a functional syndrome [7,12,13].

**Table 135.1** Rare pancreatic neuroendocrine tumors.

| Name | Biologically active peptide(s) secreted | Estimated incidence (new cases/$10^6$ population/year) | Tumor location | Malignant (%) | Associated with MEN1 (%) | Main symptoms/signs |
|---|---|---|---|---|---|---|
| Glucagonoma | Glucagon | 0.01–0.1 | Pancreas (100%) | 50–80 | 1–20 | Rash (67–90%); glucose intolerance (38–87%); weight loss (66–96%) |
| VIPoma | Vasoactive intestinal peptide | 0.05–0.2 | Pancreas (90%, adult); other (10%, neural, adrenal, periganglionic) | 40–70 | 6 | Diarrhea (90–100%); hypokalemia (80–100%); dehydration (83%) |
| Somatostatinoma | Somatostatin | Rare | Pancreas (55%); duodenum/jejunum (44%) | >70 | 45 | Diabetes mellitus (63–90%); cholelithiases (65–90%); diarrhea (35–90%) |
| GRHoma | Growth hormone-releasing hormone | Unknown | Pancreas (30%); lung (54%); jejunum (7%); other (13%) | >60 | 16 | Acromegaly (100%) |
| ACTHoma | ACTH | Rare | Pancreas (4–16% all ectopic Cushing) | >95 | Rare | Cushing syndrome (100%) |
| PanNET causing carcinoid syndrome | (Serotonin; tachykinin) | Rare | Pancreas (<1% all carcinoids) | 60–88 | Rare | Carcinoid syndrome |
| PanNET causing hypercalcemia (PTHrpoma) | PTHrp; others unknown | Rare | Pancreas (rare cause of hypercalcemia) | 84 | Rare | Abdominal pain due to hepatic metastases, symptoms due to hypercalcemia |
| PanNET secreting calcitonin | Calcitonin | Rare | Pancreas (rare cause of hypercalcitonemia) | >80 | 16 | Diarrhea (50%) |
| PanNET secreting renin | Renin | Rare | Pancreas | Unknown | No | Hypertension |
| PanNET secreting luteinizing hormone | Luteinizing hormone | Rare | Pancreas | Unknown | No | Anovulation, virilization (female); reduced libido (male) |
| PanNET secreting erythropoietin | Erythropoietin | Rare | Pancreas | 100 | No | Polycythemia |
| PanNET secreting IGF-II | Insulin-like growth factor II | Rare | Pancreas | Unknown | No | Hypoglycemia |

## Prognosis and Survival

Most rare PanNET present with metastatic disease and patients' survival time is determined by the growth of the tumor rather than the hormone excess state. Five-year survival for the group with advanced disease is 29–45% [3,4,6,7]. All of the survival or prognostic data on the individual rare PanNET come from retrospective studies and in recent studies their results are often included in noninsulinoma or nongastrinoma series that include nonfunctional PanNET. These studies demonstrated tumor Ki-67 index ≥62%, presence of lymph node metastasis, presence of cytokeratin-19 staining, and various molecular features that were associated with a poor prognosis [4,15].

## Diagnosis

Rare PanNET characteristically present with the symptoms of the specific hormone excess state, and in most cases present late in the disease course when advanced disease is already present [4,6,7]. In a few of patients with a rare PanNET, a second functional syndrome may develop over time. Therefore, the diagnosis of all rare PanNET requires the demonstration of an inappropriate elevation of the specific serum hormones combined with clinical and/or laboratory evidence of oversecretion of the appropriate hormone [3–5,16,17]. The diagnosis of functional rare PanNET requires clinical evidence of hormonal overexpression and is not based solely on immunohistochemical results [3–5,16,17].

General markers such as serum chromogranin A also support the presence of a neuroendocrine tumor, and may be helpful for monitoring during the disease's course [3,5,17,18].

All biochemical tests should be performed at first visit. PanNET causing Cushing syndrome should be suspected from the clinical examination and history, and the diagnosis established by performing 24-hour urinary cortisol determinations, midnight plasma or salivary cortisol assessments, and dexamethasone suppression tests as needed [9,17].

## Tumor Localization

Tumor localization studies are important in all patients with rare PanNET. Tumor localization studies are necessary to determine whether surgical resection is indicated, to localize the primary tumor, to determine the extent of the disease and whether metastatic disease to the liver or distant sites is present, and to assess changes in tumor extent with treatments. All aspects of their management require knowledge of tumor extent. It is important to know that the majority of all pancreatic functional tumors except insulinomas are malignant. Accurate localization of the tumor can result in complete surgical resection with cure of PanNET (10–40%).

Numerous localization studies have been recommended, including conventional imaging studies (computed tomography [CT], magnetic resonance imaging [MRI], ultrasonography [US]), selective angiography, SASI test, SRS, and endoscopic ultrasonography (EUS), in addition to various intraoperative localization methods including intraoperative ultrasonography (IOU).

Most prospective studies show that the sensitivity of conventional imaging studies for localizing the primary tumor is 10–50%, angiography 20–50%, and SRS 30–70% [19]. The use of SRS changes management in 15–45% of patients with PanNET. For SRS and all conventional studies, tumor size is an important variable and tumors smaller than 1 cm are missed in 50% or more cases. The combined use of multidetector computed tomography (MDCT) scanning or MRI and SRS is always recommended. Conventional imaging studies suggesting vascular or tissue invasion may provide important information on whether surgical resection is contraindicated.

If measurement of target hormone is easy accessible, the SASI test is the most reliable approach for tumor localization. The SASI test was first described for localization of gastrinoma, and has gradually proved useful for the localization of other functional PanNET [2,20–22]. At the time of abdominal arteriography, secretagogue is injected into the splenic artery, the gastroduodenal artery, and the superior mesenteric artery. Then 2 mL blood samples are drawn from the hepatic vein through a catheter inserted via the femoral vein, before and 20, 40, and 60 seconds after the injection of secretagogue to detect the change in hormone levels in hepatic venous blood. When the rise in hormone levels at 40 seconds after injection is significantly higher than the measurement errors, the artery is diagnosed as a feeding artery of the tumor. Functioning tumor is then located in the feeding area of the identified feeding artery.

Functional localization studies are not limited by tumor size but are somewhat invasive. Prospective studies of the metastatic liver disease from a malignant PanNET showed that CT and US could detect their presence in 30–80% of patients with metastases, MRI and angiography in 50–85%, and SRS in 70–95% [23]. IOU should be routinely used to assess and identify PanNET [24].

EUS is particularly sensitive for PanNET; however, its ability to detect small duodenal tumors is controversial. Hence EUS is not universally recommended as a first-line procedure in the investigation of rare PanNET. It

may be used in circumstances where MDCT, MRI, and SRS are inconclusive, especially preoperatively. However, in patients with rare PanNET presenting with lymph node metastasis, EUS is rarely necessary. EUS may be helpful in patients with large or aggressive tumors define to more clearly the tumor involvement where surgery is considered.

Insufficient data are available to recommend positron emission tomography (PET)/CT methods on a routine basis, its use remains investigational, and its availability is limited. If results with the earlier recommended imaging are unclear or negative in a patient with rare PanNET, $^{68}$Ga-labeled somatostatin analog PET should be considered with performance by an experienced center.

A number of studies have demonstrated that PET, especially with $^{68}$Ga-labeled somatostatin analogs (DOTA-TOC [DOTA-Tyr-octreotide], DOTA-TATE [DOTA-Tyr-octreotate], DOTA-NOC [DOTA-Nal-octreotide]) when combined with CT ([$^{68}$Ga]DOTA-TOC PET/CT, for example), has high specificity and is more sensitive that SRS or other modalities [25–28]. At present it is not available in many centers and the exact place in the localization algorithm where it should be used has not been clearly defined.

Standard PET with [$^{18}$F]fluoro-2-deoxy-D-glucose (FDG-PET) is not efficient in detecting well-differentiated tumors but may have some value in the detection of aggressive poorly differentiated pancreatic neuroendocrine carcinomas [7]. Other examinations that may be useful are [$^{18}$F]DOPA-PET or [$^{11}$C]-5-HTP-PET if available and costs are affordable.

## Surgical Treatment

The best treatment for rare PanNET is curative surgical resection. This needs to be performed before liver metastasis develops. Indications for surgery depend on clinical symptom control, tumor size, location, extent, malignancy, and metastatic spread [3,4,7,24,29]. Curative surgery should be indicated whenever possible, even in the presence of metastatic disease, including resectable metastatic disease to the liver and when the patient can tolerate the surgery[3,4,7,24,29]. The types of surgery include pancreaticoduodenectomy, distal pancreatectomy, tumor enucleation, and enucleation in combination with resection depending on the location of the primary tumor.

Curative surgery is always recommended following optimal symptomatic control of the clinical syndrome by medical treatment. Owing to the usually large size of the tumor and the high prevalence of lymph node metastasis in rare PanNET, curative surgery should include pancreatic resection with lymph node dissection through laparotomy. In the case of localized lymph node metastasis or more extensive disease spread, surgery should also be considered if at least 90% of the gross tumor can be resectable.

Laparoscopic resection is currently not recommended because lymphadenectomy and careful inspection for invasion and metastases are needed [7]. Surgery for lymph node metastasis may be performed during treatment of the primary tumor. Cytoreductive surgery should be considered when the metastatic disease is localized or more than 90% of the tumor load can be resected, which may help to improve hormonal control and perhaps extend survival.

## Medical Treatment

Several decades ago, the major cause of death of patients was the untreated effects of the hormone excess state; therefore, it is important to control the hormone levels [4,7], which can be achieved with the combined use of medical, surgical, and radiologic therapies.

Both somatostatin analogs and interferon have been shown to be effective in the control of symptoms in rare PanNET [30]. Somatostatin analogs are an effective treatment in the control of symptoms of rare PanNET, especially in patients with VIPomas, GRHomas, and glucagonomas [30]. Long-acting somatostatin analogs are also reported to be effective in controlling the excess hormone secretion in some cases of somatostatinomas. If somatostatin analogs are ineffective or lose efficacy in controlling the hormone excess state, treatment with interferon may be effective at controlling the symptoms, either alone or in combination with somatostatin analogs.

Somatostatin analogs also have antigrowth effects on PanNET. For the control of symptoms, somatostatin analog therapy should be initiated with the short-acting substance for 1–2 days with titration according to clinical response. The patient can then be transferred to slow-release lanreotide-SR i.m., lanreotide autogel s.c., or octreotide long-acting release i.m. every 4 weeks [31]. Likewise, interferon treatment may help control symptoms of the hormone excess state in rare PanNET, although it has been less well studied than the use of somatostatin analogs. It is reported to be effective in VIPomas not responding to somatostatin analogs and also in isolated cases when combined with somatostatin to control the symptoms of a rare PanNET, which with somatostatin treatment alone there was inadequate symptom control; however, this requires confirmation in a controlled manner [32].

Prospective studies of mammalian target of rapamycin (mTOR) inhibitors with or without octreotide and

tyrosine kinase inhibitors have shown significant prolongation of the survival time of patients with gastrinoma. New cytotoxic chemotherapy with temozolomide and capecitabine has also been reported to be effective.

## Introduction

Neuroendocrine tumors (NET) of the pancreas, duodenum, and biliary tract constitute a rare and heterogeneous group of neoplasms derived from the embryogenetically defined "foregut." Most likely, they originate from pluripotent neuroendocrine stem cells distributed throughout the human body. Traditionally, the term "carcinoids" has been used to define these tumors. Once it became evident that "carcinoids" encompass a unique cluster of tumors with an expansive range of morphologic and biologic characteristics, modern classifications of these neoplasms adopted the terms "neuroendocrine tumor," "neuroendocrine carcinoma," and "neuroendocrine neoplasia" [1].

One of the hallmarks of NET and also of neuroendocrine carcinoma (NEC) is the synthesis and secretion of numerous amines and peptides capable of inducing distinct clinical syndromes. In addition to tumor-specific hormones including insulin and gastrin, proteins such as neuron-specific enolase (NSE), chromogranin A (ChA), pancreastatin, and synaptophysin—commonly expressed in neuroendocrine cells—are produced. Not only do such proteins serve for immunohistochemical diagnosis of NET, they have also been recognized as clinically useful tumor markers in clinical practice. Additional characteristic features of NET encompass specific amine uptake mechanisms and cell surface peptide receptors, namely for somatostatin, that have utility in diagnosis and treatment [2,3].

Foregut NET can occur sporadically or as a component of the genetically determined autosomal dominant syndromes multiple endocrine neoplasia type 1 (MEN1) and MEN4, a recently described, very rare type of MEN. In MEN1-associated pancreatic tumors and in up to 40% of sporadic tumors, loss of the wild-type *MEN1* (MEN1 tumor suppressor gene, menin) allele located on 11q13 can be identified [4]. In cases of heredity, multicentric tumor manifestation should be expected.

## Neuroendocrine Tumors of the Pancreas

Of the NET originating from the pancreas, 65–80% are hormonally active. Although the majority of such tumors secrete insulin or gastrin, less commonly secretion of vasoactive intestinal polypeptide (VIP), glucagon, growth hormone-releasing factor (GRF), or somatostatin can also be observed. Particularly rare are serotonin-producing tumors, with fewer than 150 cases documented in the literature [5]. Tumor nomenclature depends upon the hormone predominantly secreted, namely: insulinoma, gastrinoma, VIPoma, glucagonoma, GRFoma, or somatostatinoma.

### Insulinomas

Insulinomas represent 60% of all pancreatic neuroendocrine tumors (PanNET). More than 90% of such tumors are benign lesions measuring 1–2 cm in size (Fig. 136.1). Approximately 10% of insulinomas are multicentric, most of them associated with MEN1, and 10% are malignant. Malignant insulinomas metastasize to the regional lymph nodes and liver. Localized or diffuse islet cell hyperplasia as a very rare cause of hyperinsulinemic hypoglycemia has been reported in adults and in children (nesidioblastosis). The clinical hallmark of the disease is neuroglycopenia, followed fairly regularly by catecholaminergic responses.

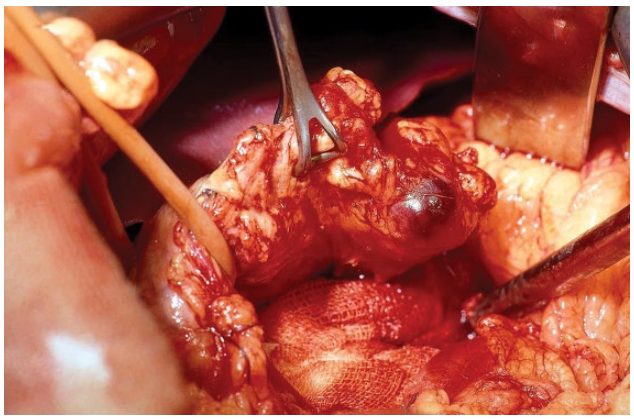

**Figure 136.1** Intraoperative finding of a 1 cm insulinoma at the tail of the pancreas.

The diagnosis of insulinoma is based on following criteria:

- the signs and symptoms of hypoglycemia during periods of fasting or exertion
- documented blood glucose levels near or below 40 mg/dL (<2.2 mmol/L)
- concomitant insulin levels of ≥6 μU/mL (43 pmol/L)
- elevated C-peptide levels (≥0.2 nmol/L)
- absence of sulfonylurea in the plasma.

As the most reliable investigative test, a 72-hour fast has been traditionally considered. In the presence of insulinoma, 80% of the patients will become symptomatic within 24 hours of fasting. The introduction of upgraded assays for insulin, proinsulin, and C-peptide might supersede the standard full 72-hour fast by a 48-hour fast [6]. Although rarely required, provocative tests (tolbutamide test, glucagon test, calcium infusion test) can be of help in cases of anomalous or equivocal standard test results. Once the biochemical diagnosis of an insulinoma has been established, search for adenopathies typical for MEN1 and meticulous evaluation of the family history must be carried out. The diagnosis of MEN1-associated insulinoma can be confirmed by DNA analysis and by proof of menin gene mutations most commonly detected in exons 2, 7, 9, and 1.

#### Localization Studies

The striking advantage of preoperative localization of PanNET has generally been recognized, although some authors suggest that skilled surgical exploration utilizing intraoperative ultrasonography (IOU) is sufficient for a successful outcome [7,8]. In the presence of newer imaging techniques and refinement of standard radiologic procedures, most lesions can be accurately identified prior to surgery.

The sensitivity of transabdominal ultrasonography (US) depends strongly on the experience of the examiner and has been reported more recently to be around 60–70%. For some authors, this is the only preoperative imaging modality. Despite improvements in computed tomography (CT) through the introduction of dynamic contrast-enhanced techniques coupled with 5 mm "cuts," the sensitivity does not exceed 40–65% [9]. In single series, encouraging results have been reported with T1-weighted fat-suppressed and dynamic gadolinium-enhanced magnetic resonance imaging (MRI) [10]. For endoscopic ultrasound (EUS) imaging of PanNET, overall sensitivity and accuracy of up to 95% have been reported [11]. Either as a single technique or in combination with fine-needle aspiration biopsy [12], EUS has emerged as one of the most valuable modalities in the imaging of PanNET. Somatostatin receptor (SR)-based imaging is not very effective in the radiologic interrogation of insulinomas since most of the lesions do not express SR subtype 2, necessary for binding of the radiolabeled octreotide. Owing to high monoamine oxidase A levels in PanNET, promising results were achieved using [$^{11}$C]harmine-labeled tracers [13]. Glucagon-like peptide-1 receptor imaging ([$^{111}$In]diethylenetriaminepentaacetic acid [DTPA]-exendin-4 single-photon emission computed tomography [SPECT]/CT) has recently been reported as an effective second-line imaging modality for patients with negative results on standard imaging.

Grant et al. [14] and Norton et al. [15] were among the first to emphasize the immense usefulness of IOU in the management of PanNET. The method not only allows the identification of the lesion, but also provides additional information concerning the relation of the tumor to the pancreatic duct, the common bile duct, the portal vein, and the superior mesenteric vessels. Particularly for tumors located within the uncinate process, exposure of the complete gland is crucial.

Assignment of insulinomas to regions of the pancreas is possible by selective transhepatic portal venous sampling for insulin. The method regionalizes the lesion to a certain part of the pancreas; however, it does not determine the specific location. Since this highly invasive technique is extremely demanding, it is reserved mainly for reoperations and MEN1-associated tumors [16]. Further improvement of tumor regionalization can be achieved by selective arterial calcium stimulation and blood sampling for insulin gradients in the hepatic veins [17], a technique originally reported by Imamura et al. for regionalization of gastrinomas [18].

#### Perioperative Management of Serum Glucose

The main goal of the preoperative preparation is to avoid severe hypoglycemia. Intravenous administration of glucose is recommended during the night before surgery. Patients suffering from severe hypoglycemia may be

treated with diazoxide or octreotide. Intraoperatively, blood glucose monitoring should continue. Increases in blood sugar levels may confirm successful insulinoma removal. More reliable confirmation concerning completeness of surgery can be gained by insulin measurement with intraoperative rapid insulin assay [19]. Shortly after insulinoma removal, transient hyperglycemia usually occurs. Since glucose levels rarely exceed 200 mg/dL, no specific treatment is necessary.

#### Surgical Management

In patients with tumors expressing malignant features or in the presence of contradictory imaging results, a standard surgical approach to the pancreas and exploration of the liver for metastases, meticulous exposure of the whole organ including the uncinate process, allowing palpation and visual assessment of anterior and posterior pancreatic surfaces, should be carried out [20]. Even if the lesion is already visible, IOU should be performed to assess the relationship of the tumor to the surrounding structures. Regardless of the specific site of the tumor, enucleation or limited parenchyma-sparing resection should be attempted as the "gold standard" for the surgical treatment of benign insulinoma. Blunt dissection close to the capsule of the tumor with the aim of avoiding injury to the main pancreatic duct is recommended in order to prevent fistula formation. The parenchymal defect can be closed or left opened. Local application of sealants can lower the incidence of postoperative fistulas, traditionally reported with an incidence of 13–40%, irrespective of the management of the enucleation cavity [21]. In addition, perioperative somatostatin administration may contribute to a reduction of pancreatic complications.

Laparoscopic resection of PanNET is feasible and safe, particularly in left-sided lesions [22,23]. The majority of patients with sporadic insulinomas localized on imaging and selected patients with MEN1-associated insulinomas nowadays undergo laparoscopic resections [24,25]. The rate of fistulas, however, remains comparable to that in open surgery. If the tumor is not identifiable, blind resections cannot be recommended. Rather than performing a blind distal pancreatectomy, the procedure should be stopped and the patient referred to a center with the possibility of advanced localization techniques and adequate surgical experience [26]. Patients with insulinomas who are not fit for surgery and not manageable conservatively may be considered for EUS-guided radiofrequency ablation using a novel needle electrode [27].

Larger lesions within the body or tail are managed by distal pancreatectomy with preservation of the spleen, if technically feasible. Very rarely seen large tumors within the head of the pancreas, or tumors located deep within the parenchyma and in close proximity to the pancreatic duct, require partial cephalectomy or even pancreaticoduodenectomy [28,29]. For tumors located within the middle portion of the gland that cannot be enucleated, central segmental pancreas resection may be the appropriate technique [30].

Insulinomas associated with the MEN1 syndrome are invariably multifocal and scattered throughout the whole pancreas. Although the number of well-documented patients is rather small, distal subtotal pancreatectomy with splenic preservation and enucleation of any tumors in the head and/or uncinate process appears to be the best procedure [31–34]. Peripancreatic lymphadenectomy is recommended in patients with concomitant gastrinoma or suspected malignancy [35].

### Gastrinoma

Zollinger–Ellison syndrome (ZES) accounts for the clinical manifestation of gastrinomas. Although virtually all gastrinomas derive from the duodenum, some patients present with additional pancreatic lesions. In 60–90% of cases, gastrinomas can be found within the "gastrinoma triangle," a region defined by the junction of the cystic and common bile duct posteriorly, the junction of the second and third portions of the duodenum inferiorly, and the junction of the pancreatic neck and body medially. Although subject to controversial debate, the existence of primary lymph node gastrinomas has been postulated [36]. The majority of the duodenal gastrinomas are multicentric and only few millimeters in size. Of them, approximately 40% are linked to the MEN1 syndrome [37]. In contrast to insulinomas, sporadic gastrinomas are frequently malignant and larger than 2 cm in diameter. Depending upon primary tumor size, liver metastases in combination with paraduodenal and peripancreatic lymph node metastases can be found at the initial diagnosis in up to 70% of patients.

#### Localization Studies

Sensitivities of standard imaging techniques (US, CT, MRI) has been reported to be between 40 and 70% for pancreatic gastrinomas 1–3 cm in size [38]. EUS provides 75% sensitivity for pancreatic gastrinomas and 50% sensitivity for duodenal wall lesions [39]. For the majority of localized gastrinomas and for metastatic disease, SR-based imaging utilizing positron emission tomography (PET)/CT technology (e.g., [$^{68}$Ga]-1,4,7,10-tetraazacyclododecane-4,7,10-tricarboxymethyl-1-yl-acetyl-D-Phe$^{1}$Try$^{3}$-octreotide ([$^{68}$Ga]DOTA-TOC) PET/CT) accounts for the single most accurate localization method [40]. In order to localize preoperatively gastrinomas that remained undetectable by standard imaging techniques, Imamura et al. developed the selective arterial secretagogue injection (SASI) test with secretin or calcium [18]. With this test, over 90% of gastrinomas can be accurately localized [41].

### Surgical Management

Surgical exploration with an attempt at tumor resection is recommended for all sporadic gastrinomas in the absence of multiple nonresectable liver metastases [42]. Compared with medical treatment, surgical tumor removal significantly reduces the risk of metachronous liver metastases. Surgical approaches can be guided by the SASI test [41]. If the test result indicates a tumor within the duodenum only, 80% of patients with sporadic gastrinomas might be successfully treated with resection of the single tumor and periduodenal lymphadenectomy. The remaining 20% typically have multiple duodenal gastrinomas or a combination of duodenal and pancreatic tumors. In patients presumed to have a sporadic gastrinoma in whom no preoperative SASI test was carried out, pancreatic and duodenal exploration are necessary. IOU, careful palpation, and endoscopic transillumination of the duodenal wall are extremely valuable aids. For larger gastrinomas in the head of the pancreas without duodenal tumor, pylorus-preserving pancreatoduodenectomy is recommended. Smaller gastrinomas may be locally resected. In the case of duodenal and pancreatic lesions, pancreatoduodenectomy represents the appropriate therapy. Distal pancreatectomy with regional lymphadenectomy is the treatment of choice for gastrinomas within the body or tail of the pancreas.

For MEN1-associated gastrinomas, recommendations for surgery are much more controversial concerning timing and extent of the procedure [43,44]. Whereas some authors are in favor of less aggressive surgery encompassing spleen-saving distal pancreatectomy, enucleation of NET within the head and uncinate process, duodenotomy and excision of NET, and regional lymph node dissection, others propose more aggressive duodenopancreatic resections in order to achieve durable eugastrinemia [45,46].

Liver metastases are the main prognostic determinant in patients with gastrinomas. No uniform guidelines for the management of tumors in advanced metastatic stage exist. Treatment options are the same as those for other NET metastasized to the liver or primary neuroendocrine tumors of the liver (see later) [47].

## Nonfunctioning Tumors

Patients with nonfunctioning (NF) (non-secreting) PanNET have no clinical symptoms related to hormonal hyperfunction and negative biochemistry for peptides secreted by the pancreatic islets. Immunohistochemically, however, expression of hormones in tumor cells can be revealed. The reported incidence of NF PanNET is 15–53% [48]. In the experience of surgical centers, the majority of such tumors are malignant. As in functioning tumors, the lesions can occur sporadically or within the MEN1 syndrome. At the time of diagnosis, most symptomatic patients are between 40 and 60 years old, presenting with abdominal pain, jaundice, and weight loss. Tumors located within the body or the tail of the pancreas may be clinically silent yet palpable as a bulky mass. In the past, the majority of tumors were diagnosed at an advanced stage. Nowadays, however, small NF NET are increasingly diagnosed incidentally on imaging for reasons unrelated to the pancreas.

Upon diagnosis, differentiation from the pancreatic adenocarcinoma must be considered. In general, patients with NF NET are in a better clinical condition. Synchronous metastases in the liver and/or lymph nodes are frequently present. In our experience, [$^{68}$Ga]DOTA-TOC PET/CT is the most valuable imaging technique for staging well-differentiated and moderately differentiated NF NET (Fig. 136.2). For higher grade tumors or poorly differentiated neuroendocrine carcinomas, [$^{18}$F] fluoro-2-deoxy-D-glucose (FDG) PET/CT is a more accurate imaging modality.

An aggressive surgical approach is the only therapy with potentially curative intent. Resection rates of 26–79% with an overall 5-year survival of 30–80% have been reported [49]. For MEN1-associated NF PanNET, no uniform suggestions exist [43]. Whereas some authors suggest resection of all tumors regardless of the size as soon as visualized, others postulate that with consideration of risk–benefit ratios, surgery may not be necessary in tumors less than 2 cm in diameter [50]. Controversy also exists regarding the management of sporadic small (<2 cm) NF NET; whereas in the opinion of some groups these tumors can be treated conservatively, others recommend surgical resection since both liver metastases and lymph node metastases have been reported in single patients with NF NET <2 cm in size [51]. Another topic under ongoing debate is the resection of primary NF PanNET in the setting of unresectable liver metastases. Although the quality of the evidence in the existing reports in favor of primary tumor resection is rather poor, the resectional approach can be justified in selected patients with tumors amendable for distal pancreatectomy and synchronous liver metastases suitable for interventional or medical treatment [52]. Most recently, peptide receptor radionuclide therapy has been introduced in the multimodal management of advanced PanNET as a potential tool for downstaging in patients with primarily nonresectable tumors [53,54].

# Neuroendocrine Tumors of the Duodenum

Histopathologically, five types of duodenal NET can be discriminated, namely duodenal gastrinomas, somatostatinomas, nonfunctioning serotonin-, gastrin-,

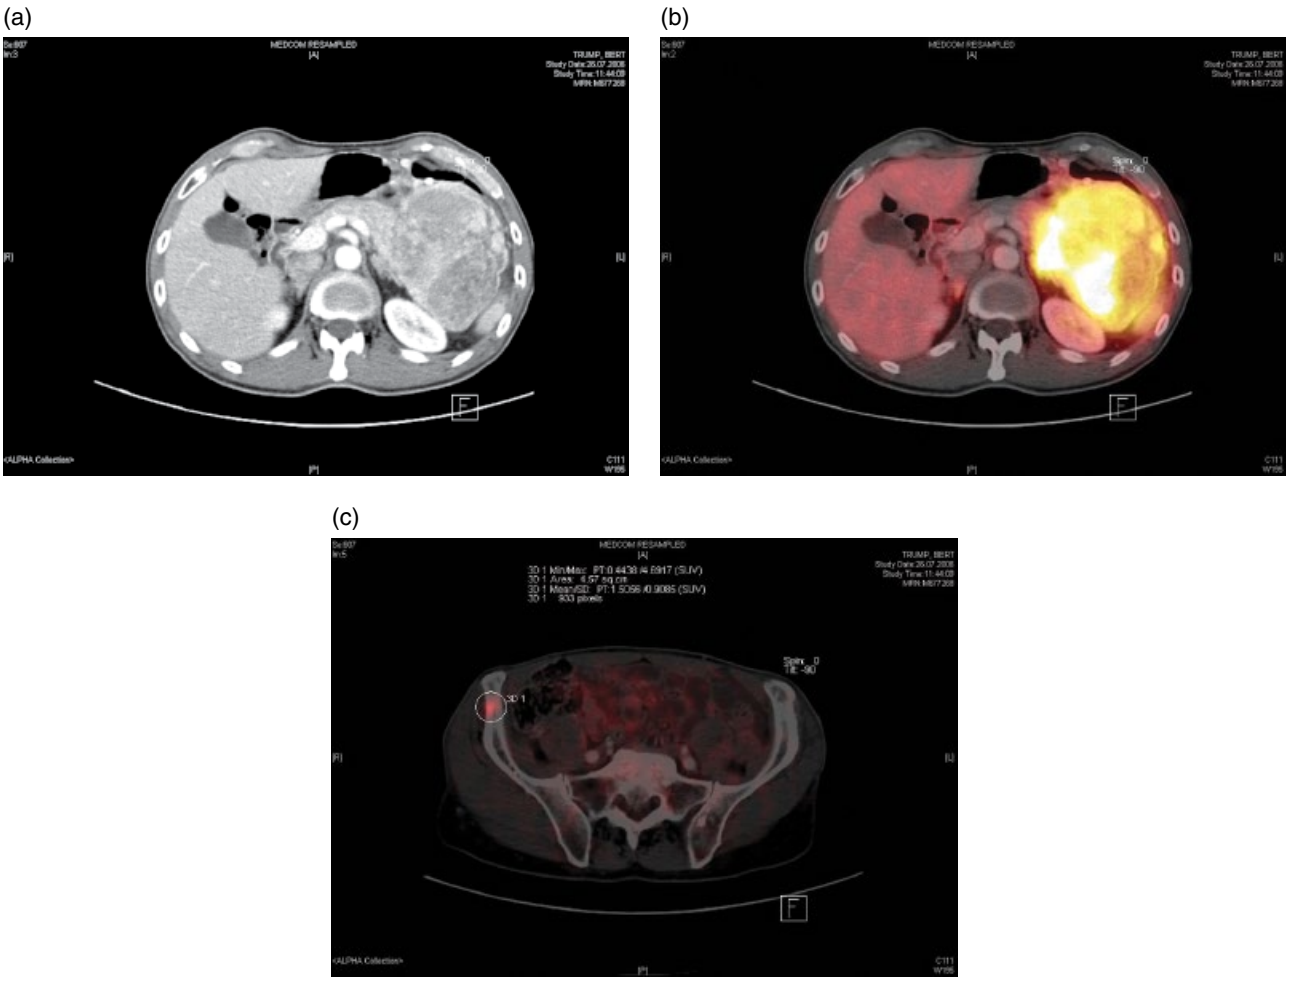

**Figure 136.2** Preoperative imaging studies in a patient with an NF NET of the pancreas. (a) On CT scan, a 20 cm diameter tumor in the left abdomen is shown. (b) [$^{68}$Ga]DOTA-TOC PET/CT demonstrates significant radionuclide uptake in the left upper abdomen. (c) Additionally, pathologic uptake, indicating a metastasis, is demonstrable within the right ilium. This finding was not seen on CT scan.

or calcitonin-producing tumors, poorly differentiated and predominantly ampullary NEC, and duodenal gangliocytic paragangliomas [5,55,56]. Approximately 30% of duodenal NET are related to von Recklinghausen disease (neurofibromatosis type 1 [NF1]), MEN1, and/or pheochromocytomas [57]. The majority of duodenal NET express ChA and NSE. In contrast to other locations, NET originating from the duodenum were found to be the only neuroendocrine lesions expressing the peptide marker xenin [58]. Based on the experience with a heterogeneous group of 99 NET of the duodenum, Burke et al. [59] determined three pathologic characteristics of the primary tumor as independent risk factors for metastatic spread: involvement of muscularis propria, size greater than 2 cm, and the presence of mitotic figures.

Gastrinomas located in the first and second portions of the duodenum account for approximately two-thirds of all duodenal NET. These tumors occur either sporadically or as a component of the MEN1 syndrome. Both sporadic and hereditary tumors are generally small (<1 cm), but multifocal in cases of familial determination. Although of small size and growth limited to the mucosa and submucosa, duodenal gastrinomas frequently present with significant lymph node metastases [3,60]. In contrast to pancreatic gastrinomas, distant metastases rarely occur in sporadic and hereditary duodenal tumors [44,55].

Duodenal somatostatinoma, located either within the ampulla of Vatar or periampullary, account for 15% of all duodenal NET. Insular growth pattern and psammoma body formation are histologic hallmarks of these tumors. In case of muscularis propria infiltration, malignancy must be assumed. Tumor size and mitotic activity have no correlation with metastatic potential [61]. Somatostatinoma syndrome, typical for PanNET expressing somatostatin, does not occur in these duodenal tumors. Association with NF1 and bilateral pheochromocytoma has been documented [62]. Owing to the

unpredictable behavior of ampullary or periampullary NET, a radical surgical approach, most frequently in the form of a Whipple procedure, is recommended [63].

NF duodenal NET encompass lesions with both favorable and less favorable prognoses. Whereas well-differentiated tumors confined to submucosa behave benignly, advanced metastases are frequently associated with poorly differentiated neoplasms. Gangliocytic paragangliomas represent a unique subgroup of duodenal NET located within the para-ampullary region, and despite a tumor size of >2 cm and infiltration of the muscularis propria, they generally have a benign clinical course.

With the exception of ampullary/periampullary NET, duodenal NET smaller than 1 cm and in the absence of signs of invasion of the muscularis propria and of metastases may be excised locally by endoscopic resection with or without submucosal saline injection [64–67]. In this regard, EUS proved to be of extremely high value. It should be stressed, however, that lymph node metastases can be found also in tumors less than 1 cm in size [68]. For tumors between 1 and 2 cm or larger, local full-thickness excision through an open transduodenal approach or segmental duodenal resection with a side-to-side duodenostomy and regional lympadenectomy is recommended in order to achieve complete and curative resection [44,69].

## Neuroendocrine Tumors of the Liver

Despite the liver being the predominant site of neuroendocrine tumor metastases, primary NET arising within the liver are rare. In a study of 13,715 carcinoid tumors accumulated by the National Cancer Institute in Bethesda, MD, over a 50-year period, only 45 primary hepatic tumors were documented [2]. Prior to the assumption that a hepatic NET presents a primary lesion, a meticulous search for extrahepatic tumor manifestation is pivotal for the effective management of such patients [70,71].

Patients with these tumors present with nonspecific hepatic clinical syndromes such as biliary obstruction or upper abdominal discomfort. In contrast to neuroendocrine liver metastases, flushing, diarrhea, bronchial construction, and carcinoid heart syndrome, which are pathognomonic for the classic carcinoid syndrome, will be found in only about 5% of cases [2]. On transabdominal US, the tumor appears as a hyperechoic lesion; nevertheless, the appearance on radiologic imaging is not characteristic [72]. The treatment strategy comprises several curative and palliative options including surgery, locally destructive techniques such as radiofrequency or laser-induced thermoablation, transarterial embolization alone or with chemotherapy, selective internal radiotherapy, somatostatin analogs, targeted medical therapy, and peptide receptor radionuclide therapy. In contrast to the poor overall 5-year survival of 18.4% reported in early studies [2], a more radical surgical approach including advanced hepatic resections or liver transplantation in selected cases and multimodal treatment concepts achieved 3-year disease-free survival rate of more than 75% [73,74].

## Neuroendocrine Tumors of the Extrahepatic Biliary Tract

These very unusual neoplasia account for 0.2–2% of all gastrointestinal NET [2]. In approximately 60% of patients, the tumor develops within the common bile duct [75–77]. Further locations are the perihilar region (28%), cystic duct (11%), and common hepatic duct (3%) [76]. Unlike adenocarcinomas of the extrahepatic biliary system, biliary NET predominantly affect female patients younger than 50 years of age. The symptom most frequently seen is painless jaundice with or without pruritus. The diagnostic spectrum includes US, CT, magnetic resonance cholangiopancreatography, endoscopic retrograde cholangiopancreatography, and percutaneous transhepatic cholangiography. For tumor staging purposes, SR-based imaging provides valuable information. As with other tumors originating from the biliary system, accurate preoperative diagnosis remains difficult, particularly regarding delineation from cholangiocarcinoma [78]. Upon microscopic examination, the tumors present with a trabecular or nesting pattern with occasional tubule formation, and cells expressing ChA, synaptophysin, serotonin, pancreatic polypeptide, and/or somatostatin [79]. Whereas local invasion is not common, metastatic lymph node involvement and liver metastases can be found in 30% of patients [75,77,80].

An aggressive surgical approach provides an overall favorable long-term prognosis. In early tumor stages and in the absence of metastases, 5-year survival of 60–100% has been documented [2,77,79]. The extent of resection depends mainly upon the size, the stage, and the location of the tumor. Common bile duct resection and Roux-en-Y hepaticojejunostomy represent the standard treatment of choice for lesions within the central portion of the common bile duct. For tumors affecting the hepatic duct bifurcation, resection of the bifurcation, in some cases in combination with partial hepatectomy, is necessary. Tumors of the distal part of the common bile duct require either segmental bile duct resection or partial pancreaticoduodenectomy (Whipple procedure). Extensive hilar lympadenectomy is a mandatory part of the procedure.

## Neuroendocrine Tumors of the Gallbladder

Approximately 0.2% of all NET of the gastrointestinal tract originate from the gallbladder [5]. They usually affect females, causing right upper abdominal discomfort and jaundice. As in NET of the extrahepatic biliary tree, the diagnosis is frequently made first after surgery for presumed cholecystitis or adenocarcinoma of the gallbladder. Histologically, the tumor cells are positive for Grimelius staining and ChA, and less commonly for NSE or pancreatic polypeptide [81,82]. Nishigami et al. pointed out that owing to the entirely different prognosis of the lesions, a discrimination between the carcinoid tumors and endocrine cell carcinomas of the gallbladder must be considered [81].Whereas classical carcinoids of the gallbladder virtually never metastasize or grow invasively, endocrine cell carcinoma (atypical carcinoids) exhibit a much more aggressive behavior [81–83]. Clear-cell carcinoid tumors of the gallbladder, either as a sporadic tumor [84] or in association with von Hippel–Lindau syndrome [85], have been reported as a distinctive entity. Immunohistochemical positivity for inhibin was found to be pathognomonic for the genetically determined tumor form [85].

Although laparoscopic resection might be feasible in a small classical carcinoid confined to the wall of the gallbladder [86], the majority of patients, particularly those with endocrine cell carcinoma, require a more radical surgical approach in terms of hepatic resection, removal of the extrahepatic bile duct, and extended hilar lymphadenectomy [83,87]. An overall 5-year survival of approximately 60% has been reported [2].

# Long-Term Outcome After Treatment of Neuroendocrine Tumors of the Pancreas

## 137

## Long-Term Outcome After Treatment of Endocrine Tumors

*Andreas Machens*[1] *and Henning Dralle*[2]

[1] *Department of Visceral, Vascular and Endocrine Surgery, Medical Faculty, Martin Luther University Halle-Wittenberg, Halle (Saale), Germany*
[2] *Department of General, Visceral and Transplantation Surgery, Section of Endocrine Surgery, University Hospital Essen, Essen, Germany*

## Introduction

Pancreatic endocrine tumors (PanNET), representing 1–2% of pancreatic neoplasms, comprise an array of heterogeneous, mostly slow-growing tumors. This wide spectrum ranges from indolent, hormone-secreting, localized, and easily accessible tumors to nonfunctioning, widely metastatic, and surgically less amenable tumors, at various time points on the tumor growth trajectory. These tumors may differ in tumor entity, clinical presentation (symptomatic versus asymptomatic), hormone secretion (functioning versus nonfunctioning), genetic background (sporadic versus hereditary), anatomic location (pancreatic head versus body and tail; anterior versus posterior pancreas), staging (primary tumor size, number and size of lymph node and distant metastases), and grading (differentiated versus poorly differentiated).

Clinical interventions, sometimes due to disparate surgical skills and the patient's physical condition, have varied because of the need to be attuned to the individual situation: enucleation versus limited resection versus extended resection; primary surgery versus reoperation; clear versus involved surgical margins; tumor resectability versus irresectability. Nor have neoadjuvant and adjuvant therapies, employing different agents and regimens, been standardized. Given the longevity of many patients with PanNET, many observation periods were short, differing in duration and the intensity of clinical monitoring. Because treatment must be commensurate with the extent of disease, surgical and nonsurgical patients form selected groups of patients defying standardization of therapy.

Because many series lumped together disparate endocrine tumors, no high-quality outcome studies have been forthcoming for any of these scenarios, leaving univariate risk factors unvalidated. Although some general principles have emerged from institutional series and tumor registries, the role and extent of surgery remain to be delineated for a number of clinical settings.

## Risk Stratification of Pancreatic Endocrine Tumors

### Tumor Staging

Measuring extent of cancer is also relevant to PanNET. In 2006, the European Neuroendocrine Tumor Society (ENETS) developed the first staging system for neuroendocrine tumors (henceforth referred to as the ENETS TNM) from the combined published experience of single centers at the level of the neuroendocrine tumor patient. A competing staging system, derived from a cancer registry database by the International Union Against Cancer, now the Union for International Cancer Control (UICC), in 2010 and now endorsed by both the American Joint Committee on Cancer (AJCC) and the World Health Organization (WHO), followed suit (henceforth referred to as the UICC/AJCC/WHO TNM).

It is noteworthy that the UICC/AJCC/WHO TNM, unlike the ENETS TNM, is the same as for exocrine pancreatic tumors and not meant for high-grade PanNET [1]. As a consequence, tumor definition and stages differ greatly between the ENETS TNM and the UICC/AJCC/WHO TNM staging systems. Of note, the UICC/AJCC/WHO TNM requires information on peripancreatic soft tissue invasion regardless of tumor size, a feature difficult to assess, to distinguish between UICC/AJCC/WHO categories pT2 and pT3.

#### Recurrence-Free Survival

Five-year recurrence-free survival rates in 123 patients with nonmetastatic, surgically resected PanNET [2] were 78, 53, and 33% for AJCC stages I, II, and III ($P < 0.01$) and 100, 70, and 53% for ENETS stages I, II, and III ($P = 0.18$). On excluding patients referred with metastatic recurrence, the 5-year recurrence-free survival rates were 90, 73, and 66% for AJCC stages I, II, and III and 100, 84, and 75% for ENETS stages I, II, and III, with recurrence rates peaking at 2 years after surgery [2].

#### Cancer-Specific Mortality

For a large series of 1072 patients with neoplasms of the endocrine pancreas and at least 2 years of follow-up from eight European centers, cancer-specific mortality was compared between the two TNM staging systems [1]. On Cox regression, the ENETS TNM system allocated patients to four significantly different ($P < 0.001$) and equally populated risk groups, with odds ratios (OR) for death of 16.2 for stage II, 51.8 for stage III, and 161.0 for stage IV compared with stage I. In contrast, the UICC/AJCC/WHO TNM compressed the disease into three differently populated classes, with OR for death of 9.6 for stage II, 9.3 for stage III, and 30.8 for stage IV compared with stage I ($P < 0.001$). Multivariable modeling revealed that curative surgery, TNM staging, and grading effectively indicated cancer-specific death. Although the ENETS and UICC/AJCC/WHO TNM staging systems independently predicted cancer-specific survival, the latter resulted in much larger 95% confidence intervals for each stage. Wider confidence intervals may reflect more limited discriminatory power of the UICC/AJCC/WHO TNM system in patients with PanNET [1].

In a series of 326 patients with sporadic, nonfunctional, surgically resected PanNET, 5-year overall survival rates were 93, 74, and 56% for AJCC stages I, II, and IV and 97, 87, 73, and 56% for ENETS stages I, II, III, and IV [3].

### Tumor Grading

Because the percentage of tumor cells staining positive on Ki-67 immunohistochemistry can be heterogeneous, more substantial tumor samples are needed to facilitate the distinction of low-grade from intermediate-grade tumors. The 2010 WHO grading, based on the mitotic count (<2, 2–20, and >20 mitoses per 10 high-power fields) and the Ki-67 index (<3, 3–20, and >20%), holds important prognostic information, especially in the absence of staging information.

In the largest cohort of patients with PanNET published to date, grading became the second most powerful independent predictor of survival after curative surgery when TNM staging, the previously second most important predictor of death, had been omitted from multivariable modeling [1].

These results were confirmed in a study of 483 patients with PanNET, in which Ki-67 (>20 versus ≤2%; $P = 0.01$) and surgical resection (yes versus no) (hazard ratio [HR] 0.92, $P = 0.001$) were the only independent predictors of survival [4]. Among patients who underwent surgery, high Ki-67 index (HR 10.4, $P = 0.02$) and poor differentiation (HR 8.2, $P = 0.03$) were the only independent predictors of clinical outcome [4].

## Surgical Considerations for Pancreatic Endocrine Tumors

Unlike functional PanNET presenting with signs and symptoms of hormone excess, nonfunctioning PanNET do not produce identifiable symptoms. This is why nonfunctioning PanNET frequently manifest with complaints caused by tumor expansion, invasion, and/or metastatic disease and generally have a graver prognosis. Some clinically "nonfunctioning" tumors synthesize hormones in quantities too low to elicit complaints (e.g., glucagonoma) or hormones unable to produce symptoms in humans (e.g., pancreatic polypeptide).

Because curative surgery determines survival more than tumor stage, the patient's clinical outcome hinges on the feasibility of complete tumor resection.

### Nonfunctioning Tumors

#### Localized Tumors

Although no high-quality data comparing expectant observation with surgical intervention have been forthcoming, pursuing a "wait and see," "first, do not harm" policy for small, nongrowing, benign-appearing tumors may be a viable alternative option in certain patients [5]. This concept is epitomized by a series of 46 patients with asymptomatic sporadic nonfunctioning PanNET <2 cm over a median follow-up of 34 months [6]. In six (13%) patients, a ≥20% increase in tumor size was observed. Median tumor growth was estimated at 0.12 mm per year. No lymph node or distant metastases were seen on serial imaging. Eight (17%) patients underwent surgery for grade 1, node-negative PanNET T1 (seven patients) or T2 (one patient) after a median of 41 months [6].

***Unifocal Tumors*** Localized tumors are easier to cure surgically when they are small, benign, stay clear of large vessels and the bile duct, and involve only the anterior aspects of the pancreas, preferably the body or tail. To develop an effective surgical treatment plan, a thorough clinical workup is essential to settle these important points before the operation and ensure that no additional tumors are missed.

There are basically three surgical techniques, each of which may be adequate depending on the circumstances of the case: tumor enucleation (leaving peritumoral tissue behind); excision (clearing peritumoral tissue together with the tumor); and pancreatic resection, which is bound to vary greatly in extent and scope depending on tumor location and type.

From an oncologic perspective, all three surgical interventions are equally effective as to clinical outcome provided that they clear the pancreatic tumor in its entirety [1,7]. Pancreatic surgery that leaves gross tumor behind is unlikely to benefit the patient. In patients without distant disease, every effort should be made to clear the mesenteric vessels of malignancy.

***Multifocal Tumors*** When additional endocrine tumors are present or the family history is suggestive of hereditary disease, specifically multiple endocrine neoplasia type 1 (MEN1) or von Hippel–Lindau syndrome (VHL), the surgical plan needs to be adjusted accordingly. All endocrine tumors identified need to be considered both individually and in conjunction with one another. Intraoperatively, the pancreas should be mobilized to allow for careful examination of the posterior aspect of the organ.

Owing to the variety of constellations conceivable, multiple tumors are notoriously difficult to standardize, hampering predictions about clinical outcome. A recent series of 60 MEN1 patients from four institutions, who harbored one or more nonfunctioning PanNET ≤2 cm, yielded progression-free survival rates of 63% at 5 years, 39% at 10 years, and 10% at 15 years, with no difference between the surgical and nonsurgical groups [8]. However, missed, unresected, and metachronous endocrine tumors, especially when malignant, can have a detrimental impact on the patient's clinical outcome.

### Metastatic Tumors

***Lymph Node Metastases*** The frequency of lymph node metastasis is higher for tumors of the pancreas larger than 1.5 cm (OR 4.7) and for tumors of the head as compared with the body and tail of the pancreas (OR 2.8) [9]. Furthermore, the time to development of liver metastases is significantly reduced for patients with lymph node metastases alone compared with those with none [10].

Disease-related survival decreases as the number of lymph nodes involved increases [10]. Overall, node-positive tumors have worse 5-year disease-specific survival rates than node-negative tumors (69–70 versus 81–90%) [11,12]. In nonfunctional PanNET ≤2 cm, the 10-year survival rate was better, reaching 87% in node-negative patients and 34% in node-positive patients [13].

These data hint at an interrelation between primary tumor size, lymph node metastasis, and liver metastasis, which signify increasing cancer-specific mortality for these three risk factors.

***Distant Liver Metastases as the Sole Systemic Manifestation*** Several retrospective studies focused on liver metastases, the predominant manifestation of systemic disease, as the sole clinical appearance of PanNET. These series included a mixture of hormone-secreting and nonfunctional, benign and malignant, sporadic and hereditary tumor entities arising from the head, body, and tail of the pancreas. This heterogeneity, compounded by different surgical interventions for disparate tumor types, grades, and stages, compromised the quality of these studies, hindering the generation of high-quality data for any tumor entity. Furthermore, liver metastases may be limited or diffuse, occurring synchronously or metachronously from first diagnosis of the primary tumor, or originating from within the residual liver tissue after hepatic resection. The prognostic ramifications of synchronous versus metachronous liver metastases are ill-defined, although the former seem to portend a bleaker prognosis than the latter. Despite these limitations, 5- and 10-year survival rates in most of these series have been in the order of 60–80 and 40–60%, respectively.

In 291 patients with poorly differentiated PanNET, the presence of distant metastasis (HR 2.41; $P < 0.001$) and lymph node metastasis (HR 2.10; $P = 0.004$), and poor differentiation (HR 6.96; $P = 0.032$) were independent predictors of worse survival, with distant metastasis having a significant impact (0 versus 43%; $P = 0.036$) on 5-year overall survival [14].

Enucleation of hepatic metastases, leaving surrounding parenchyma behind, is associated with greater short-term morbidity than hepatic resection, which entails the excision of metastases together with the surrounding liver parenchyma. In light of these data, it is challenging to conduct head-to-head comparisons between enucleation of and hepatic resection for liver metastases from PanNET. To facilitate surgical decisions, information about the biological behavior of the PanNET at hand (low versus high risk) is needed. According to current thinking, debulking needs to reduce the liver tumor burden by as much as 90% to improve outcome [15]. In some patients, total hepatectomy with subsequent liver transplantation has been used. Liver resection has been shown to improve symptom relief and survival compared with nonsurgical therapy [16].

***Widespread Systemic Disease*** In 8% of patients, malignant PanNET have spread to other distant organs, usually the lung [17]. Peritoneal carcinomatosis is uncommon in patients with foregut-derived neuroendocrine tumors but, if present, is frequently associated with liver metastases [18]. When the disease is widespread and

affects distant sites other than the liver, extended surgery may not change the clinical course. In this scenario, adjuvant treatments, including targeted therapies, come into play.

## Functioning Tumors

Whereas nonfunctioning tumors often become clinically apparent through complaints caused by tumor expansion, invasion, or metastatic disease, functional tumors, such as insulinoma, gastrinoma, and vasoactive intestinal peptide-releasing tumor (VIPoma) tend to be diagnosed at earlier stages when they present with signs and symptoms of hormone excess. The nature and intensity of these clinical signs and symptoms depend on both hormone type(s) and the quantities of the secreted hormone(s). In hereditary disease, regionalization of PanNET by selective arterial stimulation tests should be performed to avoid overlooking secondary functioning tumors [19].

Hormone excess typically produces clinical complaints that are more debilitating and diminish health-related quality of life more than those produced by tumor expansion, invasion, or metastatic disease. Hormonal symptoms cannot resolve if secondary hormone-secreting tumors are missed on enucleation or pancreatic resection, usually in hereditary conditions, or may occur again if the resection is inadequate, failing to remove the tumor in its entirety.

### Insulinoma

Because it almost always is benign, insulinoma forms an ideal surgical target for enucleation. Surgical cure rates for insulinoma are excellent, approaching 99% in experienced hands. Rare instances of failure were due to missed secondary insulinomas in the context of MEN1, malignant insulinomas that (i) were misdiagnosed as benign, (ii) were too large to be removed completely, or (iii) at first diagnosis had spread beyond the confines of the pancreas to involve regional nodes and distant organs, including the liver.

Malignant insulinoma takes a more varied clinical course. Some present with isolated lymph node metastases from the outset, whereas others, developing clinically apparent solitary or multiple liver metastases in the course of the disease, recur later on. Owing to the rarity and variable presentation of malignant insulinoma, comparative effectiveness research investigating surgical resection techniques for benign or malignant insulinoma has not been performed.

In patients with insulinoma, the clinical–histopathologic risk profile is heavily stacked in favor of surgical cure: small tumors, benign in nature; young patients with little, if any, comorbidities; enucleation or very limited pancreatic resection required only. As a natural consequence, patients with insulinoma, as a group, enjoy one of the best clinical outcomes among all patients with PanNET [1].

### Gastrinoma

Contrary to previous assumptions, sporadic gastrinomas are solitary tumors that rarely originate from within the pancreas (16%). Patients with gastrinoma also are younger than patients with nonfunctioning PanNET [1]. Most gastrinomas arise from outside the pancreas [20]: the duodenum (57%), lymph nodes (19%), or ectopic sites (9%). Because most duodenal gastrinomas (83%) do not exceed 10 mm in greatest dimension, transduodenal exploration is necessary to localize and eliminate the tumoral source of gastrin excess [20]. Multiple duodenal gastrinoma is such an exceptional condition that duodenectomy or pancreaticoduodenectomy is unwarranted in the absence of a definite surgical target identified on imaging and/or intraoperative digital palpation.

Metastatic liver disease is the principal cause of death in patients with gastrinoma. Although prospective clinical trials randomizing surgical, medical, and supportive care treatment are unfeasible on ethical grounds, retrospective data support the use of extended surgery in an effort to decrease metachronous liver metastasis. A study of a large series of 124 patients with nonmetastatic Zollinger–Ellison syndrome (ZES) compared 98 patients with abdominal surgery for gastrinoma with 26 patients similar in extent of disease and follow-up who were managed conservatively [21]. In the surgical group, the incidence of hepatic metastases was 3%, as opposed to 23 % in the medical group. Within the limitations of this observational study, these data pointed toward the usefulness of early transduodenal exploration and tumor resection coupled with resection of liver metastases and supported by adjuvant therapy.

### Glucagonoma, Somatostatinoma, and VIPoma

Most glucagonomas and somatostatinomas are considered "nonfunctional" even when they present with characteristic signs and symptoms, as with necrolytic migratory erythema, which is pathognomonic of glucagonoma. Somatostatinomas, lacking characteristic stigmata, are often so large at the time of diagnosis that they can no longer be enucleated.

VIPoma typically causes Verner–Morrison syndrome, which is characterized by watery diarrhea, hypokalemia, and achlorhydria (WDHA). These tumors, being the subject matter of single reports or small case series, are extremely rare, precluding the generation of comprehensive evidence-based data.

## Conclusion

Although great strides have been made in terms of staging and grading of PanNET, it has proved challenging to assemble large enough series of patients with PanNET and sufficiently long follow-up periods that would permit the adjustment of postoperative outcome for a large number of confounding variables: tumor entity, clinical presentation, hormone secretion, genetic background, location within the pancreas, tumor stage and grade, type and extent of surgery, surgical margins, and neoadjuvant and adjuvant therapies.

Because adjuvant chemotherapy and targeted therapies are palliative rather than curative, adoption of extended surgery has been advocated for the majority of patients with PanNET who are reasonably fit to tolerate the procedure. Although the need for surgical removal of larger tumors is undisputed in the absence of systemic disease, this need is much less evident for smaller tumors, many of which warrant expectant observation. There is a dire need for predictive molecular markers that afford better risk stratification of PanNET than currently provided for by Ki-67 grading and current imaging modalities.

## Introduction

Periampullary tumors include both benign and malignant neoplasms arising at or near the ampulla of Vater. The hallmark symptom of these tumors is painless obstructive jaundice, arising from their common location. The vast majority of periampullary tumors are malignant, with pancreatic adenocarcinoma being the most prevalent, followed by cancers of the ampulla of Vater, distal common bile duct, and duodenum, respectively. Surgical resection is the mainstay of therapy for periampullary tumors. Almost all resectable malignant and most benign tumors in this area are ultimately managed with pancreaticoduodenectomy. In patients with unresectable disease, relief of biliary obstruction, through either biliary stenting or surgical biliary bypass, is essential for palliation. Determining the exact etiology of a periampullary malignancy can be challenging for both the surgeon and the pathologist. The clinical presentation, preoperative imaging studies, and intraoperative findings may not allow differentiation of the specific site of origin. The most common location for periampullary malignancy is the head of the pancreas, which accounts for 55–65% of tumors identified in resected specimens (Table 138.1). The incidence of ampullary, distal common bile duct, and duodenal carcinomas presented in the table is somewhat higher than their overall incidence, because they have higher rates of resectability than tumors arising in the head of the pancreas. With this in mind, analysis of patients with both resectable and unresectable disease would suggest adenocarcinoma of the pancreas accounts for up to 90% of cases.

Although indolent neoplasms such as neuroendocrine tumors or benign tumors (e.g., adenomas) occasionally occur in the periampullary region, they are much less frequent. The benign tumors occasionally present with unrelenting jaundice secondary to bile duct obstruction, as seen with periampullary carcinoma. Therefore, benign disease is sometimes mistaken for carcinoma in a persistently jaundiced patient. The more common clinical scenario involves distinguishing malignant biliary obstruction from fibrosing chronic pancreatitis or the benign condition, autoimmune pancreatitis (also known as IgG4-associated pancreatitis or lymphoplasmacytic sclerosing pancreatitis) [1,2].

The management of pancreatic cancer is discussed in depth in Section 5. Therefore, this chapter reviews the clinical presentation and diagnostic strategy for periampullary neoplasms.

## Clinical Presentation

Many of the difficulties in the treatment of periampullary carcinomas result from the difficulty in diagnosing the disease in its early stages. Early symptoms of periampullary cancer tend to be nonspecific and are often minimized by both the patient and the physician. This frequently leads to a delay of weeks to several months in making the diagnosis. It is often not until the patient develops jaundice that the diagnosis is made. Jaundice is usually progressive, relentless, and often associated with significant pruritis. For tumors of the ampulla of Vater, distal common bile duct, and periampullary duodenum, clinical jaundice tends to present early, contributing to a higher resectability rate with these lesions compared with tumors of the pancreas. The development of jaundice in any patient over age 40 should arouse suspicion of a periampullary neoplasm and warrants an aggressive pursuit of the diagnosis. Ampullary carcinoma can

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

**Table 138.1** Relative frequencies of resected periampullary cancers.

| Location | Percentage |
|---|---|
| Head of pancreas | 60 |
| Ampulla of Vater | 20 |
| Distal common bile duct | 10 |
| Duodenum | 10 |

present with intermittent jaundice either due to a polypoid tumor that only intermittently obstructs the bile duct orifice or as a result of growth and necrosis leading to transient biliary obstruction during the growth phase. In this case, it requires a high level of suspicion on the part of the primary physician to pursue the appropriate evaluation.

Other symptoms of periampullary neoplasms include abdominal pain, anorexia, nausea, and weight loss. Moderate intensity pain may be present as a result of obstruction of the biliary or pancreatic duct. This pain in the epigastrium or right upper quadrant is often described as dull, may be accompanied by back pain, and is often aggravated by eating. Duodenal obstruction causing vomiting is usually a late manifestation of periampullary cancers, although duodenal cancers may circumferentially narrow the lumen at an earlier stage. Melena or hematemesis may occur as a result of significant bleeding from ampullary or duodenal tumors, although commonly blood loss is chronic and intermittent. Finally, an unexplained attack of pancreatitis in an older patient must be thoroughly investigated once the acute attack has subsided, as this may be the first manifestation of a periampullary neoplasm. In a report by Rattner et al. [3] acute pancreatitis was the initial symptom in 25% of patients with ampullary neoplasms. Similarly, intraductal papillary mucinous neoplasms can also present with abdominal pain and hyperamylasemia due to ductal obstruction by mucin [4,5].

In addition to the presenting symptoms, the patient's past medical and family history may also be highly relevant. Patients with the hereditary disorders of Gardner's syndrome and familial adenomatous polyposis of the colon have more than a 200-fold increased risk of ampullary and duodenal carcinomas compared with the general population [6]. In most of these patients, the polyps will be multiple and involve much of the duodenal mucosa.

In many patients, physical findings are absent, especially early in the course. The most common findings in patients with periampullary cancers are jaundice and hepatomegaly. Hepatomegaly usually reflects congestion associated with biliary obstruction, and does not imply the presence of metastatic disease. The gallbladder may also be palpable in approximately 25% of patients. Occult fecal blood is found in those patients with periampullary cancers that bleed into the intestinal lumen.

## Diagnostic Evaluation

### Laboratory Data

There are no specific diagnostic laboratory tests for periampullary carcinoma. Virtually all patients present with abnormal liver functions tests, characteristic of extrahepatic obstruction, including increased plasma concentrations of bilirubin and alkaline phosphatase. A patient's transaminases may also be elevated, but usually not to the same extent as the alkaline phosphatase. In cases of malignant obstruction, marked elevations of bilirubin greater than 10–15 mg/dL may be seen. If extrahepatic obstruction has been longstanding, the prothrombin time may also be prolonged. Anemia may also be present with periampullary cancers arising from the duodenum or ampulla, as these patients are more likely to experience clinically significant bleeding.

Elevation of the tumor-associated carbohydrate antigen (CA) 19-9 above 37 kU/L has been reported to have a sensitivity of 81% and a specificity of 90% for pancreatic adenocarcinoma [7]. The sensitivity of CA 19-9 for the diagnosis of cholangiocarcinoma is approximately 70% [8,9]. Unfortunately, CA 19-9 concentrations are frequently normal in early stages of pancreatic and periampullary neoplasms and elevated CA 19-9 levels are seen in many benign hepatobiliary processes, such as pancreatitis and cholestasis. In addition, approximately 6% Caucasian and up to 22% of non-Caucasian patients have Lewis A-B genotype and do not make CA 19-9 [10]. Although a number of genetic markers or alterations have been associated with pancreatic cancer (K*ras*, p53, SMAD4, CDKN2A), little such information is available for nonpancreatic periampullary neoplasms [10,11].

### Imaging and Radiologic Evaluation

Early diagnosis of periampullary cancer requires an appropriate level of clinical suspicion and aggressiveness in pursuing the diagnosis. Prompt evaluation of a patient with jaundice offers the opportunity for early diagnosis. Any patient presenting with jaundice should undergo focused diagnostic imaging in order to evaluate the level of biliary obstruction, the most likely etiology of the abnormality, and the resectability of the lesion if a tumor is identified.

#### Ultrasonography

Transabdominal ultrasound may be the initial imaging modality for patients presenting with abdominal pain or obstructive jaundice as it documents the presence of

gallstones or other biliary or hepatic abnormalities that may mimic malignancy (e.g., Mirizzi syndrome). Ultrasound can also accurately define the level of biliary obstruction, thereby narrowing the differential diagnosis. Other important findings that can be visualized with ultrasound include ascites, liver metastases, and regional lymphadenopathy. A major limitation of ultrasound in the periampullary region is a 15–20% rate of technically inadequate studies, which can be due to patient habitus, intervening bowel gas, or technical limitations of the operator. Conversely, advantages of ultrasound include a lack of radiation exposure and relative low cost.

#### Computed Tomography

Despite the advantages of ultrasound, the high accuracy and reproducibility of computed tomography (CT) and its widespread availability make it the most useful and often most cost-effective test for the evaluation of a patient with a suspected periampullary malignancy [12]. CT can detect pancreatic masses as small as 1 cm and provides important information about the level of biliary obstruction with respect to the pancreatic parenchyma if no mass is seen (Fig. 138.1). The optimal technique for evaluation of the periampullary region involves administration of both intravenous and oral contrast and acquisition of 1–2 mm cuts within a single breath-hold during both arterial and venous phases of intravenous contrast enhancement. Scans obtained during the rapid intravenous injection of an iodinated contrast agent result in an increase in parenchymal evaluation as well as excellent contrast enhancement of the peripancreatic blood vessels. This technique not only results in clear delineation of the tumor, but may also demonstrate involvement of adjacent major visceral vessels, such as the portal vein or superior mesenteric complex, suggesting borderline resectability. CT has nearly 100% sensitivity for the detection of liver metastases at least 1 cm in size [13]. It can also demonstrate ascites and often evidence of peritoneal metastases.

The value of CT lies in the virtual absence of technically unsatisfactory examinations and its high accuracy for the detection and staging of periampullary carcinoma. The positive predictive value associated with CT determination of unresectability is greater than 90% [14]. Magnetic resonance imaging (MRI) is equivalent, but not superior, to CT for either detection of or staging of periampullary tumors, but has a higher cost [15]. It does offer the advantage of avoiding exposure to radiation or ionic contrast, so is the preferred test for patients with contrast allergies or renal insufficiency.

#### Magnetic Resonance Cholangiopancreatography

Magnetic resonance cholangiopancreatography (MRCP) is a noninvasive method for determining the most likely etiology of a pancreaticobiliary abnormality. It is most helpful in evaluating abnormalities of the proximal bile ducts and liver. In periampullary lesions, the thick-slab magnetic resonance images will delineate the biliary and pancreatic ductal anatomy [14] with detail that is similar to the more invasive techniques of endoscopic or percutaneous cholangiography. The other magnetic resonance sequences will define the presence or absence of a mass, the level of obstruction, and the location of any abnormality relative to the regional vessels.

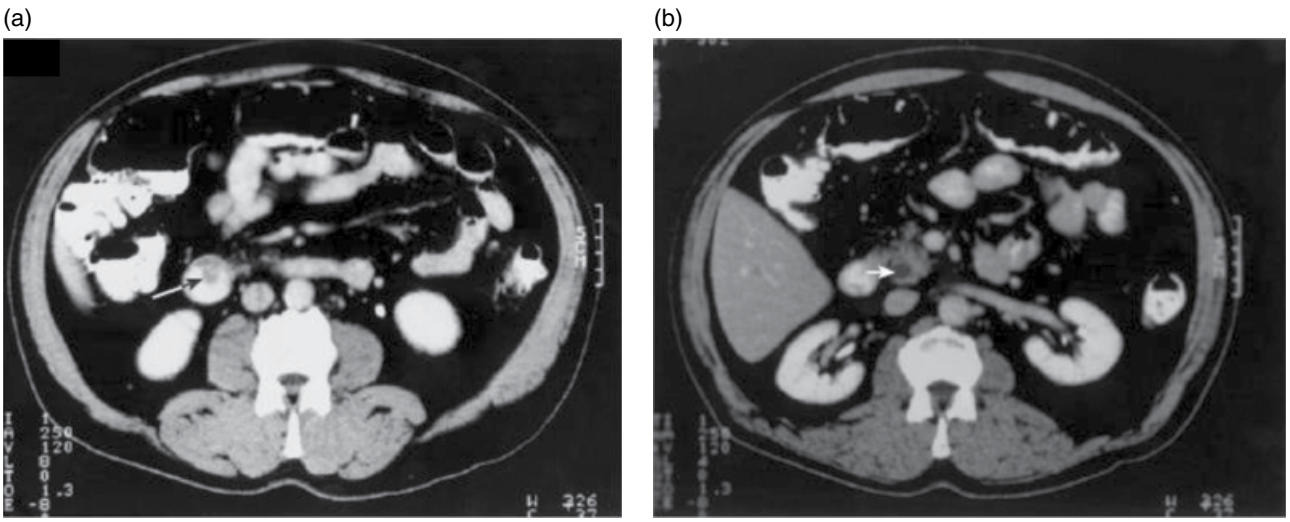

**Figure 138.1** CT scans of a patient with obstructive jaundice due to ampullary carcinoma. (a) Scan demonstrates a 30 cm ampullary mass (arrow). (b) Scan at a higher level demonstrating bile duct dilatation within pancreatic parenchyma, indicating distal duct obstruction (arrow).

### Endoscopic Ultrasound

Endoscopic ultrasound (EUS) is a diagnostic modality that combines and modifies the techniques of gastrointestinal endoscopy and ultrasound. This combination decreases the distance between the ultrasonic source and the organ of interest, thereby markedly improving the resolution and imaging of the surrounding structures. Real-time EUS enables the clinician to evaluate and integrate, during the same examination, mucosal, vascular, ductal, and parenchymal abnormalities (Fig. 138.2). It allows detection of periampullary tumors, evaluation of their size and depth of invasion, as well as assessment of regional lymph nodes. EUS appears to be superior to CT and MRI for the detection of small pancreatic tumors (<2 cm) [16,17]. However, the sensitivity of EUS decreases in the setting of chronic pancreatitis [14]. EUS assessment of depth of invasion (T stage) has an overall accuracy of about 73% with accuracy increasing with higher T stages [18,19]. In the case of mucosally based tumors, such as ampullary and duodenal neoplasms, EUS is particularly valuable for assessment of depth (T stage) and invasion of surrounding structures. Although results are not conclusive, several reports have also indicated that EUS is more sensitive and accurate for detection of vascular invasion than CT [16,20]. The reported accuracy of EUS assessment of lymph node status has ranged from 63% to 84%, which is at least equivalent to CT, although this may be operator dependent [14,16,21,22]. Finally, EUS can be used to guide fine-needle aspiration (FNA) of both the primary lesion and suspicious regional lymph nodes. In addition to having a reasonable diagnostic accuracy, a study by Micames et al. [23] suggests that patients undergoing EUS-guided FNA, as opposed to CT-guided percutaneous FNA, are less likely to subsequently develop peritoneal carcinomatosis.

Limitations of EUS include its need for skill in both operating and interpreting, its invasive nature, and its limited view, which does not allow evaluation for distant metastases. The combination of CT and EUS is better than either alone in determining resectability in patients with periampullary cancers, and a strategy of CT for all patients with suspected periampullary malignancies, followed by EUS in those patients in whom CT does not clearly demonstrated unresectability has been shown to be the most cost-effective strategy for preoperative staging and determination of resectability in these tumors [22,24].

### Endoscopy/Cholangiography

Upper endoscopy is useful for defining the extent, size, and gross appearance of a periampullary mucosal lesion and allows simultaneous performance of an endoscopic biopsy and cytologic brushings. However, the endoscopic appearance of an ampullary lesion is often similar for benign and malignant tumors (Fig. 138.3). Furthermore, endoscopic biopsies of periampullary malignancies may be inaccurate in 15–25% of patients, yielding false-negative results, largely due to sampling error. The demonstration

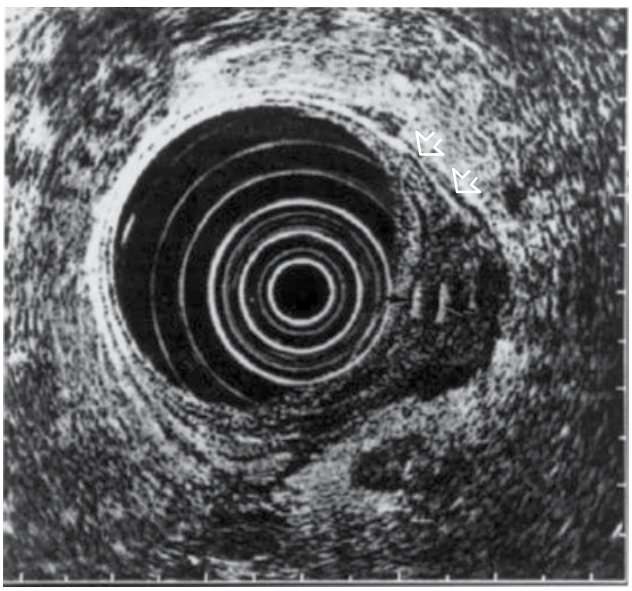

**Figure 138.2** EUS scan of ampullary tumor, represented by the hypoechoic area on the right. An endoprosthesis (small black arrows) can be seen running through the center of the tumor. The tumor infiltrates beyond the muscularis propria (open arrows) into the pancreas.

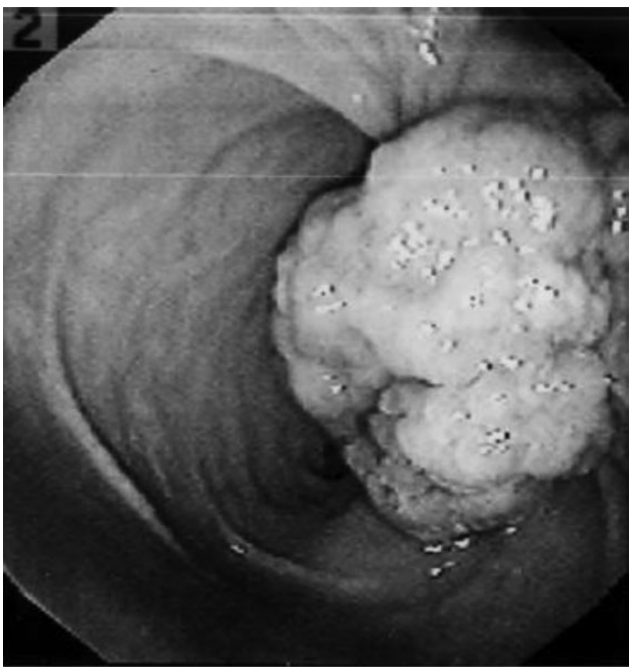

**Figure 138.3** Endoscopic appearance of benign villous adenoma.

of malignancy on biopsy specimens is definitive, but diagnosis of a benign adenoma does not rule out the presence of an adenocarcinoma elsewhere in the adenoma. Another important consideration is that ampullary adenomas are considered a premalignant condition since they tend to progress to carcinoma [25]. Therefore, regardless of whether or not the biopsy shows malignant or benign histology, complete resection (either operative or endoscopic) is warranted.

Cholangiography can be performed via either a percutaneous or an endoscopic approach. In most patients, however, percutanoues transhepatic cholangiography (PTC) offers little advantage over endoscopic retrograde cholangiopancreatography (ERCP), has a greater morbidity, and should be considered only if an endoscopic cholangiogram is technically not possible, such as after resection or bypass.

Prior to the improvements in current imaging and the advent of MRCP, ERCP was a routine part of evaluation of patients with suspected periampullary tumors. A cytologic diagnosis could often be made based on brushing of the lesion. With ERCP or MRCP, pancreatic or ampullary carcinomas are most often assumed when abnormalities of both the pancreatic and bile ducts are seen, yielding a "double-duct" sign (Fig. 138.4), whereas bile duct cancers typically show a characteristic "apple-core" appearance with an often normal pancreatic duct. ERCP offers the advantage over PTC of allowing a pancreaticogram to be performed, which may be important if pancreatitis is in the differential diagnosis [26].

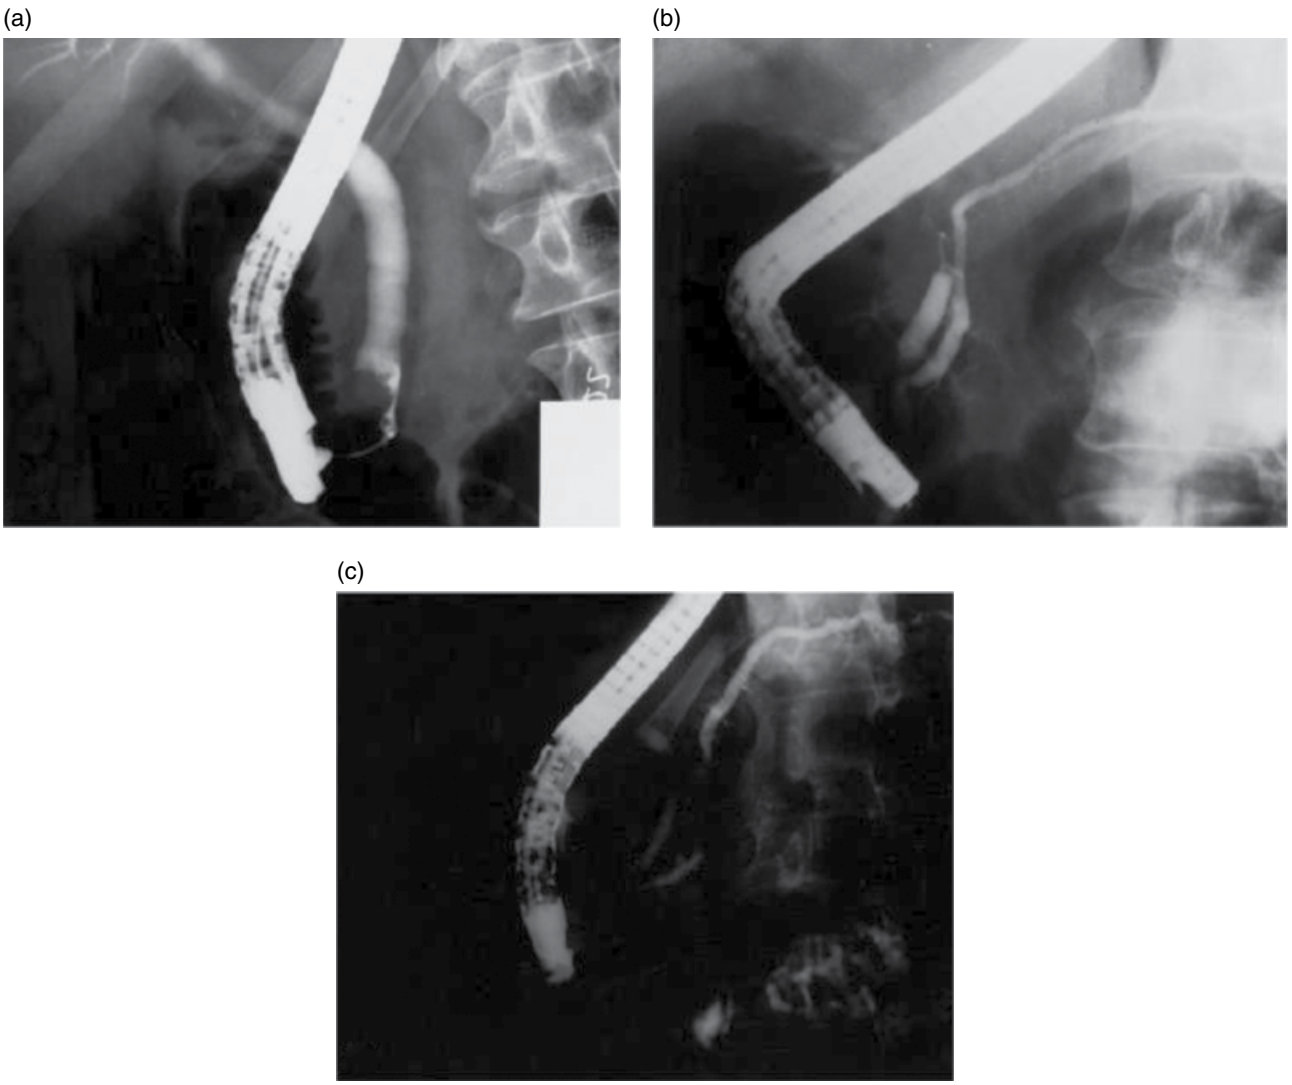

**Figure 138.4** (a) ERCP showing ampullary carcinoma obstructing the distal common bile duct. (b) ERCP with distal common bile duct carcioma. Note the normal appearance of the main pancreatic duct, indicating a bile duct origin for the tumor. (c) ERCP of a pancreatic carcinoma, with partial obstruction of both the main pancreatic duct and the common bile duct ("double- duct" sign).

The most common indication for ERCP in patients with periampullary tumors is for placement of an endoscopic stent in the common bile duct to relieve biliary obstruction preoperatively or for palliation. Although stent placement may result in colonization of the biliary tree and a higher wound infection rate in resected patients [27–29], it is indicated for medical reasons in a number of clinical circumstances: (i) in patients who present with symptoms of cholangitis requiring immediate intervention to treat the biliary infection; (ii) in patients presenting with intractable pruritus needing to be relieved during the period of preoperative evaluation; and (iii) in patients with hyperbilirubinemia associated with vitamin K deficiency, which will correct with relief of the biliary obstruction. Under these circumstances, at least 2–3 weeks should be waited prior to definitive resection to allow the metabolized bilirubin to normalize and to ensure the absence of active infection after instrumentation. A common current indication for endoscopic biliary stenting is to relieve jaundice when there is an anticipated delay in scheduling the surgical procedure to allow referral to a high-volume institution or for planned neoadjuvant therapy. In the latter situation, the use of a metallic stent is indicated to avoid recurrence of biliary obstruction with cholangitis in the midst of neoadjuvant therapy [30,31].

## Preoperative Staging

Since its introduction by Whipple et al. in 1935 [32], pancreaticoduodenectomy has been the most effective treatment for periampullary carcinomas. Perioperative morbidity and mortality rates have improved over the past decades, with mortality rates of 2% or less and morbidity rates of 30–40% expected in patients currently treated at high-volume hospitals [33–35]. The goal of preoperative staging is to determine which tumors are potentially resectable and have not already metastasized to distant sites or directly invaded the major peripancreatic vessels. Improvement in preoperative imaging and the addition of EUS to our clinical armamentarium have allowed better selection of patients for operation, with fewer patients being found to be unresectable at the time of operation, thereby minimizing unnecessary morbidity. Nonoperative techniques for the management of obstructive jaundice secondary to a periampullary tumor have also improved and can provide adequate palliation for most patients with unresectable neoplasms. Although the response is less durable than with surgical palliation, nonoperative palliation is often the most appropriate therapy for patients with a short life expectancy. These improvements in nonoperative management have made appropriate staging more important. In the past, laparotomy was required in all patients in order to establish the diagnosis and, thereafter, resection or operative palliation was performed.

The modalities currently considered most useful in staging patients with periampullary neoplasms are dual-phase CT and EUS. Dynamic spiral CT is currently the most valuable of these studies, playing a role in both diagnosis and staging of periampullary neoplasms. Its primary advantages are the lower cost and noninvasive nature of the technique. CT scans detect liver metastases (>1 cm) or large peritoneal implants. Obstruction and/or encasement of the major visceral arteries and veins in the region can be defined by loss of the perivascular fat planes and encroachment on the vessel lumen or the development of venous collaterals in the area (Fig. 138.5).

EUS is primarily used for determining local resectability with respect to visceral vessel invasion. EUS can also provide local staging by evaluating T stage. In the situation of a questionable lymph node status, it can also be used to perform FNA for cytologic evaluation of the nodes. However, EUS cannot be used as the sole modality for staging. Given its inability to adequately exclude peritoneal or hepatic metastases, it should be combined with CT for complete staging.

One of the limitations of CT is its poor sensitivity for detection lesions on the liver, omentum, or peritoneal surface that are less than 1 cm in size. For this reason, laparoscopy has been suggested as a method of further minimally invasive staging. In the past, advocates of laparoscopy have reported that more than 40% of patients previously staged by CT were found to have small metastases at laparoscopy [36]. Although reaching different conclusions about whether laparoscopy should be used, more recent reports have shown that staging laparoscopy

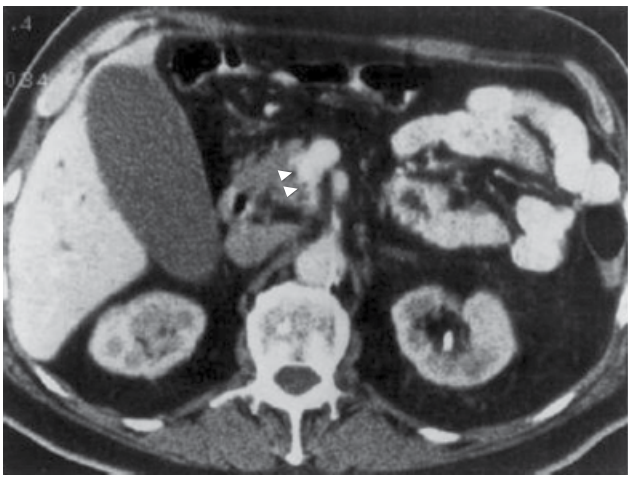

**Figure 138.5** Spiral CT demonstates superior mesenteric vein involvement by tumor–vessel contiguity. Abnormal enhancement of the medial border of the head and uncinate process of the pancreas is seen (arrowheads)

subsequent to CT staging, even when combined with laparoscopic ultrasound, identifies only an additional 10–14% of patients with unresectable disease [37,38]. This yield is even lower for patients with ampullary and duodenal tumors [38]. One cost-effectiveness analysis found that despite improving the rate of unresectability, diagnostic laparoscopy was not cost-effective in patients with periampullary malignancies [39].

## Determination of Extent of Resection

Local resection of an ampullary tumor with reimplantation of the pancreatic and common bile ducts was first described by Halsted in 1899 [40]. Recently, local resection of the ampulla of Vater has been reappraised for small (<3 cm) benign ampullary tumors or low-grade ampullary carcinomas. The most important criterion for determining malignancy is confirmation by histologic diagnosis. Although multiple endoscopic biopsies can detect malignancy in most patients with ampullary carcinoma, up to 25% of such biopsies will be negative [41–43]. This problem can even be extended to frozen-section analysis of resected specimens, which can fail to detect malignancy in 14% of patients [44,45]. The use of EUS provides another method for selecting patients for local resection. However, it is essential to acknowledge that EUS cannot replace histologic evaluation. EUS cannot differentiate a T1 carcinoma (limited to the submucosa) from an adenoma; however, T3 and T4 tumors are easily differentiated from an adenoma or early carcinoma by EUS. In a series reported by Mukai et al. [46], EUS accurately defined wall-depth penetration in 78% of ampullary carcinomas. Underestimating the depth of tumor penetration seldom occurs, while overestimation is more common and is often due to edema of the submucosa from associated pancreatitis, which occurs in up to one-third of T1 lesions [47]. Finally, as noted above, EUS cannot definitively determine the presence or absence of regional lymph node metastases;

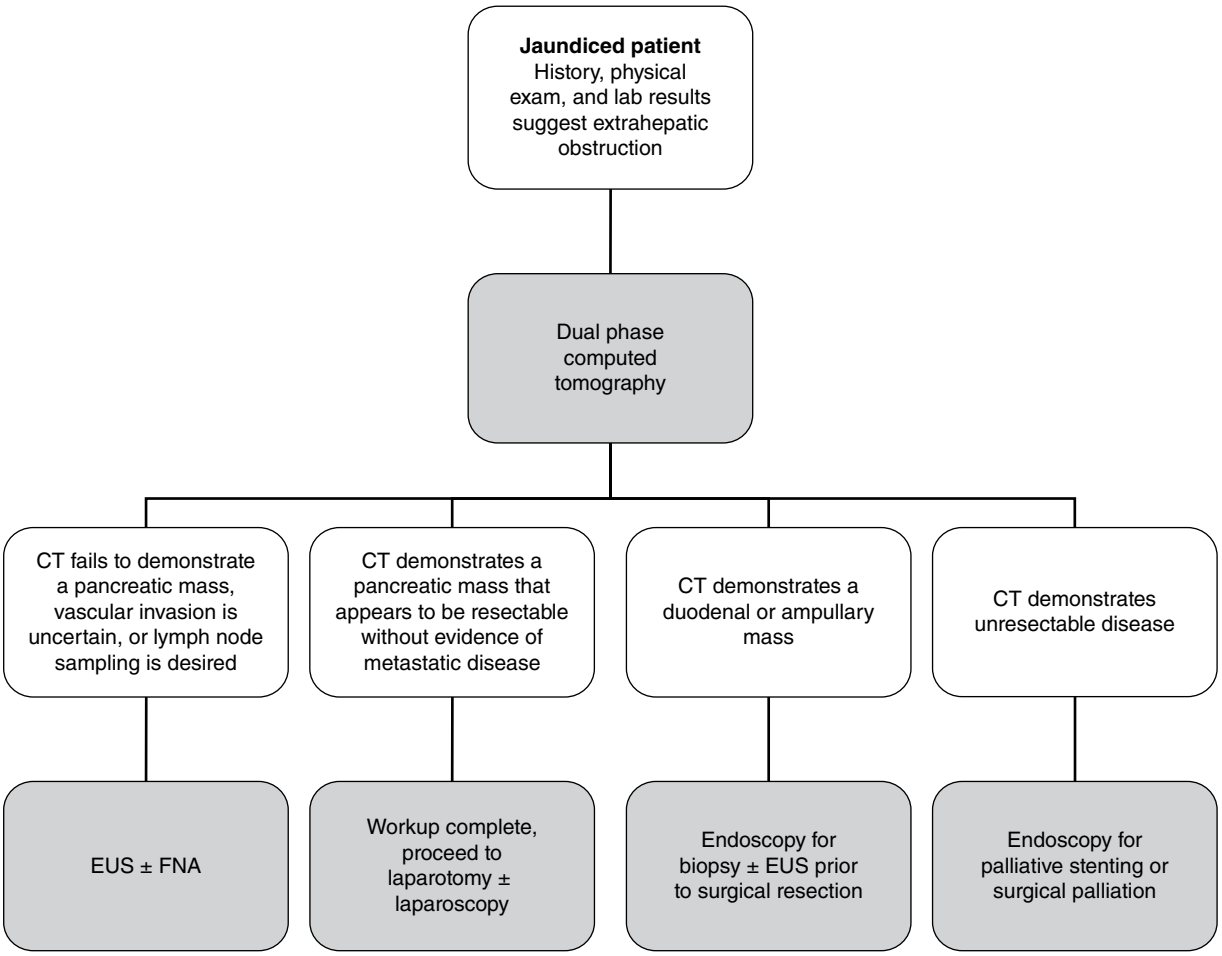

**Figure 138.6** Algorithm for the workup of a jaundiced patient. CT, computed tomography; EUS, endoscopic ultrasound; FNA, fine-needle aspiration.

because of these limitations, EUS, while providing extremely useful information, cannot be the only criterion used to choose between ampullectomy and pancreaticoduodenectomy.

## Summary

Patients with periampullary tumors typically present with painless jaundice and a hepatic profile consistent with obstructive jaundice (Fig. 138.6). If the history and physical examination do not point to gallstone disease or another benign etiology, the most high-yield initial imaging study is high-quality dual-phase CT. If CT demonstrates a lesion that is typical for pancreatic or distal bile duct carcinoma, and does not provide any evidence of unresectability (i.e., invasion of major vascular structures or distant metastases), the surgeon may choose to proceed directly to resection without a tissue diagnosis. If CT suggests an ampullary or duodenal tumor, endoscopic evaluation with biopsy and potentially EUS should be performed. In the situation of an uncertain diagnosis or where there is a question of involvement of major vascular structures, EUS should be performed. EUS-guided FNA is able to yield a diagnosis in up to 90% of pancreatic cancers [48]. The presence of vascular invasion and lymph node metastases can also be further evaluated with EUS, potentially sparing the patient an unnecessary operation and expediting referral for nonsurgical treatments such as aggressive neoadjuvant therapy, which has been shown in recent series to lead to tumor "downsizing" and resectability in a number of cases [49,50]. With the current level of sophistication of CT and a talented endoscopist, this combination of imaging is able to accurately stage a majority of patients and thus laparotomy will rarely identify occult metastatic disease or local unresectability. Diagnostic staging laparoscopy should be considered in patients with large periampullary pancreatic cancers. This technique will detect occult metastatic disease in an additional 10% of patients [38]. The ability of perform laparoscopic palliative procedures may expand the indications for laparoscopic staging.

## Carcinoma of Papilla (Ampulla of Vater)

The ampulla of Vater is a complex anatomic and histologic structure. Histologically, it consists of four compartments featuring three types of epithelia: (i) The distal common bile duct (CBD) and pancreatic duct are lined by pancreatobiliary-type ductal epithelium. (ii) The mucosa of the papilla of Vater itself shows a specialized epithelium with features that resemble gastric foveolar epithelium and scattered goblet cells. (iii) The duodenum-facing surface of the papilla is virtually identical to the duodenal mucosa elsewhere. (iv) On the wall of the ampulla is Oddi musculature, within which are pancreatobiliary-type ductules lying individually and in clusters. These different compartments not only have distinct histologic and functional properties but also bring with them their own chemical milieu, which makes this small region highly complex and challenging. Thus it is not surprising that there are vastly different impressions regarding the characteristics of the cancers of this region. Recently, careful analysis of tumors of this area processed with more standardized grossing protocols [1,2] have led to refined classification and elucidated the specific characteristics of tumors arising from the different compartments [3–5].

### Preinvasive Neoplasms

A significant proportion of the ampullary cancers (estimated more than a third) arise from adenomatous lesions (i.e., preinvasive mass-forming neoplasia), which are also called tumoral intraepithelial neoplasms [6,7]. According to their location, these can be put into two groups [3,7]: adenomas of the ampullary duodenum and intra-ampullary papillary tubular neoplasms.

#### Adenomas of the Ampullary Duodenum

Adenomas with all the characteristics of colonic adenomas also arise from the duodenal surface of the ampulla. They can be sporadic or associated with familial adenomatous polyposis (FAP) syndrome. In fact, ampulla is a common extracolonic site of FAP involvement [8–12].

Adenomas of the ampullary duodenum are more likely to harbor an invasive carcinoma than similarly sized colorectal adenomas. Invasive carcinomas that arise in adenomas are often hidden in the deep creases of the tumor at the base of the polyp and are difficult to detect in surface biopsies. Microscopically, adenomas of the ampullary duodenum are similar to those that occur in the large intestine but present some challenges in their diagnosis at the pathologic level. For example, reactive changes can mimic adenomas closely [13,14]. More importantly, when an underlying invasive carcinoma of the pancreas or bile duct involves the ampullary epithelium by colonization ("cancerization") of the mucosal basement membrane, it can closely simulate (pseudo-adenomatous change) a native in situ disease [15].

#### Intra-Ampullary Papillary Tubular Neoplasms

Intra-ampullary papillary tubular neoplasms (IAPN) are adenomatous (tumoral intraepithelial neoplasms) lesions that occur almost exclusively within the ampulla [7,16]. They represent the intra-ampullary counterpart of intraductal neoplasms of the pancreas (IPMN) and biliary tract (IPNB). Papillary or polypoid tumors can fill the ampullary channel and distal segment of the CBD or main pancreatic duct. By definition, involvement of the

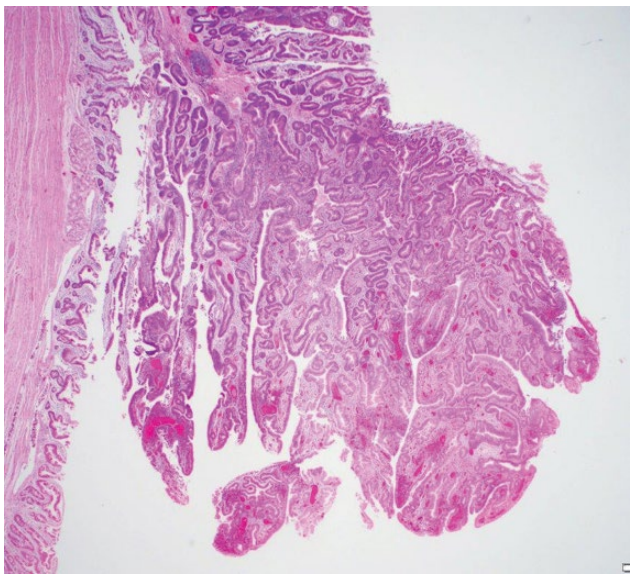

**Figure 139.1** Intra-ampullary papillary tubular neoplasm is preinvasive tumor growth within the ampulla. It shows various degrees of papillary and tubular growth.

ampullary duodenum and intramucosal extension into the proximal aspect of the CBD and main pancreatic duct is minimal (<25%) [17]. The mean age of affected patients is 64 years with male predominance [13,17].

Gross examination of the ampullary duodenum typically reveals a hemispheric elevation of intact mucosa, often with a patulous papilla orifice from which nodules of friable granular material protrude into the duodenal lumen [1]. Ulceration may be evident, but overt mucinous discharge, characteristic of pancreatic intraductal neoplasms, is seldom encountered. On sectioning the ampullary wall, the tumors are characterized by a prominent exophytic growth pattern within the ampulla, in the dilated distal bile duct and pancreatic duct. Microscopically, IAPN show various degrees of papillary or tubular growth (Fig. 139.1). Most have a mixture of these patterns. They exhibit a spectrum of dysplasia, and most cases show a mixture of low-grade dysplasia (the criteria is the same as that used for adenomas of ampullary duodenum) and high-grade dysplasia, which is defined as substantial cytologic atypia and architectural complexity. Unlike adenomas of the ampullary duodenum, approximately 50% of IAPN show mixed (intestinal, gastric, pancreatobiliary) differentiation [7]. Approximately 75% of IAPN are associated with invasive carcinoma at the time of diagnosis, but the invasive component is usually less than 1 cm in diameter [7]. Invasion is mostly tubular and often shows a mixture of intestinal and gastropancreatobiliary features. Since the invasive carcinoma is often small, proper sampling and examination becomes crucial. It should be noted that because of the complexity of this site it becomes very difficult to distinguish true invasive carcinoma from adenomatous (preinvasive) cells pagetoidly extending into complex glandular units in a pseudo-invasive pattern.

The hybrid nature of these lesions is also reflected in their immunophenotype. More than 50% of cases coexpress CK7 and CK20 [7]. Immunostaining for MUC2 and CDX2 is positive in cases with intestinal differentiation; immunostaining for MUC1, MUC5AC, and MUC6 are positive in cases with gastropancreatobiliary differentiation. However, overlaps are very common, and a significant proportion of the cases reveal mixed immunophenotype [7,18].

Noninvasive cases have an excellent prognosis. However, cases with extensive high-grade dysplasia can recur and this recurrence can be seen many years after the resection [7]. Therefore, long-term follow-up is warranted, even in noninvasive cases. Cases with invasive carcinoma are associated with better survival than conventional (invasive) ampullary carcinomas unaccompanied by an IAPN (3-year survival of 69% vs. 44%) [7]. This survival advantage is likely attributable to early detection of invasion but also reflects differences in tumor biology [3,19].

## Invasive Adenocarcinomas

Until recently, the definition of ampullary cancer lacked uniformity, with most studies analyzing them under the rubric of "periampullary cancers" along with pancreatic and CBD cancers. Furthermore, in many studies noninvasive carcinomas (adenomatous lesions with carcinoma in situ) have also been included in analysis of "ampullary cancers." These variations in definition have led to the vastly different reports regarding the characteristics and behavior of ampullary cancer. Nonstandardized and limited pathologic evaluations seem to have been a great contributor to this variation as well. In January 2016, refined definitions were provided and adopted by the College of American Pathologists (CAP); these currently serve as the main guide for the documentation of ampullary tumors in the United States. According to this scheme, four categories are recognized as "ampulla of Vater" cancers. Their clinicopathologic characteristics are described in the following sections [3].

### (Peri)ampullary Duodenal Cancers

(Peri)ampullary duodenal cancers arise from the ampullary duodenum (duodenum-facing surface of the ampulla that is lined by intestinal epithelium normally), which form bulky ulcero-vegetating lesions readily observed in the duodenal lumen, in which the ampullary orifice is often eccentrically located (Fig. 139.2a). They typically prove to have a prominent adenoma component and

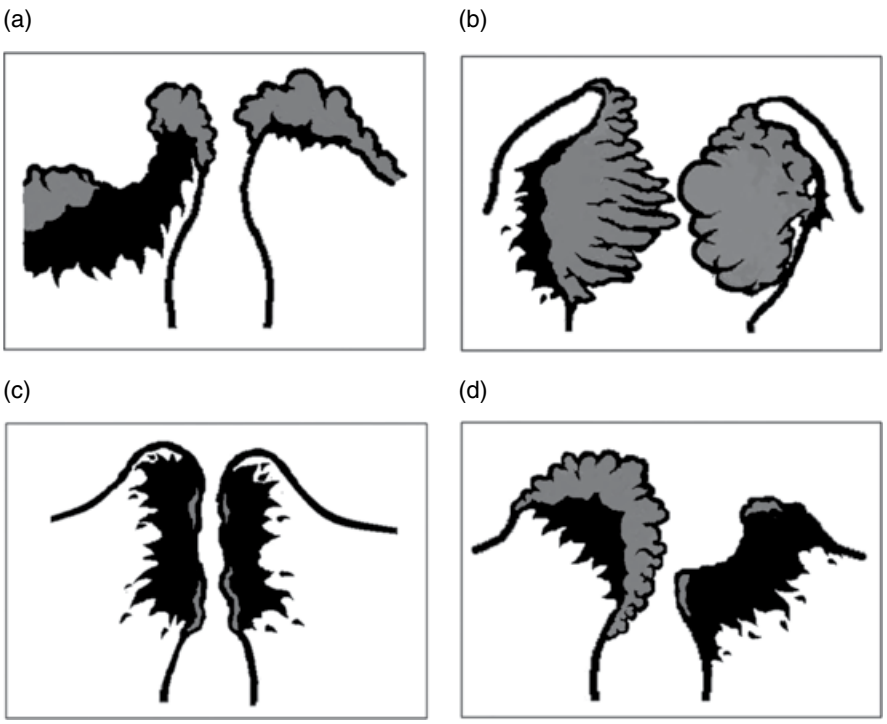

**Figure 139.2** Subtypes of ampullary carcinoma. The diagrams illustrate four subtypes of ampullary carcinoma: gray color indicates the preinvasive component and black color indicates the invasive component. (a) (Peri)ampullary duodenal carcinomas form ulcerovegative tumors that grow predominantly (>75%) on the duodenal surface of the ampulla. (b) Intra-ampullary papillary tubular neoplasm (IAPN)-associated carcinomas are characterized by a prominent preinvasive neoplasm that grows predominantly as an exophytic mass within the ampullary channel. (c) Ampullary duct carcinomas show minimal or no preinvasive lesion, and instead form a plaque-like stricture at the distal ends of the ducts. (d) Ampullary carcinomas not otherwise specified (ampullary-NOS): carcinomas arise from the papilla of Vater.

their invasive component is most commonly intestinal or mixed mucinous intestinal phenotype. Although they are usually very large (>4 cm) and produce lymph node metastases (~60%), their behavior is often significantly better than expected.

#### Intra-Ampullary Papillary Tubular Neoplasm-Associated Carcinomas

IAPN-associated carcinomas are characterized by preinvasive mucosal nodules located *within* the ampullary channel (i.e., distal portions of the CBD and main pancreatic duct). From the duodenal perspective, these tumors are less impressive, they show a dilated orifice, from which granular material may protrude into the lumen of the bowel. Upon sectioning the ampullary wall, the main bulk of the tumor is elucidated and typically reveals light tan, friable nodules (Fig. 139.2b). Probes placed in the CBD and pancreatic duct typically exit into the center of the lesion. They are by default rich in adenomatous component and microscopic examination often reveals only a small invasive carcinoma, and thus, not surprisingly, the prognosis is relatively good (median survival close to 10 years), especially if invasion is limited in amount; however, many cases experience recurrences in long-term follow-up.

#### Ampullary Duct Carcinoma

Ampullary duct carcinoma is the other category that can be technically regarded under the "intra-ampullary" tumor category but they are biologically very different from the IAPN-associated carcinomas discussed above. In essence, they are intra-ampullary counterparts of pancreatic ductal adenocarcinomas and distal CBD carcinomas (DBDC). Ampullary ductal cancers by default do not have a significant adenomatous (preinvasive neoplasm) component, and instead form circumferential scirrhous lesions that constrict the distal end of the CBD and pancreatic duct, with preservation (or minimal alteration) of the papilla of Vater and ampullary duodenal mucosa. Therefore, from the duodenal perspective, these tumors are fairly underwhelming, and typically show a button-like elevation of mucosa or a small, subtle ulcerating lesion (Fig. 139.2c). If proper dissection approaches are not employed, ampullary duct carcinomas can easily be missed because they are small and subtle. Microscopically, they often prove to be pancreatobiliary-type carcinomas. Although these tumors are usually less than 2 cm in diameter, they have a high rate of lymph node metastasis (57%) and an aggressive behavior (median 38 months), the worst among the ampullary

carcinoma subtypes, but nevertheless significantly better than pancreatic ductal adenocarcinomas.

#### Ampullary Carcinomas Not Otherwise Specified

Ampullary carcinomas not otherwise specified (ampullary-NOS) includes two subsets of tumors: (i) those that are presumed to arise from the papilla of Vater itself (i.e., the edge of mucosa where the CBD and main pancreatic duct merge into the duodenal mucosa) (Fig. 139.2d) and thus do not qualify for one of the three categories discussed earlier and (ii) those that cannot be confidently placed into one of the three categories above because of inadequate processing in the gross room. In our archival database, this group constituted >50% of the cases in the earlier years, but with the improved grossing and classification, more recently, <10% are placed in this category.

Microscopically, ampullary adenocarcinomas are highly versatile in their morphologic appearance. Most are "tubular type," characterized by glandular arrangement. Few of these "tubular" adenocarcinomas are pure intestinal-type tumors that are similar to conventional colonic adenocarcinomas (Fig. 139.3a). They are commonly associated with intestinal-type adenomas. An extensive mucinous component (>50% of the tumor volume) justifies a diagnosis of mucinous adenocarcinoma [20].

Those that resemble pancreatic or bile duct adenocarcinomas are called *pancreatobiliary-type adenocarcinomas* (Fig. 139.3b). Most ampullary cancers that are ampullary duct origin prove to be of this type.

A significant proportion of ampullary carcinomas (>40% in our experience) have a mixed phenotypic appearance and are difficult to place into one of the categories as intestinal or pancreatobiliary [7,18,21]. If noninvasive carcinomas and carcinomas of neighboring sites (pancreatic and CBD) are excluded carefully and the true ampullary carcinomas with the refined definition are analyzed separately, the survival advantage of the intestinal-type over pancreatobiliary-type adenocarcinomas proves to be much less significant [18,22] than previously reported [23–28].

Recently, immunohistochemically based classifications of ampullary carcinomas have been proposed [29,30] and are now being utilized by oncologists in management protocols. These panels are based on the observation that the intestinal phenotype tends to stain for MUC2, CK20, and CDX2 and the pancreatobiliary phenotype stains positively for MUC1 and CK7. However, in carefully selected cohorts analyzing true ampullary carcinomas with the refined definitions, these putative lineage markers and their corresponding panels fail to show direct and significant correlation with prognosis [22]. Having said that, we have found MUC5AC, the gastric marker, which has been overlooked in almost all of the ampullary studies, to be a significant prognosticator of ampullary carcinoma [22].

Since ampullary carcinomas are highly heterogeneous, one ought to be careful when making generalizations regarding its molecular alterations [31]. *KRAS* mutations are found in approximately 40% of cases [31–35] and increased expression of p53 is detected in 70% of cases [32,36–39]. Sixty-four percent of ampullary carcinomas that arise in FAP contain *APC* gene mutations, but only 17% of sporadic ampullary carcinomas carry this type of mutation [40]. Mutations of the β-catenin gene

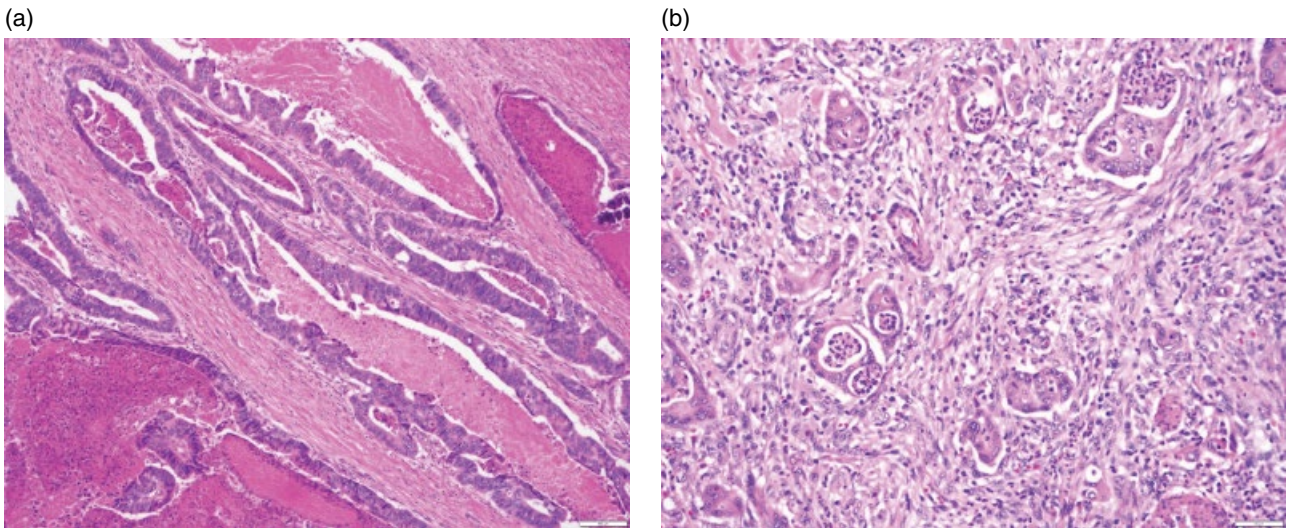

**Figure 139.3** Intestinal-type adenocarcinomas are characterized by longer branching and interconnected tubules with narrower lumina. They often have necrotic/granular debris in their lumina. The cells are more columnar shaped and pseudostratified. Pancreatobiliary-type adenocarcinomas usually form widely scattered, small, well-formed tubules lined by 1- to 2-cell layers of more cuboidal nuclei.

(*CTNNB1*) and alterations of the *SMAD4* (*DPC4*) gene are rare in ampullary carcinomas [41,42]. A small proportion of poorly differentiated ampullary carcinomas with morphologic features that resemble medullary carcinomas of the large bowel demonstrate microsatellite instability [18], and in fact, a recent study has shown that loss of DNA mismatch repair proteins may be as common as in colorectal cancers [43], although the earlier literature had conflicting results on this [44]. Genome array has been utilized to classify ampullary carcinoma into biliary-like and intestinal-like subtypes [45].

Ampullary carcinomas have an overall survival rate far better than pancreatic and DBDC. The 5-year survival rate is approximately 40% [3,19,46–48]. Even the ampullary duct carcinomas, which are mostly pancreatobiliary-type adenocarcinomas (i.e., ampullary counterparts of CBD cancers and pancreatic ductal adenocarcinomas) have a much better prognosis than ordinary pancreatic ductal adenocarcinomas. Invasion size is considered to be an important factor. Ampullary carcinomas often arise from a precursor (adenomatous) lesion, and the mean size of the invasive component is usually significantly smaller than primary pancreatic carcinomas [46]. For instance, IAPN-associated invasive carcinomas often have only a small invasive component (mean 1.5 cm) [3,7]. Not surprisingly, they have a better prognosis [3,7]. Positive margins occur in less than 5% of ampullary carcinomas, compared with at least 35% of pancreatic tumors [46]. The carcinomas arising from the four distinct compartments of the ampulla have different biologic behavior as discussed earlier. Other factors associated with prognosis include tumor budding and perineural and lymphovascular invasion [19,49–53].

### Uncommon Carcinomas in Ampulla

There are other carcinoma types that occur in the ampulla, such as poorly cohesive carcinoma (with or without signet ring cells), medullary carcinoma, and mucinous (colloid) carcinoma [13,14,54–56]. These have some specific associations. For example, poorly cohesive cell carcinomas are usually diagnosed at advanced stage and behave aggressively [55]. In contrast, medullary carcinomas are closely associated with microsatellite instability, and despite their large size and poorly differentiated appearance, their clinical behavior appears to be similar, if not better, than that of other ampullary cancers [54]. Mucinous carcinomas are often of ampullary duodenal origin, often present as advanced tumor and higher lymph node metastasis rate but their prognosis does not seem to be significantly worse. Unlike their lower gastrointestinal counterparts, they do not show association with microsatellite instability [56].

## Distal Common Bile Duct Carcinoma

DBDC is relatively uncommon and thus poorly characterized. Established risk factors for these tumors include parasites and congenital/anatomic variations such as choledochal cyst [57,58] and pancreatobiliary maljunction [59,60] and we have also seen examples associated with low (intrapancreatic) union of cystic and common hepatic ducts [47].

One of the biggest challenges regarding DBDC has been in its definition as to what really qualifies for this category. CBD involvement is extremely common in pancreatic ductal adenocarcinomas if careful sampling is performed [61], and can even show focal circumferential involvement. In addition, ampullary ductal carcinomas are often classified by pathologists as distal CBD carcinoma. Therefore, many studies have included cases from these secondary sites into the analysis of DBDC. Careful dissection of the resection specimens and correlation of the findings with the imaging and clinical findings become crucial in establishing the true primary site in many cases [47]. A recent study reported that intrapancreatic tumors symmetrically/concentrically involving the CBD are likely to be DBDC, which are frequently associated with high-grade biliary dysplasia, lack *KRAS* mutations, and have a superior prognosis with an actual 5-year overall survival of 35%; whereas asymmetric/eccentric involvement generally implies a pancreatic ductal adenocarcinoma, which are commonly associated with high-grade pancreatic intraepithelial neoplasia (PanIN), *KRAS* mutations, and a poor 5-year overall survival of 17% [47,62]. Microscopically, DBDC commonly exhibit a small tubular pattern, having a similar morphology to pancreatic ductal adenocarcinoma. In addition, intraglandular neutrophil-rich debris is often seen [47]. Median survival is better than that for pancreatic ductal adenocarcinoma, but worse than for ampullary carcinoma [47,62]. Poor prognostic indicators include node metastasis, lymphovascular invasion, size of invasion, and margin positivity [47,62]. T-staging of the tumors based on depth of invasion or size is shown to be much more applicable and prognostically relevant [5,47,63].

The vast majority of biliary tract cancers are adenocarcinomas of the pancreatobiliary type. These are very similar to ordinary pancreatic ductal adenocarcinomas and are often histologically indistinguishable from each other except for subtle differences [47].

### Incipient Cancers (Preinvasive Neoplasms)

#### Biliary Intraepithelial Neoplasms

Biliary intraepithelial neoplasia (BilIN) is the term used for nontumor-forming dysplastic lesions in the biliary tract [64]. These flat lesions cannot be detected by

preoperative image analysis or even macroscopic examination. In the current World Health Organization (WHO) guide (2010 edition), the BilIN classification scheme employed a three-tiered approach (BilIN-1, -2, and -3) based on the degree of epithelial atypia [65]. However, it is becoming clear that both biologically and for management purposes, a two-tiered system is more applicable: low grade (encompassing BilIN-1 and -2), and the term high grade for BilIN-3/carcinoma in situ. Since BilIN is most commonly detected incidentally in association with invasive carcinoma, its biological behavior and natural history have been difficult to determine. There are no reliable data regarding the risk of progression of BilIN in the absence of invasive carcinoma. Low-grade dysplasia (BilIN-1 and -2) is largely believed to be clinically inconsequential; however, high-grade dysplasia is believed to be a significant lesion that is often associated with (or progress into) invasive carcinoma with relatively high risk, and thus warrants careful clinical attention [6,66]. It should be noted here that high-grade BilIN can also be detected in resection of risk lesions, such as choledochal cyst, pancreatobiliary maljunction, or primary sclerosing lesions.

Although many biliary carcinomas arise in association with nontumoral dysplastic lesions (BilINs), an estimated 10% arise in mass-forming preinvasive neoplasms (tumoral intraepithelial neoplasms). These are, in essence, biliary counterparts of pancreatic intraductal papillary mucinous neoplasms or intraductal tubulopapillary neoplasms [4,67], or IAPN [7] or intracholecystic papillary tubular neoplasms [68], and comprise two distinct categories: intraductal papillary neoplasm of the bile duct (IPNB) [69,70] and intraductal tubulopapillary neoplasm (ITPN) [71].

#### Intraductal Papillary Neoplasms of the Bile Ducts

IPNB show a florid papillary proliferation of atypical epithelium that fills the bile duct and may lead to a fusiform or cystic dilatation of the affected duct segment [69]. It may be multifocal and extensive ("papillomatosis"). IPNB can be detected by imaging and gross examination. The degree of cytologic atypia is graded with the criteria used for BilIN. Similar to intraductal papillary mucinous neoplasm of the pancreas, IPNB is classified into gastric, intestinal, pancreatobiliary, and oncocytic types [69]. IPNB are often associated with invasive carcinomas [69,71] but invasive carcinomas arising from these tumoral intraepithelial neoplasms have a much more protracted clinical course than those arising from BilIN. Of note, as in the pancreas, those arising in oncocytic examples are currently classified as oncocytic variants of IPNB, but are increasingly being recognized as a separate entity of intraductal oncocytic papillary neoplasm (IOPN), as in the pancreas [72,73] and they are very distinctive in terms of both behavior and molecular characteristics.

#### Intraductal Tubulopapillary Neoplasm

ITPN, initially described in the pancreas, is now also a well-established entity in the biliary tract [71], characterized by prominent tubular configuration of relatively mucin-poor cells. Nodular growth pattern is characteristic and solid areas can be seen [71]. Punctate or geographic foci of necrosis can be present in a "comedocarcinomalike pattern" [71]. ITPN show a pancreatobiliary epithelial phenotype with MUC1 (80%) and MUC6 (30%) expression and negativity for MUC2 and MUC5AC [71]. Molecular pathways altered in ITPN seem to be different from both ordinary cholangiocarcinomas as well as from IPNB. Most ITPN are associated with invasive carcinomas but still have a protracted clinical course [71].

## Nonampullary Duodenal Carcinoma

Nonampullary duodenal carcinomas (NADC) are rare and, when studied, frequently have been grouped with jejuno-ileal adenocarcinoma. However recent studies have shown that they have several distinctive characteristics [74,75]. Those occurring in the distal duodenum can be associated with intestinal-type adenomas; however, many, especially the proximal examples, often form plaque/ulcero-plaque-like lesions rather than arising from large vegetating adenomatous lesions. Mismatch repair protein deficiency was found in 13% of NADC overall, and more commonly in those with the plaque-like growth and pushing-border infiltration [74]. Proximal examples may be arising from Brunner glands or metaplastic gastric-like epithelium [74] and are presumed to have different etiopathogenesis and biology than the colonic adenocarcinomas. In addition, NADC, similar to ampullary carcinomas, are seldom pure "intestinal" type, and instead often exhibit a striking degree of morphologic versatility, with the gastropancreatobiliary being the predominant type and also unusual carcinoma types not described in the remainder of gastrointestinal tract [74,75]. This is also reflected in the frequency with which the hybrid immunophenotype is seen, with less than 50% expressing "intestinal lineage markers" MUC2, CDX2, and CK20 [74]. The presence of gastric pancreatobiliary histology appears to be associated with more aggressive behavior [74,75], and thus it is important to attempt to recognize and report this lineage (no matter the quantity) in any NADC case. The prognosis for NADC is fairly similar to that for ampullary duodenal cancers and better than that for the ampullary ductal cancers discussed earlier (5-year survival 29% vs. 57%)

[74]. More importantly, the prognosis of NADC is incomparably better than that of pancreatic ductal adenocarcinoma [74]. This is important, because, for NADC that occurs close to the pancreas, pancreatic ductal adenocarcinoma with secondary invasion into duodenum becomes an important and highly challenging differential and the latter has been shown to have highly aggressive behavior [61].

## Pathologic Staging of Cancers of this Region

Because of anatomic complexity, the pathologic staging of carcinomas of this region is fraught with challenges. It appears that some of the problems of reproducibility and applicability that have been identified in recent publications [76] are being addressed in the 8th edition of the American Joint Committee on Cancer manual. However, many will continue to present problems in daily practice. Readers are referred to the pertinent publications in this matter [76].

## Neuroendocrine Neoplasms and Related Tumors

Neuroendocrine neoplasms should be regarded as being in two vastly distinct groups: well-differentiated neuroendocrine tumors and poorly differentiated neuroendocrine carcinomas (PD-NEC). Well-differentiated neuroendocrine tumors constitute a heterogeneous group of neoplasms [20] including ordinary carcinoids (often showing serotonin production), "ampullary somatostatinomas" [77] (glandular psammomatous carcinoids with somatostatin positivity at the cellular level), gastrinomas, and other hormonal types as well as nonfunctional tumors [78,79]. Ampullary somatostatinomas are worth specific mention because they seem to be unique to the ampulla, and conversely, a significant proportion of neuroendocrine tumors in the ampulla prove to be of this type. These can be associated with neurofibromatosis and gastrointestinal stromal tumors. Although they are low-grade tumors, they are often infiltrative and show lymph node metastasis in close to half of the cases, but seem to behave in a very protracted fashion nevertheless [77,80,81]. Neuroendocrine tumors are graded based on mitotic activity and Ki-67 index. Accurate counting of Ki-67 can be challenging [82]. Eye-balling is discouraged. Currently, a manual count performed on camera-captured printed images of tumor hotspots appears to be the most practical approach [82].

A distinct but related entity is *duodenal gangliocytic paraganglioma*, a neoplasm that combines features of a well-differentiated neuroendocrine tumor with those of a nerve sheath tumor admixed with ganglion cells [83–86]. This is a very peculiar entity that is almost unique to ampulla and duodenum in the vicinity of the ampulla. The vast majority of the cases seem to be benign with only a few showing lymph node metastasis, and even those seem to have benign behavior.

PD-NEC of this region need to be distinguished from the well-differentiated neuroendocrine tumors. They often occur in association with adenocarcinomas or glandular preinvasive neoplasms (adenomatous lesions). They are typically high-grade carcinomas, recognizable as such by morphology, showing highly atypical cytology (with differential diagnosis of other poorly differentiated carcinomas, melanomas, and lymphomas) as well as brisk mitotic activity and necrosis characteristic of high-grade malignancies. Ki-67 labeling index is typically higher than 50%. Retinoblastoma gene alteration is common. Recent studies suggest that such tumors warrant *cis*-platinum treatment, as opposed to the well-differentiated neuroendocrine tumors which grow slowly and not only do not require *cis*-platinum, but also do not benefit much from it. They have a highly aggressive behavior.

## Pseudotumors that Commonly Mimic Cancer

### Paraduodenal Pancreatitis

*Paraduodenal* (*groove*) *pancreatitis* (PDP) often present with the clinical/imaging picture of "periampullary cancer"; in fact, close to two-thirds of PDP cases are preoperatively diagnosed as "cancer" [87–90]. PDP occurs predominantly in male patients who are generally younger (mean age 50 years) than the patients with cancer (mean age 64 years), and with a history of alcohol, smoking, diabetes, or prior gallstone disease [87–90]. Grossly, there is typically a pseudotumor characterized by thickening and scarring of the duodenal wall, particularly in the area corresponding to the minor papilla, but it often extends to the adjacent pancreatic head tissue, often with sieve-like cystic changes in the duodenal wall. Often, there is marked mucosal nodularity in this region as well, but ulceration is uncommon.

*Fibroinflammatory biliary stricture* (FIBS) [91] is the name proposed for idiopathic sclerosing pseudotumors that result in stricture of the bile ducts that leads to cholangiocarcinoma diagnosis. It is unrelated to autoimmune pancreatitis, primary sclerosing cholangitis, cholangiocarcinoma, prior bile duct injury or repair, and

choledocholithiasis [91]. By comparison with patients having bile duct cancer, FIBS patients present at a significantly younger age, are more likely to be female, and have a high incidence of coexisting autoimmune diseases [91]. A subset of these cases appear to represent IgG4-related sclerosing cholangitis. Because preoperative cytology is not diagnostic of FIBS, surgical resection remains the mainstay of diagnosis and treatment, while immunosuppression may reduce the risk of recurrence.

## Secondary Tumors

Almost every malignant neoplasm described in the body can also occur in this region [6,66]. These include melanomas, lymphomas, and sarcomas, all of which can mimic primary cancers and thus ought to be considered in the differential diagnosis of more common adenocarcinomas, both at clinical and pathologic evaluation.

## Introduction

Ampullary malignancies belong to the family of periampullary tumors, which arise from ampulla of Vater. The significant premalignant potential and strategic location of ampullary neoplasms makes them unique [1]. Typically ampullary tumors are classified as benign or malignant. Benign neoplasms account for less than 10% of periampullary neoplasms [1,2] and ampullary carcinomas are the second most common periampullary carcinomas (after pancreatic adenocarcinoma) [3]. Although ampullary adenomas are classified as benign, they have a tendency to undergo malignant transformation. The true ampullary cancer is usually difficult to distinguish from other periampullary malignancies and is usually diagnosed at an earlier stage, which means it has a better prognosis compared to periampullary cancers originating from the bile or pancreatic duct [2]. An aggressive diagnostic and therapeutic approach is therefore needed for these lesions.

## Epidemiology and Biologic Behavior

In autopsy series, periampullary adenoma prevalence is estimated to be 0.04–0.12 [4,5], however prevalence increases with the widespread availability of flexible endoscopy and screening programs. The incidence of ampullary carcinoma is 4–6 cases per million population and accounts for 4–8% of periampullary carcinomas [6,7]. Caucasian populations are mostly affected [6], there is a male predominance [7], and the peak incidence is in the seventh decade.

Both benign and malignant ampullary tumors arise in the setting of a genetic syndrome or spontaneously. Familial adenomatous polyposis (FAP) is the most common genetic predisposition [8] and most patients with FAP manifest some degree of dysplasia in the ampulla [9,10]. The second most common cause of death in patients with FAP is periampullary tumor [7]. Gardner syndrome, Lynch syndrome, neurofibromatosis type 1, and Muir–Torre syndrome are the other reported genetic predispositions for ampullary carcinoma [11–14].

Local factors are believed to play an important role in sporadic tumors and the earliest histopathologic changes are seen in the common pancreatobiliary channel, followed by the pancreatic duct [15]. Concentrated bile is thought to produce mutagenic effects on ductal epithelium resulting in epithelial apoptosis that is prone to malignant transformation [16]. On the other hand, chronic liver fluke infection is reported to be a risk factor for ampullary carcinoma [7].

## Pathology and Pathogenesis

Ampullary malignancies are classified macroscopically as: (i) intra-ampullary (intramural protruding), (ii) periampullary (extramural protruding), or (iii) ulcerating ampullary [7]. Ulcerating ampullary lesions have high lymph node metastasis rate and are mostly diagnosed at an advanced stage. Adenocarcinoma account for 75% of ampullary neoplasms, followed by benign adenomas (20%) and neuroendocrine tumors (5%) [3]. Villous and tubulovillous adenomas are the most common benign lesions; the others include hemangioma, lipoma, leiomyoma, lymphangioma, and leiomyofibroma [1,8–10,16,17]. Adenocarcinoma (90%) is the most common ampullary malignancy [3] (Box 140.1).

Most of the ampullary neoplasms exhibit an adenoma–carcinoma sequence, which can be seen elsewhere in

gastrointestinal tract [18–26]. Ampullary neoplasms are classified histopathologically into pancreatobiliary and intestinal types [27,28]. The intestinal type classically arises from an adenoma, however a premalignant precursor lesion is often absent in the pancreaticobiliary type [7,9]. *KRAS* mutation is common (24–40%) in ampullary carcinogenesis, and is also observed in colon cancer [29,30]. p53 overexpression is also a common (46%) molecular finding. Immunochemically, the intestinal type expresses apomucin (MUC2) and cytokeratin 20 and the pancreatobiliary type overexpresses cytokeratin 7, but not MUC2 [31]. Although several studies suggest that the biology of ampullary neoplasms is similar to the intestinal type (ampullary neoplasms are histologically more often identical in intestinal origin, exhibiting adenoma–carcinoma sequence, and *KRAS* mutation is common) [9,29,32], rather than the pancreaticobiliary type (which is believed to have a worse prognosis), current literature reveals comparable results regarding the frequency, metastasis rates, and prognosis of these two types [27,28,31].

## Clinical Features

As with ampullary adenomas, the presenting symptoms of ampullary adenocarcinomas are nonspecific (the most common is painless obstructive jaundice, which is seen in two-thirds of patients) [33–37]. Occult gastrointestinal bleeding, diarrhea, fatigue, weight loss, and duodenal obstruction may be the symptoms associated with ampullary cancer. Due to cholestasis, 25% of ampullary adenomas develop common bile duct stones [38]. Furthermore, small distal intraductal benign adenomas simulate an ampullary malignancy and may cause significant biliary obstruction [39].

## Diagnosis and Staging of Ampullary Malignancy

Because ampullary adenomas have a premalignant potential and an occult focus of carcinoma may be present within an adenoma [18,24,40–42], the primary concern in evaluating ampullary lesions is to rule out malignancy. Diagnosis is usually established by the combination of radiology, endoscopy, and histology, which are also similar in evaluating both ampullary adenoma and carcinoma. However, without complete resection, it is usually difficult to differentiate between them. Ampullary carcinomas are frequently diagnosed with their macroscopic appearance on endoscopy and histopathologic examination of the obtained biopsy specimen. In patients with obstructive jaundice, transabdominal ultrasound (TUS) is the first choice of imaging to rule out other causes such as choledocholithiasis and pancreaticobiliary tumors, however it rarely reveals the neoplasm itself. In the setting of staging and preoperative evaluation, as well as differentiating an ampullary adenoma from carcinoma, cross-sectional techniques and endoscopic ultrasound (EUS) are usually preferred.

### Cross-Sectional Imaging

Although computed tomography (CT) is superior to TUS in evaluating ampullary lesions, it is not sensitive enough for staging and detecting small lesions. It is also highly accurate in detecting distant metastasis, which usually includes lymph nodes, peritoneum, liver, bone, and lungs. Magnetic resonance imaging (MRI) can provide more detailed images of the ampulla and periampullary tissue [43]. Ampullary cancers are usually hypodense distinct masses on MRI with magnetic resonance cholangiopancreatography (MRCP). A double-duct sign" (dilation of both pancreatic and bile duct) or only the dilated bile duct can be observed, however single dilation of pancreatic duct is rare [44]. Positron emission tomography has not been well studied in detecting ampullary malignancies, but is highly sensitive in detecting distant metastasis [45].

### Endoscopy

Most ampullary lesions are apparent endoscopically. Ulcerated masses, lesions >3 cm, ampullary rigidity, and nonlifting of the periampullary component with submucosal injection are highly suspicious for malignancy.

The ampulla is best examined and biopsied with a side-viewing duodenoscope. Endoscopic retrograde cholangiopancreatography (ERCP) does not only help obtain biopsies, it also excludes an associated stricture or stone and permits an evaluation of the adenoma's extension into the pancreatic or biliary duct (Fig. 140.1). However, endoscopic forceps biopsies have high false-negative rates (16–70%) and comparable diagnostic accuracy rates (45–80%) [46–50]. In addition, sphincterotomy may interfere with the performance of biopsy in detecting a malignancy [51,52]. Obtaining multiple biopsies can increase its performance [42]. As a general rule, negative endoscopic biopsy for malignancy does not completely exclude a malignant focus in an adenoma. Therefore, diagnostic accuracy of biopsies can be increased by obtaining at least six biopsies, preferably at least 48 hours following sphincterotomy [40,41], and by complete resection of ampullary adenomas (endoscopic ampullectomy). Moreover, narrow band imaging with magnification endoscopy has been suggested to have a possible role in differential diagnosis of ampullary masses, since, in contrast with carcinomas, abnormal vessels are not present in ampullary adenomas [53].

## Endoscopic Ultrasound

With its ability to place an ultrasound transducer in close proximity to the ampulla, EUS is superior to CT, MRI, and TUS for tumor staging and is as sensitive as duodenoscopy in detecting small ampullary tumors (Fig. 140.2). EUS and intraductal ultrasonography provide detailed information about the endoscopic appearance, tumor size, localization, tumor extension, and existence of metastatic lymph nodes. These data help the preoperative staging of ampullary malignancy [54–64].

EUS-guided fine-needle aspiration (FNA) can assist in providing tissue from ampulla, lymph nodes, and surrounding deeper structures. However, as for endoscopic biopsies, EUS-FNA does not rule out a malignant focus within an adenoma. Besides, the overall accuracy of EUS-guided fine-needle biopsy (EUS-FNB) is reported to be 89%, with 82% sensitivity and 100% specificity [65].

EUS is the best modality for T-staging of ampullary carcinoma (invasion of adjacent organs), which is reported to have 70–90% accuracy in several studies [56,66,67]. EUS also has 70% sensitivity and 90% specificity for detecting vascular invasion [68,69]. On EUS, T2 is

**Figure 140.1** (a) Ampullary adenoma on forward-viewing endoscopy. (b) CT image of the same lesion. (c) Endoscopic retrograde cholangiopancreatography of the same patient showing distally complete obstruction of bile duct.

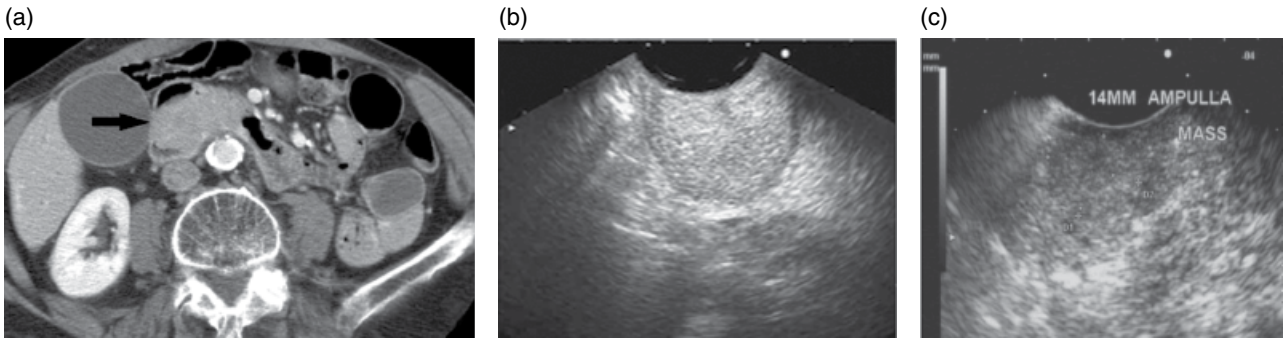

**Figure 140.2** (a) A large soft tissue mass consistent with ampullary cancer in duodenal wall on CT. (b) Ampullary adenoma on endoscopic ultrasound (EUS). (c) 14 mm ampullary cancer on EUS.

called when the tumor invades the muscularis propria of the duodenum, T3 is extension into the pancreas <2 cm, T4 is extension into the pancreas >2 cm or contiguous spread to adjacent organs. However, the accuracy of EUS for N-staging is lower, with a sensitivity of 21–71% and a specificity of 38–100% [54,67,69,70].

### Staging

Ampullary tumors are commonly classified according to the American Joint Committee on Cancer (AJCC)/International Union Against Cancer (UICC) Staging, TNM staging system [71] (Table 140.1). For Stages 0, IA, IB, IIA, IIB, III, and IV, 5-year survival rate has been reported as 49%, 40%, 44%, 33%, 26%, 16%, and 4%, respectively [27,31]. Lymph node metastasis is a negative predictor for overall survival [72,73], however, at perioperative evaluation 42–60% of patients are reported to have metastases [74,75].

**Table 140.1** TNM and American Joint Committee on Cancer (AJCC)/International Union Against Cancer (UICC) Staging Systems for Ampullary Cancer.

| TNM stage | Criteria |
|---|---|
| Tx | Primary tumor cannot be assessed |
| T0 | No evidence of primary tumor |
| Tis | Carcinoma in situ |
| T1 | Tumor limited to ampulla of Vater or sphincter of Oddi |
| T2 | Tumor invades duodenal wall |
| T3 | Tumor invades pancreas |
| T4 | Tumor invades peripancreatic soft tissue or other adjacent organ or structures other than pancreas |
| Nx | Regional lymph nodes cannot be assessed |
| N0 | No regional lymph node metastases |
| N1 | Regional lymph node metastases |
| M0 | No distant metastases |
| M1 | Distant metastases |

| AJCC/UICC Stage | Tumor | Node | Metastasis |
|---|---|---|---|
| 0 | Tis | NO | MO |
| IA | T1 | NO | MO |
| IB | T2 | NO | MO |
| IIA | T3 | NO | MO |
| IIB | T1–T3 | N1 | M0 |
| III | T4 | Any N | M0 |
| IVB | Any T | Any N | M1 |

## Management and Treatment

It can be difficult to differentiate an ampullary adenoma including a carcinoma focus and true ampullary carcinomas from other periampullary cancers (prognosis is better in ampullary carcinomas). Furthermore, there are no consensus and guidelines regarding the optimal management of patients with ampullary adenomas. It is not clearly defined who requires excision (endoscopic or surgical) and who should be followed-up with surveillance endoscopy [76]. The initial assessment in diagnosis is looking for a sign of malignancy with ERCP, which is also useful in differential diagnosis. EUS is usually preferred for further preoperative evaluation and staging.

Removal of the adenoma is suggested in cases with sporadic adenoma, especially those that have high-grade dysplasia or are causing a symptom. Endoscopic surveillance with biopsies every 6–12 months may be recommended when a patient declines excision. In cases with FAP, excision should be suggested since prognosis seems better compared with sporadic cases [77]. On the other hand, removal of ampullary adenoma does not eradicate cancer risk, because multiple upper intestinal adenomas are usually present in patients with FAP.

There are three excision options for ampullary neoplasms: endoscopic ampullectomy (Fig. 140.3), surgical ampullectomy (surgical local excision), and Whipple's procedure (pancreaticoduodenectomy). The decision is based on the degree of surgical risk, life expectancy, the stage of malignancy, and the patient's wishes. Although there are no definite criteria on which patients require endoscopic or surgical removal, especially in centers that are not experienced in advanced endoscopy, patients with large lesions, adenomas that contain carcinoma, lymph node involvement, and adenoma ingrowth into bile duct or pancreatic duct on EUS should be referred to surgery. Patients with ampullary carcinoma without lymph node and vessel involvement and who are in early stages (Tis and T1) should be candidates for endoscopic ampullectomy [78]. There are comparable reports in the literature regarding the size or diameter above which an ampullary mass should not be removed endoscopically. Lesions ranging from 1.3 cm to 4 cm are reported to be treated endoscopically [38,74,79–81]. Generally, lesions less than 2–3 cm should be suggested for endoscopic ampullectomy in the absence of other malignant findings.

The only curative treatment for carcinoma and to eliminate histologic progression to carcinoma and eradicate a malignant focus within an adenoma is R0 (margin-negative) resection. Although pancreaticoduodenectomy has been associated with higher morbidity and mortality rates compared with surgical ampullectomy, it achieves curative excision for ampullary adenomas with almost no local recurrence risk [75,82,83], and 90% curative

**Figure 140.3** (a) Ampullary adenoma in a patient with familial adenomatous polyposis. (b) Endoscopic appearance of the lesion 2 weeks after endoscopic ampullectomy. (c) Endoscopic appearance of the lesion 3 months after endoscopic ampullectomy.

**Table 140.2** Stage-based approach to endoscopic and surgical management of ampullary malignancy.

| Stage | Therapeutic approach High operative risk | Low operative risk |
|---|---|---|
| T0 adenoma | Endoscopic ampullectomy | Endoscopic ampullectomy |
| T1a malignancy | Endoscopic ampullectomy | Whipple |
| T2 malignancy | Endoscopic ablation | Whipple |
| T3 malignancy | Stenting | Whipple |
| T4 malignancy | Stenting | Biliary bypass |

resection rates for carcinomas [84–88]. In addition, surveillance endoscopies are not needed thereafter. On the other hand, with the advantages of lower morbidity and mortality rates, surgical ampullectomy has 0–50% recurrence rates for adenomas and lower survival in ampullary carcinoma patients compared with pancreaticoduodenectomy [48,89–94]. Patients with evident malignancy on an adenoma should be suggested for pancreaticoduodenectomy rather than either endoscopic or local surgical excision. After pancreaticoduodenectomy, 5-year survival rates for lymph node metastasis-negative patients are 59–70%, and for positive patients rates are 16–25% [95–97]. Although some studies report that endoscopic ampullectomy has lower morbidity and similar efficacy rates (46–93%) than surgical ampullectomy (0–30%), the role of endoscopic ampullectomy is still controversial [98,99]. Complete removal of the neoplasm is the aim of the procedure and en bloc excision is the preferred method, since occult carcinoma and negative margins should be ensured entirely. Monopolar or bipolar coagulation [2,42] argon plasma coagulation [80,81], photodynamic therapy [40], and Nd:YAG laser ablation [2,40,100] are thermal ablation methods when piecemeal excision is performed and the lesion cannot be excised completely. A stage-based approach to surgical and endoscopic management of ampullary malignancy is summarized in Table 140.2.

After ampullary cancer resection neither the National Comprehensive Cancer Network (NCCN) [101] nor the European Society for Medical Oncology (ESMO) [102] guidelines include management strategies. However, especially in lymph node-positive patients, two large randomized controlled studies suggested adjuvant chemotherapy and chemoradiation therapy with a median survival of 58 and 76 months [103] and an increased 5-year survival rate from 6% to 28% [97]. In addition, there is no consensus on the management of unresectable ampullary carcinomas, and the optimal chemotherapy regimen for true ampullary cancers has not been established yet.

Nonsurgical therapy methods such as endoscopic ampullectomy, photodynamic therapy, and laser ablation should be provided in the palliative treatment of patients with ampullary carcinoma who decline surgery or those are not candidates for surgery. As a cancer-related complication, duodenal and biliary obstructions are the major causes of morbidity in unresectable ampullary cancers. These patients can be treated palliatively either by surgical bypass or endoscopic stenting [104–110].

## Posttreatment Surveillance

Patients with ampullary adenoma who have been treated with either endoscopic or surgical ampullectomy are at risk of recurrence and require endoscopic surveillance. In contrast, surveillance is not needed after pancreaticoduodenectomy except for patients with FAP. The suggested surveillance is endoscopic evaluation after 1–6 months of ampullectomy and repeated evaluations in 3–12 months for 2 years. After 2 years, surveillance may continue as with the surveillance of flat colonic polyps (every 3 years if initial histology shows high-grade dysplasia, otherwise every 5 years) [76]. Since patients with FAP are at risk of development of upper intestinal polyps other than ampullary adenomas, patients with FAP require regular endoscopic surveillance according to the Spigelman classification [111]. In patients with ampullary cancer, endoscopic surveillance similar to that for locally resected ampullary adenomas may be recommended, although no guidelines are available.

## Long-Term Results of Surgical Resection

Factors affecting prognosis after surgery include the depth of invasion, lymph node involvement, and surgical clean margins [6,21,48,87,112]. For patients with node-negative cancer 5-year survival rate is 64–80% and for node positives 17–50% [29,48,84,86,96,113–115]. In a series, 5-year overall survival was 84%, 70%, 27%, and 0% for Stages I, II, III, and IV, respectively [48,112].

# Endoscopic Treatment of Adenomas of the Ampulla of Vater: Techniques, Results, Benefits, and Limitations

*Natsuyo Yamamoto, Hiroyuki Isayama, and Kazuhiko Koike*

*Department of Gastroenterology, Graduate School of Medicine, University of Tokyo, Tokyo, Japan*

## Introduction

Tumors of the ampulla of Vater are comparatively rare and arise from the duodenal papilla. Symptoms of ampullary tumor include biliary colic, obstructive jaundice, recurrent cholangitis, and pancreatitis. These are arise due to obstruction of the bile and pancreatic ducts. Occult bleeding is relatively common. However, most ampullary tumors are asymptomatic. They are often found incidentally by screening endoscopy. There is no consensus on when ampullary adenomas should be followed up and when they should be resected.

Ampullary tumors are thought to develop either from the intestinal epithelium or the epithelium covering the pancreatobiliary ducts. Most ampullary tumors are adenomas or adenocarcinomas [1]. From the results of familial adenomatous polyposis surveillance, ampullary adenoma is thought to be associated with the progression of adenoma to carcinoma and is recognized as a premalignant lesion, as is colonic adenoma [2–5]. Though the natural history of ampullary adenoma has not been well investigated in sporadic lesions, many endoscopists advocate the resection of ampullary adenoma in this regard.

## Endoscopic Papillectomy

Classically, surgical resection (pancreaticoduodenectomy or transduodenal ampullectomy) has been recognized as the gold standard for treatment of ampullary adenoma. Surgical resection has the advantage of a low recurrence rate, but it is too invasive for cases of localized ampullary adenoma. Currently, endoscopic papillectomy has been accepted as a less invasive alternative to surgical treatment for cases of ampullary adenoma in patients for whom curative resection was possible.

Endoscopic papillectomy was first documented by Suzuki et al. in 1983 [6] and by Binmoeller et al. [7] in 1993 in English. It involves the resection of the mucosa and submucosa of the duodenal wall, in the area of the anatomical attachments of the ampulla of Vater, including the tissue around the bile duct and the pancreatic duct orifices [8].

At present, the indications for endoscopic papillectomy are still not established. The American Society for Gastrointestinal Endoscopy 2015 guideline did not show selection criteria for endoscopic papillectomy [9]. From previous reports, endoscopic papillectomy is accepted for patients with ampullary adenomas smaller than 4–5 cm [10] without ductal extension. Intraductal involvement of the lesion is considered as a noncurative lesion, or those with a high risk of recurrence [11]. Ampullary cancer is not recommended for endoscopic resection because of the risk of lymph node metastasis. In contrast, high-grade dysplasia or carcinoma which is restricted to the mucosal layer is reported to be suitable for endoscopic papillectomy; there is a rare risk of lymph node metastasis [12].

## Preprocedural Evaluation

The preprocedural diagnosis of ampullary tumor is performed through endoscopic appearance, biopsy, endoscopic ultrasound (EUS), and endoscopic retrograde cholangiopancreatography (ERCP) with intraductal ultrasonography (IDUS).

### Endoscopic Appearance and Pathological Diagnosis

A duodenoscope is generally used to visualize ampullary tumors. The typical endoscopic finding of ampullary adenoma is a villous tumor. The characteristic feature distinguishing between adenoma and adenocarcinoma is the presence of ulceration, which has been observed in patients with malignancy but never in patients with benign disease. The fold convergence of the duodenum wall around the ampulla indicates tumor invasion into the duodenal wall. However, ampullary adenomas cannot always be distinguished from ampullary carcinomas according to endoscopic appearance alone. Observation of the ampullary tumor with narrow-band imaging (NBI) is reported to be helpful for providing endoscopic images of microvessels and the surface structure of tumors [13] or to enhance tumor margins [14].

Biopsy is very important in differentiating adenoma from carcinoma or other tumors. However, the accuracy of biopsy is reportedly not high, at around 70% [15–18]. It is thought that severe atypism is observed in the ampullopancreatobiliary common duct rather than in the ampulla–duodenum. Therefore, biopsy must be taken from the deep portion of the orifice. When adenocarcinoma is suspected, biopsy followed by endoscopic sphincterotomy [19] or EUS-guided fine-needle aspiration are considered. However, it is also reported that the sensitivity of biopsy did not change after sphincterotomy [20]. In these results, endoscopic papillectomy is sometimes performed as diagnostic treatment or a major biopsy prior to surgery.

### Endoscopic Retrograde Cholangiopancreatography, Intraductal Ultrasonography, and Endoscopic Ultrasound

ERCP with both biliary and pancreatic duct evaluation should be performed at the time of endoscopic resection to assess for evidence of extension into either ductal system. IDUS is inserted through the working channel of the jejunoscope and into the bile and pancreatic ducts after cholangiopancreatography. IDUS may be useful for imaging the detailed anatomy of the ampulla of Vater.

EUS is essential for deciding whether or not endoscopic resection is indicated. The EUS provides information on the presence of invasion to the muscularis propria, intraductal extension of the lesion, and metastasis to regional lymph nodes. EUS is reported as being superior to computed tomography (CT), magnetic resonance imaging, or transabdominal ultrasonography as a diagnostic modality [21,22]. In meta-analysis, the pooled sensitivity and specificity of EUS in the diagnosis of T1-stage tumors were 77% and 78% [23]. The combination of EUS and IDUS was reported to improve the accuracy of preprocedural diagnosis [21].

It is uncertain whether all cases of ampullary adenoma require EUS before endoscopic resection. Some experts suggest that EUS is not required when the tumor is 1 cm or less in diameter or when obvious endoscopic signs of malignancy are not present [24].

## Techniques

In general, endoscopic papillectomy is performed with a duodenoscope in the same manner as polypectomy, using a snare, followed by pancreatic duct stenting for prophylaxis of postprocedural pancreatitis (Fig. 141.1).

Achieving en bloc resection without complication is fundamental in performing endoscopic papillectomy. Complete pathologic evaluation is important for the evaluation of the resected margins or malignant foci with invasiveness, as previous pathologic diagnosis is often incomplete. In a few case reports, balloon catheter-assisted papillectomy was documented to facilitate en bloc resection [25,26]. Piecemeal resection is performed for large lesions, which aims to decrease complications and recurrence. However, histopathologic evaluation of the resected margin is then difficult. There are no data comparing safety or recurrence rates between en bloc and piecemeal resections.

### Submucosal Lifting

Submucosal injection with epinephrine diluted in saline solution and indigo carmine prior to endoscopic papillectomy has been performed in some reports [27, 28]. Submucosal lifting may reliably indicate malignancy, may prevent the effect of electrosurgical current, and therefore may prevent postprocedure pancreatitis. It may be useful for cases with predominant lateral periampullary extension [29]. However, the mucosal tissue at ampullary lesions does not lift because of tethering by the biliary and pancreatic ducts. In addition, the elevation of mucosal tissue around the papilla makes snaring difficult. Therefore mucosal injection is not routinely recommended. Recently, “underwater ampullectomy” without submucosal lifting for lateral spreading tumor has been introduced, but its effectiveness is still under investigation [30].

### Snaring and Transection

Electrosurgical snare resection is the most common technique. There is no specific type or size of snare for endoscopic ampullectomy. The snare is placed with the tip on the oral side of the lesion. The snare is closed at

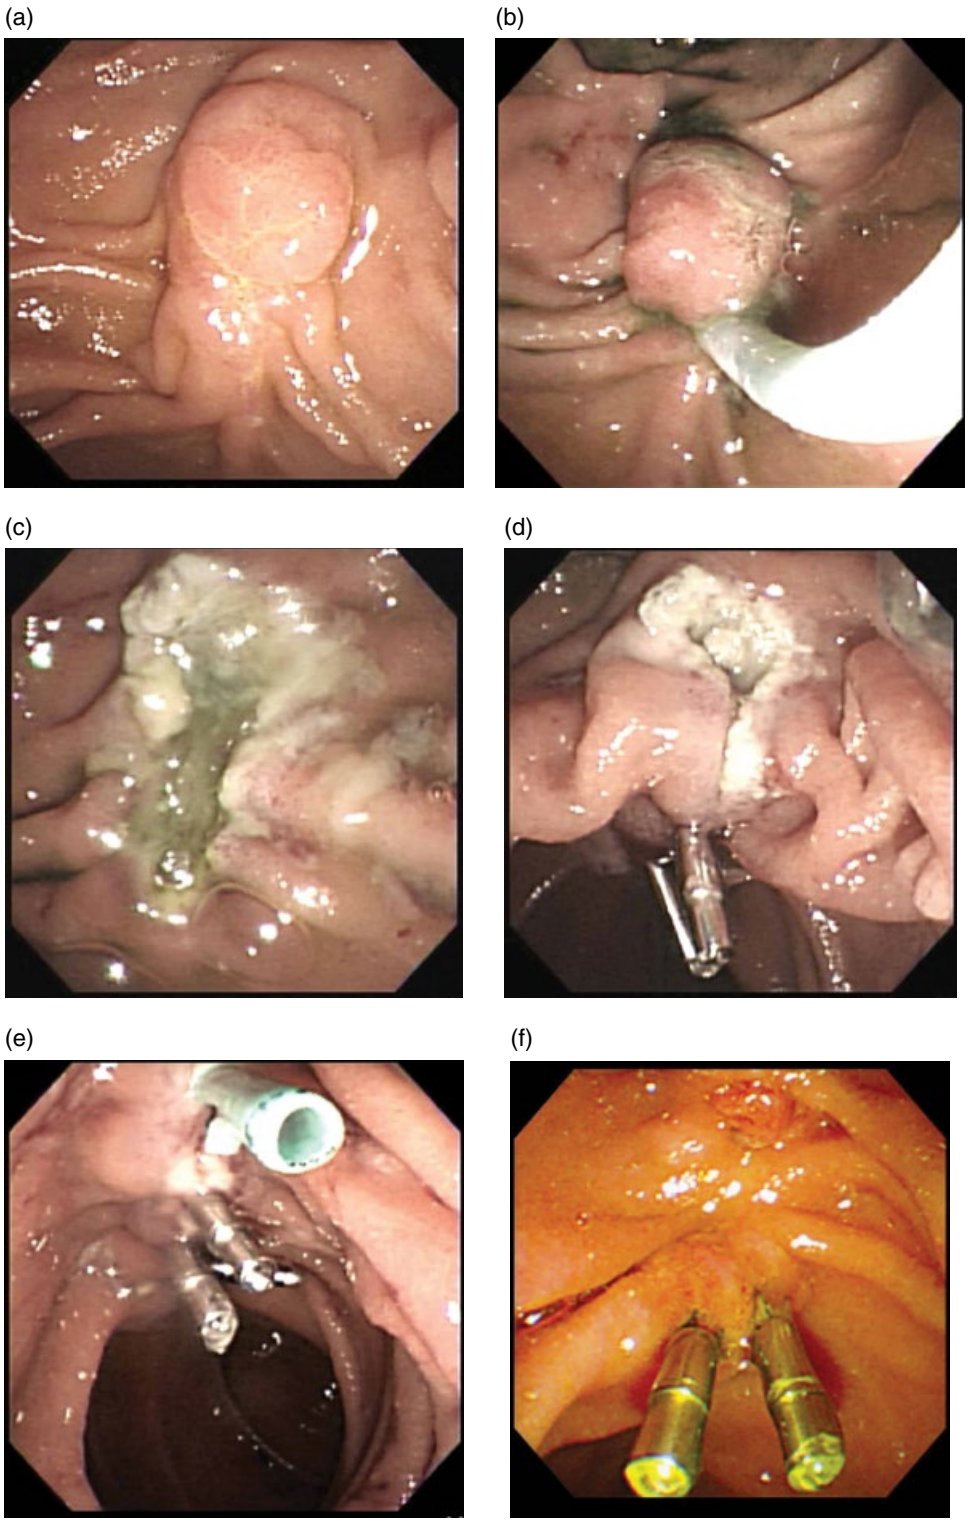

**Figure 141.1** Technique of en bloc ampullectomy by snaring. (a) Endoscopic view of ampullary adenoma. (b) The adenoma is grasped by a snare. (c) The adenoma is resected. (d) The anal side of the ulcer was closed by using clipping to prevent bleeding. (e) A 5F pancreatic stent is placed for the prevention of obstructive pancreatitis. (f) Endoscopic view at 1 year after the resection.

the base, and the lesion is resected. In some reports, an incision is made with an electrosurgical needle knife circumferentially around the lesion to facilitate snare capture [17]. Although there are no general recommendations regarding the optimal current and power output, there are reports of both pure cutting and blended cutting. Many endoscopists prefer the "blended" or "ERBE Endocut" mode, which aims to decrease bleeding by coagulation.

### Retrieval of the Resected Tumor

Retrieval of the specimen is very important for accurate evaluation and tumor staging. Immediately after the transection, the specimen is grasped by a snare and removed from the body in order to avoid intestinal migration. If the specimen is large, a basket catheter or net forceps should be used. It is important that the tissue is not collected by aspiration through the endoscope, as this will cause the specimen to fragment, making it impossible to evaluate the cut end histopathologically.

### Treatment of Remnant Tissue

Snares, biopsy forceps, and thermal ablation such as argon plasma coagulation are used for the treatment. Argon plasma coagulation is the most common, and is useful for ablating remnant tumor as well as for hemostasis or prophylaxis of postprocedural bleeding. However it must be carefully applied to the tissue around the pancreatic and bile duct orifice because it may induce bile duct obstruction or pancreatitis by the thermal effect.

### Sphincterotomy/Pancreatic and Biliary Stent Placement

Sphincterotomy is often performed during endoscopic papillectomy to facilitate pancreatic and biliary drainage after resection. Some studies suggest that bilateral sphincterotomy with pancreatic duct stent placement before resection would avoid the difficulty of locating the orifice at the base of the ampullary lesion [27].

Pancreatic stent placement is recommended to prevent postprocedural pancreatitis. In general, a pancreatic stent of 5F or 3F diameter is used after the resection of the tumor. The techniques of bilateral sphincterotomy with pancreatic duct stent placement before resection [27], pancreatic duct wire-guided endoscopic papillectomy, or retrieval of intraductally migrated pancreatic stents after endoscopic papillectomy [31] have been introduced.

The aim of pancreatic stenting is to maintain the pancreatic duct orifice and to prevent pancreatic duct obstruction. One small randomized control trial concluded that pancreatic stenting prevented postprocedural pancreatitis [32]. However, pancreatic damage by thermal ablation cannot be prevented. A recent retrospective study also suggested that routine pancreatic stent placement may not be necessary.

Apart from the risk of postprocedural pancreatitis, obstructive cholangitis does not frequently occur except when caused by obstruction by a clot due to major bleeding. Prophylactic biliary stent placement is generally unnecessary.

## Clinical Results

Curative resection by endoscopic papillectomy is reported to be achieved in 52–92% of cases [7,11,16,17,27,33–35]. Multiple procedures may be required to completely remove all adenomatous tissue. Larger lesions are more likely to be incompletely excised at the initial endoscopic procedure. The recurrence rate of ampullary adenoma after endoscopic papillectomy is reported to be 0–33%, with a median follow-up period of from 19 to 65 months [16,17,33–36].

## Complications

At present, endoscopic papillectomy is considered a less invasive option then surgery, but is a high-risk endoscopic procedure. Therefore the procedure requires specialist expertise. Careful observation after the procedure is important to detect acute complications.

Endoscopic papillectomy is associated with an increased risk of postprocedural pancreatitis, which is reported to be 3–25% [16,37]. Pancreatitis is considered to occur due to obstruction of the pancreatic duct and thermal damage to the pancreatic parenchyma. Currently, as described earlier, pancreatic stent placement is recommended though it does not prevent pancreatitis in all cases.

Postprocedural bleeding is also a serious complication. The duodenal papilla is a hypervascular area and bleeding is often observed on the anal side of the resected margin [38]. Postprocedural bleeding can be treated by adrenaline injection, argon plasma coagulation, and clipping. Hemostatic procedures may induce perforation or pancreatitis. Therefore excessive hemostasis should be avoided.

Perforation usually occurs in the retroperitoneal area. The patient may not have peritoneal irritation signs. However, pancreatitis or bleeding is often observed concurrently with perforation. When perforation is

suspected, evaluation by CT scan is informative. If perforation occurs, surgery may be considered, but selected patients can be treated conservatively with antibiotics [16,17,27].

Late adverse events include the development of pancreatic or biliary stenosis [7,16,17,27,34,35].

## Postprocedural Surveillance

Although there is no consensus, surveillance post procedure is important for detecting local recurrence. There are some reports that in sporadic cases of duodenal adenoma including ampullary adenoma there is a higher risk for the development of colorectal neoplasia [39]. At present screening colonoscopy should be performed in patients with duodenal or ampullary adenomas [9].

## Conclusions

Endoscopic papillectomy has been established as a first-line treatment for ampullary adenoma without ductal extension. There is still no consensus on preprocedural assessment, technique of endoscopic papillectomy, management of complications, or surveillance. Biopsy, EUS evaluation for large lesions, ERCP for further information, pancreatic stent placement for the prevention of pancreatitis, and endoscopic surveillance are recommended.

## Introduction

Cancer of the ampulla of Vater is a neoplastic lesion of two anatomically different structures of the duodenal wall, including the papilla and ampulla. Histologically, the ampulla of Vater is complex and consists of three different cell types lining the duodenum, common bile duct, and pancreatic main duct. Neoplastic lesions of the ampulla have histologically corresponding different cellular characteristics. From a histological point of view, determination of the origin of a periampullary tumor is often uncertain and it may be difficult to determine whether it is duodenal, ampullary, papillary, distal bile duct, or pancreatic cancer. Adenoma of the papilla is not infrequent (see Chapter 141); cancer of the ampulla seems to be the most frequent periampullary malignancy, but the ratio to pancreatic head cancer is 1:12. Carcinoma of the papilla of Vater, defined as the junction of the biliary and pancreatic ducts within the duodenum, accounts for 6–20% of all periampullary tumors. Ampullary cancers frequently contain adenomatous tissue, which is considered a precursor lesion [1–4].

An adenoma–carcinoma sequence with stepwise accumulation of genetic alterations, similar to colorectal cancer, has been proposed for tumors of the ampulla [5,6]. Because the ampulla is lined with epithelial cells derived either from biliary and pancreatic or duodenal lineages, many ampullary adenocarcinomas exhibit different histologic subtypes. Histologic, immunohistologic, and molecular biologic characteristics have established an intestinal and pancreatobiliary histologic subtype of neoplasia [7,8]. The prevailing cancer cell type is intestinal (45%) compared to the pancreatobiliary type (27%) [9]. The influence of the histologic cell type of the tumor on prognosis is not yet clearly established. Patients with a resected pancreatobiliary-type cancer have a significantly poorer prognosis than those with intestinal-type cancers [9].

Ampullary adenocarcinoma is also related to the extracolonic tumor spectrum of hereditary nonpolyposis colorectal cancer syndrome (HNPCC) [10]. The question of whether carcinomas from intestinal and pancreaticobiliary types of the ampullary region develop under different molecular pathologic conditions remains unanswered. Many ampullary carcinomas develop from preexisting adenomas. Residual tissue of papillary adenomas can be found in 30–60% of ampullary carcinomas. More than 95% of benign ampullary neoplasms are adenomas of the intestinal type [11]. These neoplasms have a tubular, villous, or mixed tubulovillous pattern and closely resemble intestinal adenomas. The favorable prognosis of periampullary carcinoma is thought to be due to early clinical presentation with upper abdominal pain, obstructive jaundice, and intestinal bleeding, leading to endoscopy and histologic diagnosis of the nature of the tumor.

## Molecular Pathology of Ampullary Cancer

Carcinomas of the ampulla display molecular alterations in the K-ras, p53, DPC4, and p16 proteins. Ampullary and ductal pancreatic carcinomas share similar molecular pathways of tumorigenesis [5]. K-ras mutations have been observed in 24–47% of ampullary carcinomas [12–14] and molecular alterations of the p53 protein in 60% [12]. Pure adenomas lack any p53 protein accumulation, whereas p53 positivity was found in 36% of carcinomas

Companion website: www.wiley.com/go/beger/thepancreas

with adenomatous tissue and in 56% of pure carcinomas. The cell cycle modulators p16, p21, and p27 have been found to be expressed at a lower level in ampullary carcinoma compared to pancreatic cancer [15]. Ampullary carcinomas in association with familial adenomatous polyposis frequently display a germline mutation in the adenomatous polyposis coli genes. Achill et al. found that 20% of ampullary carcinomas displayed a high level of microsatellite instability (MSI) [16]. Ampullary cancers with a high level of MSI showed a significantly better clinical outcome than microsatellite-stable tumors [9,17]. The MSI-phenotype is an early event, developing in the adenoma stage and is detectable in precursor lesions.

In addition to their histology, the two ampullary cancer subtypes display distinct molecular and immunohistologic characteristics that allow their discrimination. The intestinal subtype cancer expresses cytokeratin 20 and the transcription factor CDX2 and stains for MUC2, whereas the pancreatobiliary subtype cancer stains for MUC1, MUC5a, and CK7, and is negative for CDX2 [5].

## Endoscopic and Surgical Treatment of Large Adenomas and Carcinoma of the Ampulla of Vater

In 1899, Halstad performed the first local extirpation of a carcinoma of the papilla of Vater in a patient with a T1 cancer by applying an ampullectomy. In 1909, Kausch was the first to successfully operate an advanced cancer of the ampulla of Vater by applying a two-staged pancreatoduodenectomy. Local surgical resection of a papillary/ampullary neoplasm is recommended for all villous and tubulovillous adenomas with a diameter >3 cm. Endoscopic resection using piecemeal or snare excision technics (see Chapter 141) are the first-choice treatment for benign adenomas of the intraduodenal segment of the papilla. Endoscopic papillectomy is currently accepted as the first-choice treatment in sporadic papillary and ampullary adenomas up to a size of 3–5 cm. The accepted criteria to apply endoscopic treatment are adenoma size, no evidence of intraductal growth, and an absence of signs of malignancy on endoscopic findings, respectively ulceration, frayability, and spontaneous bleeding [18]. The application of endoscopic treatment for a papillary adenoma should be weighed against the procedure-related complications. To achieve complete excision, normally two to four separate endoscopic resection procedures are required. The recurrence rate after a mean follow-up time of 3 years was reported to be up to 15% and the endoscopic procedure-related mortality was 0.3%. Up to 15% of the patients eventually required a surgical resection following endoscopic resection because of incomplete cancer cell clearance [3].

**Box 142.1 Indications for surgical ampullectomy for neoplasm of the ampulla of Vater**

- Villous/tubulovillous adenoma >3–5 cm maximum diameter
- Adenoma with intraampullary/intraductal extension [4]
- Adenoma + severe dysplasia/carcinoma in situ
- T1a, N0, M0, G1/2 carcinoma restricted to mucosa/submucosa
- Carcinoid tumor of papilla of Vater, T1

*Source:* Modified from Yoon et al. 2005 [18]. Reproduced with permission of Wolters Kluwer Health.

Because of a high level of recurrence (up to 37%) after endoscopic resection of adenomas with intra-ampullary and intraductal extensions, an oncologic ampullectomy should be the first-choice treatment (Box 142.1). Because up to 30% of benign villous and tubulovillous adenomas of the papilla are associated with severe dysplasia or carcinoma in situ, a curative ampullectomy is recommended [20]. For low-risk Tis and T1aN0M0G1/2 ampullary cancer restricted to mucosal and submucosal layers, application of a local resection using a surgical ampullectomy is the most effective treatment modality (Table 142.1).

The ampulla of Vater has a distinct pattern of lymphatic drainage and, in contrast to pancreatic head tumor with a diffuse lymphatic spread, tumors of the

papilla and ampulla tend to involve a local group of lymph nodes near the papillary segment of the duodenum, even in advanced cancers. These morphological features make ampullary neoplastic lesions a distinct clinical entity, yielding a substantial benefit in survival when infiltration does not include pancreatic tissue. However, patients who have a high-risk lesion belonging histologically to the cancer type pT1N0G3/4 grading class should have a radical oncologic Kausch–Whipple type resection.

## Ampullectomy for Large Adenomas and Low-Risk Ampullary Cancer

Ampullectomy for low-risk ampullary cancer is a local surgical technique, which intends to resect en bloc the adenomatous cancer tissue, including resection of the papillary entrance of the common bile duct and the pancreatic main duct (Fig. 142.1). The observed overall surgery-related frequency of complications is approximately 32%. The most frequent local complications are fistulas of the pancreatic and biliary systems, which occur in approximately 9% of cases. Reinterventions or reoperations of 7.5%, are caused by severe grade of pancreatic fistula (International Study Group on Pancreatic Fistula [ISGPF] grades B and C), or duodenal fistula or periduodenal abscess. However, the hospital mortality of 0.6% after ampullectomy is low (Table 142.2).

For patients with a low-risk ampullary cancer, an ampullectomy should be combined with lymph node dissection of the anterior and posterior pancreatic head lymph nodes to ensure oncologic curative resection. A close correlation exists between the invasion depth, tumor size, and lymph- ode metastases [18–20] (Table 142.1). Lymph node involvement of the anterior or/and posterior pancreatic head lymph nodes was found in ampullary pT1a cancer of a size up to 1 cm and lymph node metastases in 12% of cases [20]. Conversion to a Kausch–Whipple resection is recommended when intraoperative or final histology reveals an advanced cancer.

## Pancreatoduodenectomy for Advanced Ampullary Cancer

Ampullary cancer of stages pT1b and T2–T3 should be treated by a Kausch–Whipple pancreatic head resection. The partial pancreatoduodenectomy includes resection of the duodenum/antrum of the stomach, distal common bile duct, gallbladder, and head of the pancreas in combination with lymph node dissection around the head of the pancreas, including all N1 and, in advanced cases, N2 lymph nodes. In high-volume centers, hospital mortality after pylorus-preserving pancreatic head resection is <5% (Table 142.2). Patients with UICC Stages I and II cancer have a significantly better prognosis after Kausch-Whipple resection than patients with advanced Stage III

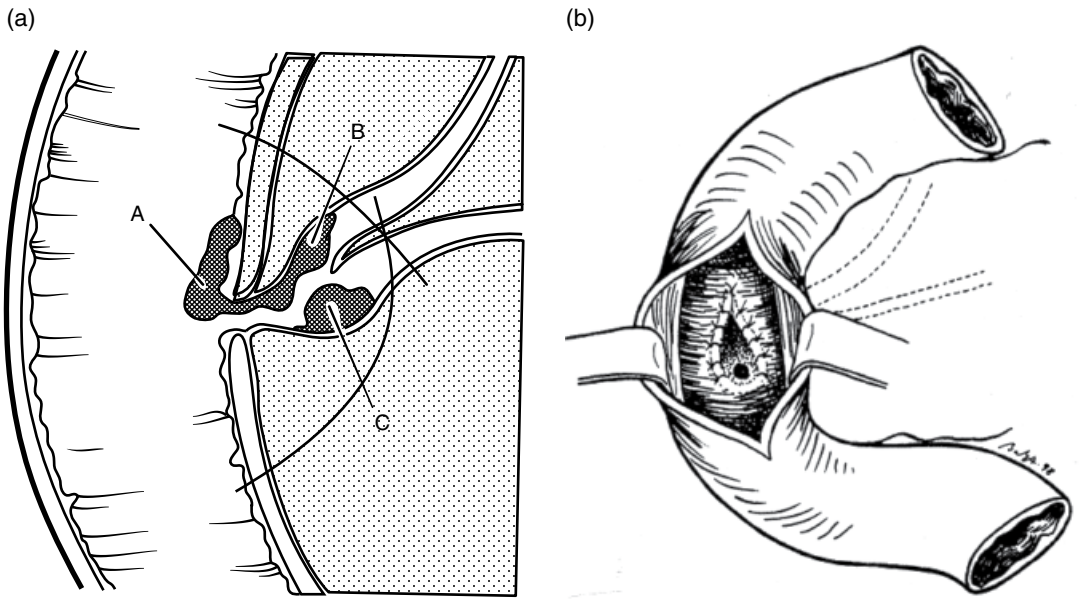

**Figure 142.1** (a) Adenomatous lesion of the ampulla of Vater. A, Adenoma of the papilla (roof of the papilla); B, adenoma of the ampulla; C, intraductal ampullary adenoma. [e] Fistula: postoperative pancreatic fistula, biliary, duodenal.

and IV cancers. Standardization of the surgical technique has led to a decrease in surgical morbidity with regard to the frequency of pancreatic fistula, postoperative hemorrhage, local abscess, biliary leakage, and delayed gastric emptying. The overall rate of surgery-related complications is up to 40% of patients. The most frequent complication is the development of local fistulas in approximately 16% of cases. The application of fast-track principles to surgical resections of ampullary cancer has resulted in a significant decrease in severe postoperative morbidity. Systemic postoperative morbidity remains at a level of up to 20–25% regarding pulmonary, cardiovascular, and renal dysfunctions. The indication for reoperation or reintervention includes local septic complications, for example, abscess and intra-abdominal and intraintestinal bleeding. The surgeons' contribution to curing patients with periampullary cancer is to perform an R0 resection, including systematic lymph node dissection and the application of highly skilled surgical techniques for pancreaticointestinal anastomosis. An important point to ensure a cure of the patient, whether applying local ampullectomy or a Kausch–Whipple pancreatic head resection for advanced ampullary cancer, is the intraoperative control of the resection margin by frozen-section investigations.

## Survival After Ampullectomy and Pancreatoduodenectomy

The chance of survival after Kausch–Whipple resection of an advanced ampullary cancer ranges within a median of 45–65 months. A published series of 1666 patients who underwent a Kausch–Whipple resection revealed a survival probability after 2 years of 62–88% and a 5-year overall survival of 35–67% (Table 142.3). The 10-year survival probability was 35–50%. The difference in survival rates after surgery is related to prognostic factors. After ampullectomy for carcinoma in situ or low-risk T1aN0G1/2 ampullary cancer, the 5-year survival probability was observed as 70–90%. After a mean follow-up time of 3.1 years for 308 ampullectomies, a recurrence occurred in 9.1% of cases (Table 142.2). The most frequent cause of recurrence was the reappearance of an intraduodenal adenoma. Independent prognostic factors for long-term survival after radical local or multiorgan resection were lymph node involvement, degree of cancer infiltration into the pancreatic tissue, and the degree of cancer cell dissemination along the nerves [43]. An incidence rate of 16% of lymph node metastases around the superior mesenteric artery was found in advanced carcinoma of the ampulla. The authors were able to identify lymphatic pathways from posterior pancreatoduodenal lymph nodes to para-aortic lymph nodes via lymph connection around the superior mesenteric artery [44]. The application of an R0 resection is the most important step to achieve long-term survival. Based on multivariate regression analysis, negative lymph nodes, an absence of infiltration into pancreatic head tissue, and an absence of perineural invasion are significant and independent oncologic factors for long-term survival after surgery for advanced ampullary cancer.

## Conclusion

Local ampullectomy is recommended for large adenomas of >3–5 cm, intra-ampullary and intraductal neoplasms, and tumors with low-risk cancer T1aN0G1/2. Surgical treatment of advanced papillary/ampullary

**Table 142.3** Long-term survival of cancer of ampulla of Vater after Kausch–Whipple type pancreatoduodenectomy.

# Surgical Treatment of Duodenal Cancer

*Fuyuhiko Motoi and Michiaki Unno*

*Department of Surgery, Tohoku University School of Medicine, Sendai, Japan*

Duodenal cancer is rare disease. Primary duodenal adenocarcinoma accounts for about 0.5% of all gastrointestinal cancers. The incidence of duodenal cancer is 5.4 per 1,000,000 [1]. It forms 60–100% of all duodenal malignancies and 30–45% of all small intestinal malignancies. Besides sporadic duodenal adenocarcinoma, other sources of adenocarcinoma include the gastrointestinal polyposis syndrome with a genetic background, such as familial adenomatous polyposis, Peutz–Jeghers syndrome, and duodenal polyposis.

Long-term survival is obtained only by complete surgical resection. The standard surgical procedure for the disease is pancreatoduodenectomy with regional lymph node dissection (lymphadenectomy). Regional lymph nodes include nodes along the inferior pancreatoduodenal artery and first jejunal artery, infra- and suprapyloric nodes, nodes along the common hepatic artery, and nodes on the posterior and superior surface of the pancreas head. En-bloc regional node dissection requires total mesoduodenum excision. Segmental partial resection of the duodenum can be applied in some cases [2], depending on the location and extent of the tumor. Partial segmental resection of the tumors in the proximal (1st part) or distal part (distal 3rd or 4th part) can achieve negative margins.

The most significant prognostic factor for duodenal cancer is resectability. Curative resection (R0 resection) determines the outcome for patients with duodenal cancer. After R0 resection, 5-year survival has been reported to be 17–74% (Table 143.1). The results obtained are 40–50% reproducible as reported by recent large series [13–15]. Deep extension of the primary tumor (T), presence of nodal metastases (N), margin-positive resection (R), large tumor size, poor histologic grade, and higher age are associated with poor prognosis after resection. In the largest series by database analysis [17] for Stage I–IV cancers, 5-year survival rates are 65.9, 50.4, 31.4, and 11.9%, respectively. Common recurrence sites are locoregional, intra-abdominal distant organ including the liver and peritoneum and extra-abdominal distant organ including lung.

Systemic chemotherapy or chemoradiotherapy has been applied after resection of advanced disease in the setting of good postoperative performance status. However, the role of adjuvant therapy for patients with duodenal cancer after resection is not well established [15]. Survival outcome after resection of duodenal cancer has not changed significantly over the past several decades [14]. Further work is needed to improve the outcome of surgical treatment for duodenal cancer.

# Surgical Treatment of Distal Cholangiocarcinoma

*Yukihiro Yokoyama, Tomoki Ebata, and Masato Nagino*

*Department of Surgery, Division of Surgical Oncology, Nagoya University Graduate School of Medicine, Nagoya, Japan*

## Introduction

Extrahepatic bile duct tumors have been conventionally classified into proximal, middle, and distal tumors. However, the American Joint Committee of Cancer (AJCC) recently published new staging criteria for extrahepatic bile duct tumors in its 7th edition [1]. In this staging system, the middle tumors have been removed, and extrahepatic bile duct tumors were newly classified as perihilar and distal bile duct tumors. TNM staging system was separated for these two subgroups because their pathologic features, surgical approach, and prognosis are different.

Distal cholangiocarcinoma is a relatively uncommon disease, comprising approximately 30% of all cholangiocarcinomas [2]. Although pancreatoduodenectomy is commonly selected as a surgical procedure for both pancreatic head cancer and distal cholangiocarcinoma, a minor arrangement in the procedure for each type of tumor is necessary as biological behavior is different. Because the incidence rate of distal cholangiocarcinoma is lower than that for pancreatic head carcinoma, there are limited publications that focus solely on the clinicopathologic features of distal cholangiocarcinoma. The hospital mortality after resection in high-volume centers for distal cholangiocarcinoma is 0–7%. The most common surgery-related complications are pancreatic fistula (7–42%) because patients have a normal soft pancreas in most cases of distal cholangiocarcinoma. Lymph node metastasis is commonly observed (38–68%) and this is a major factor that determines prognosis after surgery.

The mode of lymph node involvement is slightly different between the middle and lower cholangiocarcinoma. The 5-year overall survival after resection of distal cholangiocarcinoma is 30–73% in patients without nodal involvement, whereas it is 4–36% in patients with nodal involvement. Other important factors that determine prognosis are depth of invasion, pancreatic invasion, perineural invasion, tumor histology, and resection margin status. The surgical approach for distal cholangiocarcinoma should be carefully arranged depending on the tumor location, longitudinal or extramural tumor extension, and mode of lymph node and perineural involvement.

## Pyloric Ring Preservation

When selecting the operative procedure for distal cholangiocarcinoma, the question of whether pylorus-preserving pancreatoduodenectomy or pancreatoduodenectomy with pyloric resection (either by conventional Whipple or subtotal stomach-preserving pancreatoduodenectomy) should be selected arises. One of the merits in removing the pyloric ring is removal of lymph nodes in the perigastric region. Mode of lymph node involvement in the perigastric region is different in pancreatic head carcinoma and in distal cholangiocarcinoma. Nakao et al. previously reported that perigastric lymph node involvement was observed in 14% in patients with pancreatic head carcinoma, whereas no patient with distal cholangiocarcinoma had a lymph node metastasis in this region [3]. Based on these observations, pylorus-preserving pancreatoduodenectomy is indicated in almost all patients with distal cholangiocarcinoma, but not for the pancreatic head carcinoma. In fact, randomized controlled trials comparing the clinical outcome between pylorus-preserving pancreatoduodenectomy and conventional pancreatoduodenectomy (thus removal of perigastric lymph nodes) for patients with periampullary carcinoma showed no significant difference in long-term survival between the two

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

procedures [4,5]. However, in the case of a tumor in the middle region of the extrahepatic bile duct, this concept is not applicable because the location of the tumor is close to the duodenal bulb. Therefore, removal of the duodenal bulb together with the pyloric ring is recommended to obtain a safe surgical margin, especially in a case with severe extramural tumor extension.

## Lymph Node Dissection

There are several reports on the prognostic factors relating to distal cholangiocarcinoma. The significant prognostic factors identified include the presence of lymph node metastasis [6–12], depth of invasion [13], pancreatic invasion [8,14,15], perineural invasion [15,16], resection margin status [7,12,15], and tumor histology [14] (Table 144.1). Among these factors, presence of lymph node metastasis has been reported to be the most important factor that determines the survival of patients with distal cholangiocarcinoma. The survival is clearly different between patients with and without lymph node involvement (Table 144.2).

As with other type of cancers, such as breast, gastric, or colorectal cancer, the number of involved nodes is critical in determining the severity of cancer progression in distal cholangiocarcinoma [9–12,16–19]. The proposed cut-off value of the number of involved lymph node was 2–5. In a report by Kiriyama et al. analyzing the largest number of patients of distal cholangiocarcinoma to date ($n = 370$) [15], median survival rate worsened with increasing number of involved lymph nodes. Survival was significantly better in patients with fewer than four than in those with four or more involved nodes (Fig. 144.1).

The total lymph node count (TLNC) examined is another important factor that has an impact on survival because inadequate assessment of lymph nodes, due to either an insufficient extent of resection or pathologic examination, results in understaging of cancer [20,21]. It should be noted that the numbers of dissected lymph nodes substantially differ depending on the extent of lymph adenectomy and additional organ resection. In particular, the TLNC can vary depending on the extent of lymphadenectomy for the perigastric and mesenteric lymph nodes. The AJCC recommend a "12-node minimum" for distal cholangiocarcinoma to prevent inadequate staging [1], but the theoretical background for this number is obscure. An optimal number of TLNC requirement for distal cholangiocarcinoma should be determined in a future study.

TLNC also changes the results of lymph node ratio (LNR), which is calculated as a ratio between the number of lymph node metastases and the total number of lymph node examined, because the greater the TLNC, the lower the LNR. According to the report by Kiriyama et al. [15], the median (range) TLNC was 19 (3–59). Nodal metastasis occurred in 157 patients (42.4%); the median (range) number of involved nodes was 2 (1–19) and LNR was 0.11 (0.02–0.80). An LNR of at least 0.17 was associated with a significantly shorter median survival (1.3 vs. 2.2 years). Another report by Kawai et al. indicated that the LNR >0.2 is an important factor to predict survival after resected middle and distal cholangiocarcinoma [16].

For distal cholangiocarcinomas, mode of nodal involvement is different depending on the location of the tumor,

according to the report by Kayahara et al., which meticulously examined the lymph nodes in different regions removed after resection of middle (Bm) and lower (Bi) cholangiocarcinomas [7]. The frequency of nodal involvement for patients with Bm was observed in the nodes along the common hepatic artery, in the hepatoduodenal ligament, and in the posterior pancreatoduodenal region. Among them, frequency was the highest in nodes in the hepatoduodenal ligament (50%). However, there was no lymph node metastasis in nodes around the superior mesenteric artery. In contrast, in patients with Bi cholangiocarcinoma, there was less nodal involvement in nodes along the common hepatic artery and more involvement in posterior pancreatoduodenal nodes. Notably, in 28% of patients with Bi cholangiocarcinoma, there was a lymph node metastasis in nodes around the superior mesenteric artery, with the highest frequency in nodes at the origin of the inferior pancreatoduodenal artery. These differences in the mode of cancer spreading through lymphatic vessels and lymph nodes should be carefully considered preoperatively when planning a surgical approach for distal cholangiocarcinoma. Radical lymph node dissection along the superior mesenteric artery is especially recommended in the case of lower cholangiocarcinoma. To accomplish a thorough lymph node dissection along the superior mesenteric artery, combined resection of the mesentery along the 1st jejunal artery and vein is recommended (Fig. 144.2).

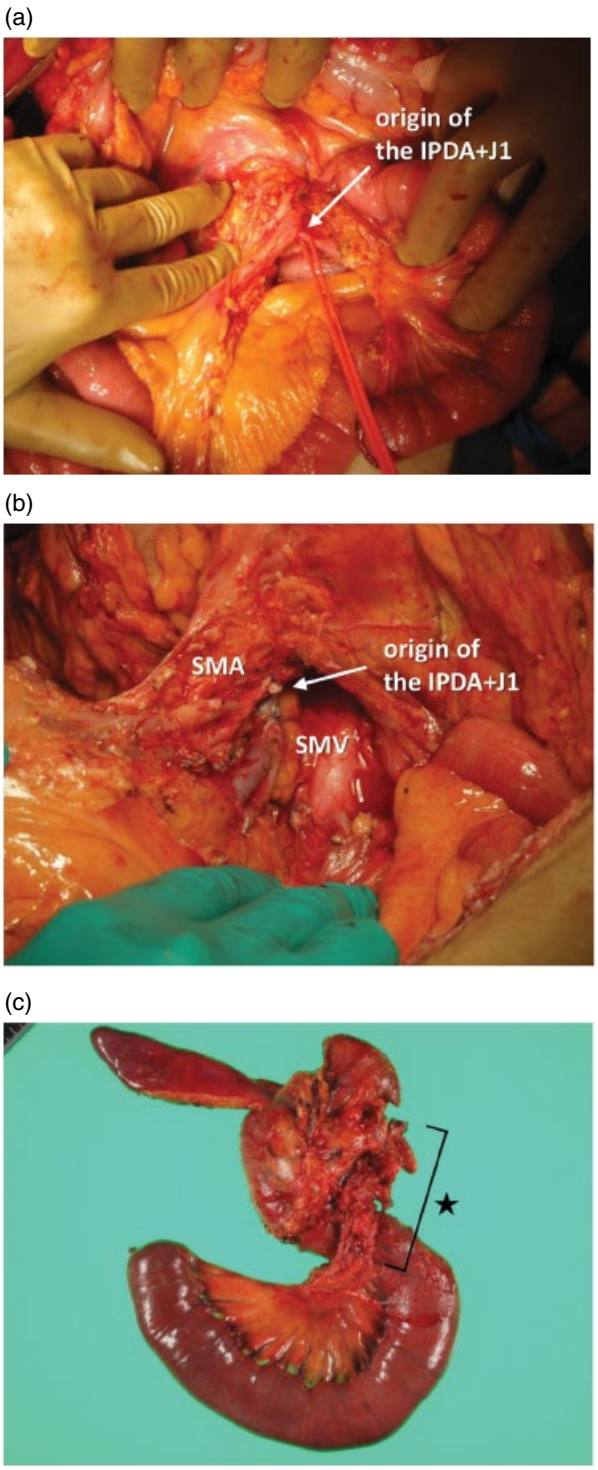

**Figure 144.2** Lymph node dissection along the superior mesenteric artery. (a) The jejunal mesentery is dissected with the common trunk of the inferior pancreatoduodenal artery (IPDA) and the 1st jejunal artery (J1). (b) After resection, the superior mesenteric artery (SMA) was exposed and the common trunk of the IPDA and the J1 was dissected at its origin. In this case, the lymph nodes along the SMA were thoroughly dissected (without nerve plexus dissection). SMV, superior mesenteric vein. (c) Macroscopic photo of the resected specimen. Star indicates lymph nodes along the SMA.

## Skeletonization of the Hepatoduodenal Ligament and Dissection of Pancreatic Head Neural Plexus

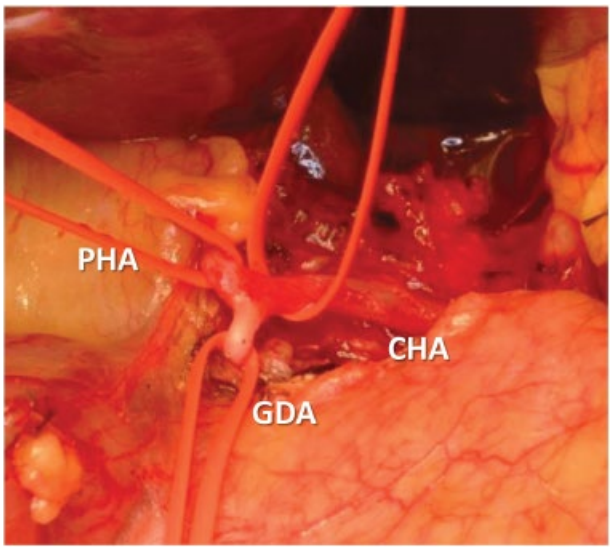
Neural plexus invasion is another important prognostic factor of cholangiocarcinoma, although its impact is not greater than that of lymph node involvement [15,16]. In the study by Bhuiya et al., the overall incidence of perineural invasion in the resected specimen of bile duct carcinoma (including perihilar cholangiocarcinoma and distal cholangiocarcinoma) was 81.4% [22]. The 5-year survival rate for patients with perineural invasion was significantly lower than that for those without perineural invasion (67% vs. 32%) [22].

In an analysis of 50 patients with distal cholangiocarcinoma, neural plexus invasion occurred in 20% of patients, particularly in the hepatoduodenal ligament and pancreatic head [7]. Neural invasion was observed more frequently when the tumors invade the subserosa. Therefore, skeletonization of the hepatoduodenal ligament including the removal of neural plexus around the hepatic artery and portal vein is recommended for the treatment of advanced distal cholangiocarcinoma (Fig. 144.3a). In contrast, dissection of the neural plexus around the hepatic artery in the hepatoduodenal ligament is not routinely recommended (unless there is an invasion of the tumor) in the pancreatoduodenectomy for the pancreatic head carcinoma (Fig. 144.3b). As with the mode of lymphatic spreading, neural invasion is mainly observed within the hepatoduodenal ligament in the middle cholangiocarcinoma, whereas that is more frequently observed in the pancreatic head plexus in the lower cholangiocarcinoma. These differences should be carefully considered in planning a surgical approach to distal cholangiocarcinoma.

## Bile Duct Cut Margin

It is now widely recognized that margin status is one of the most critical predictors of long-term survival in cholangiocarcinoma [23]. After surgical resection for extrahepatic cholangiocarcinoma, invasive carcinoma at ductal resection margins appears to have a strong adverse effect on patient survival. Superficial spreading is sometimes observed in cholangiocarcinoma (approximately 15% of all tumors according to the report by Igami et al.) [24]. Histologically, superficial spreading is more commonly observed in papillary and well-differentiated adenocarcinomas than in other types of carcinoma [24]. When considering the site of proximal bile duct cut margin in the pancreatoduodenectomy for distal cholangiocarcinoma, the extent of superficial spreading from the main tumor should be carefully examined either by

(a)



(b)

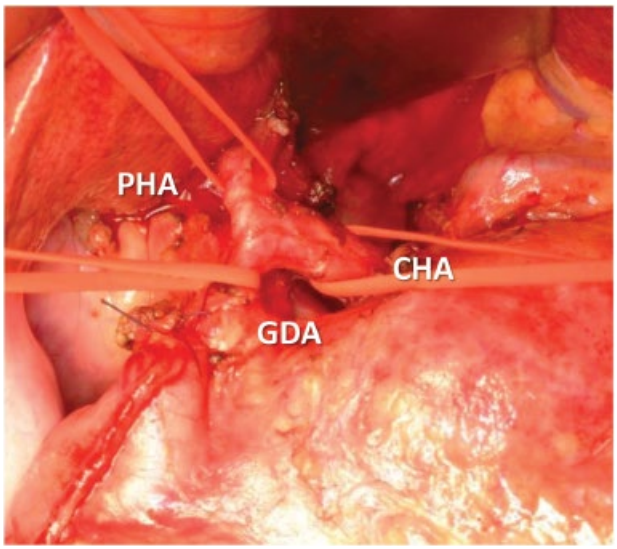


**Figure 144.3** Skeletonization of the hepatoduodenal ligament. (a) The neural plexus around the common hepatic artery (CHA) and the proper hepatic artery (PHA) were dissected with the lymph nodes and surrounding tissues (a case of the distal cholangiocarcinoma). GDA, gastroduodenal artery. (b) The lymph nodes around the CHA and the PHA were dissected by preserving neural plexus (a case of the pancreatic head carcinoma).

cholangiography, intraductal ultrasonography, and/or mucosal biopsy. It is also important to examine the proximal bile duct cut margin by intraoperative frozen sectioning to avoid a residual carcinoma at the bile duct cut margin. It should be noted, however, that the clinical significance of the residual carcinoma in situ at the bile duct cut margin is controversial. Several reports indicated that the residual carcinoma "in situ" in the proximal cut margin of the bile duct does not have an impact on survival [24–26], although a positive margin with "invasive" carcinoma is the independent risk factors of survival after surgery for distal cholangiocarcinoma [7,12,15]. Nevertheless, some patients have poor prognosis after surgery with residual carcinoma in situ. There may be a difference in the biological malignant potential between patients who do survive long term with residual carcinoma in situ and those who do not [27]. This should be clarified in a further biological approach.

## Surgery-Related Complications

Pancreatoduodenectomy is commonly selected as a surgical procedure for distal cholangiocarcinoma. Extrahepatic bile duct resection is selected only for cases of middle cholangiocarcinoma with limited tumor extension. The morbidity and mortality rates after resection of distal cholangiocarcinoma are 19–54% and 0–7%, respectively [7,8,11–14]. In general, the main pancreatic duct is not affected by the tumor in the distal bile duct and patients have a normal soft pancreas with small main pancreatic duct. Therefore, the rate of pancreatic fistula is more commonly observed in patients with distal cholangiocarcinoma (7–42%) than in patients with pancreatic head cancer [7,8,14]. Other commonly observed complications include biliary fistula (0.1–3%), delayed gastric emptying (0.1–10%), bleeding (2–7%), and intra-abdominal abscess (2–7%) [8,12,14,23].

## Summary

When a surgeon performs a pancreatoduodenectomy for distal cholangiocarcinoma, dissection of the pyloric ring (pylorus-preserving, subtotal stomach-preserving, or conventional pancreatoduodenectomy), extent of lymph node dissection (dissect lymph nodes along the superior mesenteric artery or not), skeletonization of hepatoduodenal ligament, and the proximal cut line of the bile should be carefully arranged depending on the tumor location as well as the intramural and extramural tumor extension.

# Adjuvant and Palliative Chemotherapy of Periampullary Cancers

*Eyas Mohamed[1], Paula Ghaneh[1], and John P. Neoptolemos[2]*

[1] *Department of Molecular and Clinical Oncology, University of Liverpool, Liverpool, UK*
[2] *Department of Surgery, University of Heidelberg, Heidelberg, Germany*

## Introduction

The term periampullary cancer encompasses three pathologically distinct tumor subtypes which are in close anatomic proximity to the pancreatico-ampullary apparatus, including tumors arising from the distal common bile duct, ampulla of Vater, and the duodenum. The incidence of these tumors remains low, with European figures ranging between 0.3 to 0.84 per 100,000 population, placing them within the European Union definition of rare cancers [1,2]. These tumors possess different biological and molecular characteristics, but they are often grouped together as their curative surgical approach would usually mandate a pancreaticoduodenectomy [3,4]. Occasionally, the true pathologic origin of the malignant process is difficult to be established until full histologic assessment of the specimen is performed [5]. The heterogeneity of the histologic and biological profiles has profound implications for their long-term survival rates and response to various available chemotherapy regimens [5,6].

Periampullary tumors demonstrate a higher resectability rate, in contrast to pancreatic tumors. The ideal treatment strategy is achieved by surgical resection, which offers a chance of cure and prolonged survival in 60–80% of patients with resectable disease on presentation [7]. The remainder usually present with manifestations consistent with locally advanced disease or evidence of distant widespread metastasis. The mainstay of therapy in this setting is achieved by palliation of symptoms, with relief of jaundice, alleviation of pain, and providing nutritional support [8]. The focus on prolonging survival by the use of adjuvant and palliative treatments should not overlook the psychologic and emotional aspects for patients affected with this debilitating disease.

At present the overall prognosis remains bleak despite adequate tumor clearance by surgical resection as the locoregional and distant relapse incidence rates are known to be high in these tumors [9]. Surgical resection alone is associated with 5-year survival rates of 20–30%. The worst prognosis is associated with positive local lymph nodes and involved surgical margins [5,10,11]. Given the above, attempts to improve long-term survival by the addition of adjuvant chemotherapy have been tested in various clinical studies.

Most of the evidence in published literature on the use of adjuvant and palliative chemotherapy is limited to institutional retrospective case series and often contains a mixture of periampullary and pancreatic tumors with limited randomized controlled trials. The heterogeneity and quality of the evidence can lead to conflicting results about the genuine value of chemotherapy in periampullary cancers. The inherent rarity of these tumors has governed the paucity of published useful data that could be translated into effective clinical and oncological management paradigms.

## Distal Cholangiocarcinoma

### Adjuvant Therapy

Patients with distal cholangiocarcinoma have the worst prognosis among periampullary cancer patients. The long-term survival figures resemble those achieved in pancreatic adenocarcinoma. Tumors arising within the intrapancreatic portion of the distal bile duct account for approximately 27–40% of all cholangiocarcinomas [12,13]. These are closely linked to tumors arising in the proximal pancreatic duct as they share the same

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

embryological origins with common phenotypic and functional characteristics. This supports the hypothesis that they should be considered as a congruent disease entity [14].

Takada et al. [15] conducted one of the first Phase III randomized controlled trials in Japan with adjuvant 5-fluorouracil (5-FU) and mitomycin C in 508 patients with resected pancreaticobiliary tumors (containing 139 patients with cholangiocarcinomas) compared to surgery alone and concluded that adjuvant chemotherapy compared to surgery alone did not have an impact on the 5-year survival rate (26.7% vs. 24%).

Following this the European Study Group for Pancreatic Cancer 3 (ESPAC-3) periampullary trial was designed to explore the benefit of adjuvant chemotherapy on overall survival in patients with resected periampullary cancer [16]. In this study 428 patients were randomized (of whom 96 had cholangiocarcinomas) to either fluorouracil- or gemcitabine-based chemotherapy versus surgery alone. The use of adjuvant treatment was associated with a potential survival advantage that did not reach statistical significance (median 43 months vs. 35 months, hazard ratio HR = 0.86, 95% CI: 0.66–1.11) but on multivariable analysis and after adjusting for prognostic variables a statistically significant survival benefit was demonstrated with adjuvant chemotherapy with HR = 0.75 (95% CI: 0.57–0.98; $P = 0.03$). The median survival of patients with cholangiocarcinoma assigned to either observation, fluorouracil plus folinic acid, or gemcitabine arms was 27.2, 18.3, 19.5 months, respectively.

These studies have demonstrated some evidence for the use of adjuvant therapy (Table 145.1). Horgan et al. [11] conducted a large meta-analysis of 20 studies, which included a randomized trial of chemotherapy, two registry, and 17 institutional series. The treatment protocol contained chemotherapy alone in three studies, radiotherapy only in nine, while eight studies contained radiation and chemotherapy combinations. There was a total of 6712 patients of whom 1797 received some form of adjuvant treatment during the course of their disease and 4915 in the surgery-only group. In this meta-analysis, the improvement in 5-year survival with any adjuvant therapy was not statistically significant (pooled odds ratio OR = 0.74, 95% CI: 0.55–1.01), however, the survival benefit from adjuvant therapy was statistically significant when the data from the two large registry series ($n = 1233$ patients) were excluded (OR = 0.53, 95% CI: 0.39–0.72). Pooled data extracted from the studies confirmed a statistical significant overall survival advantage for any adjuvant therapy in node-positive disease (OR = 0.49, 95% CI: 0.30–0.80) and patients with margin-positive disease (OR = 0.36, 95% CI: 0.19–0.68).

These studies have demonstrated survival benefit for the use of adjuvant treatment in patients with cholangiocarcinoma especially in those with poor prognostic indicators [20,21]. Currently there are two randomized controlled trials under way of adjuvant therapy in patients with resected cholangiocarcainoma: the BILCAP trial using adjuvant capecitabine and the French PRODIGE-12 trial studying combination gemcitabine and oxaliplatin. Both studies have completed accrual and their results will provide further prospectively validated evidence on the use of adjuvant treatment in patients with resected bile duct cancer.

## Palliative Therapy

The benefits of systemic chemotherapy in addition to best supportive care in patients with metastatic and recurrent distal cholangiocarcinoma are well established. Patients treated with chemotherapy were noted to have a significantly better median overall survival of more than 6 months with a better quality of life. The reported high incidence of local relapse and distant recurrence would advocate early referral for palliation treatment in patients with satisfactory performance status [20,22].

Eckel and Schmid [23] performed a pooled analysis of 104 trials examining the role of chemotherapy in advanced biliary tract cancer which showed combination treatment to have a better treatment effect compared to monoagent therapies. The gemcitabine- and platinum-based combinations demonstrated the greatest benefit in the pooled analysis.

The randomized Phase III study ABC-02 [24] of up to 6 months of gemcitabine versus gemcitabine and cisplatin recruited 410 patients (73 distal cholangiocarcinomas) with unresectable, recurrent, or metastatic biliary tract carcinoma (Table 145.2). This trial demonstrated a significant overall survival advantage with the combination arm versus the gemcitabine arm (11.7 months vs. 8.1 months; HR = 0.64, 95% CI: 0.52–0.80) and a median progression-free survival of 8.0 months versus 5.0 months (HR = 0.63, 95% CI: 0.51–0.77), respectively. Patients who received the combination therapy were 36% less likely to die at any time compared to those who received gemcitabine alone (HR = 0.64, 95% CI: 0.52–0.80). Grade 3 and 4 toxicities occurred with similar frequency in both study arms without any substantial difference. The combination of gemcitabine and cisplatin is the first-line treatment of choice recommended by the European Society of Medical Oncology (ESMO) [25] in patients with favorable performance status (PS 0–1). Patients with PS 2 should be considered for gemcitabine monotherapy while oxaliplatin could be substituted for cisplatin in patients with impaired renal function. A second trial by the same group looking at oxaliplatin and

## Duodenal Adenocarcinoma

### Adjuvant Therapy

Complete surgical resection with regional lymphadenectomy confers prolonged survival for patients with duodenal cancer. Important prognostic factors include the degree of tumor differentiation and local lymph nodes involvement. Several studies have shown no survival benefit for the routine use of adjuvant chemotherapy in completely resected, nodal disease-free duodenal adenocarcinoma [29,30]. Increased number of involved lymph nodes is associated with decreased overall survival with 5-year survival ranging from 68% for node negative patients to 17% when four or more lymph nodes were involved [18] with high incidences of local and distant recurrence [31–33].

The global low incidence of duodenal adenocarcinoma and challenges in conducting adequately powered future studies was reflected in the ESPAC-3 trial which contained only 10 patients with duodenal adenocarcinoma in addition to 25 nondescriptive periampullary tumors out of the original study cohort (see Table 145.1). The eight patients who were assigned to observation in this group survived a median of 28.7 months (95% CI: 4.7–∞ months); 12 patients in the fluorouracil plus folinic acid group survived 22.4 months (95% CI: 9.6–54.6 months); and 15 had high but not estimable survival with gemcitabine therapy [16].

There is currently no agreed regimen as a first-line therapy but many centers would advocate the use of adjuvant oxaliplatin-based chemotherapy in patients with high-risk features (e.g., nodal metastasis) similar to the recommendations for resected colonic adenocarcinoma. Other regimens which demonstrated disease-related activity are capecitabine and oxaliplatin (CAPOX), 5-FU and leucovorin with oxaliplatin (FOLFOX), 5-FU and leucovorin with irinotecan (FOLFIRI) [27,28,34]. To date there are no randomized controlled trials testing the superiority of any of these combinations.

Chemoradiation has been tested in the adjuvant setting and showed improvement in locoregional control but this did not translate into any survival benefit [35]. In a retrospective series published by Poultsides et al. [18] from a single institution, 122 patients with local lymph node involvement showed no difference in overall survival with adjuvant chemoradiotherapy compared to patients who underwent surgery alone (5-year survival 47% vs. 48%, $P = 0.82$) [36].

An international collaboration for the study of rare tumors has launched an open-label, randomized controlled multicenter trial (BALLARD trial) to assess the efficacy of 6 months of adjuvant chemotherapy compared to observation only in Stage I–III resected small bowel adenocarcinoma. The study will also compare fluoropyrimidine monotherapy versus fluoropyrimidine plus oxaliplatin. Recruitment into the study is currently ongoing and is expected to finish by 2020.

### Palliative Therapy

A number of studies support the use of palliative chemotherapy in patients with recurrent and metastatic duodenal adenocarcinoma (see Table 145.2) as it adds a clear

survival benefit over best supportive care [29,37,38]. The Eastern Cooperative Oncology Group (ECOG) published one of the early studies on 31 patients with locally advanced and metastatic small bowel tumors who received combination treatment 5-FU, doxorubicin, and mitomycin C with a median survival of 8 months [26].

Zaanan et al. [27] published results of a retrospective study of 99 patients with advanced and metastatic small bowel adenocarcinoma (55 duodenal) comparing first-line treatments with FOLFOX, leucovorin–FU, FOLFIRI, and leucovorin–FU–cisplatin. In the report, 48 patients with advanced cancer who received FOLFOX as front-line therapy had a median progression-free survival of 7.4 months and median overall survival of 17.8 months. A study by Overman et al. [28] conducted at M.D. Anderson Cancer Center evaluated the combination of capecitabine and oxaliplatin (CAPOX) in 30 patients with either metastatic or locally advanced small bowel or ampullary adenocarcinoma. In the 18 patients who had small bowel adenocarcinoma, the response rate was 61%, with a median time to progression of 9.8 months and median overall survival of 20.4 months. Of note, 10% of treated patients had a complete radiographic response to CAPOX therapy. The treatment combination of fluoropyrimidine and oxaliplatin was also reported to have a better disease activity in Phase II randomized controlled trials. Three studies, including that by Overman et al., combining a fluoropyrimidine with oxaliplatin have shown similar activity with response rates of 42–50%, and a median time to progression ranging from 7.8 to 9.8 months [28,39,40].

Other studies have tested different agents, including irinotecan- and gemcitabine-based treatments which were found to have some disease activity in a small number of patients [27]. Targeted therapies such as antivascular endothelial growth factor receptor (VEGFR) or antiepidermal growth factor receptor (EGFR) therapies have not been evaluated in any formal study as yet and therefore there is currently no evidence to support their use outside the context of experimentation in a clinical trial.

## Ampullary Carcinoma

### Adjuvant Therapy

Ampullary carcinomas constitute 0.2% of the tumors arising in the gastrointestinal tract. These tumors show different immunohistochemical differentiation and molecular characteristics including alterations of *KRAS*, *SMAD4*, and *APC* genes. The intestinal subtype mimics behavioral and oncogenic responses similar to duodenal adenocarcinoma, while the pancreaticobiliary subtype tends to be more aggressive, resembling pancreatic ductal adenocarcinoma with poor prognosis and unfavorable outcomes [41–44]. One of the earliest randomized controlled trials was published by Bakkevold et al. in 1993 [17]. This study demonstrated a median survival of 23 months versus 11 months ($P = 0.02$) using adjuvant combination chemotherapy agents 5-FU, doxorubicin, and mitomycin C in 61 patients (14 ampullary, 47 pancreatic tumors) who underwent a radical resection versus observation but with limited 5-year survival (4 vs. 8 years, respectively) and increased treatment-related toxicity.

ESPAC-3 [16] remains the landmark study in evaluating the role of adjuvant chemotherapy in periampullary carcinomas (see Table 145.1). There were 297 patients with ampullary adenocarcinoma who were randomized to either observation, 5-FU/leucovorin, or gemcitabine. The use of adjuvant chemotherapy demonstrated a trend toward improved overall survival favoring the chemotherapy group versus observation (median overall survival of 43 vs. 35 months, $P = 0.25$). Moreover, when the analysis was limited to patients with ampullary cancer, those treated with gemcitabine had a remarkable survival that was almost double that in the observation group (median 71 vs. 41 months). Subsequent analysis did not show different treatment responsiveness between intestinal and pancreaticobiliary subtypes.

The ESPAC-4 trial [45] randomized 730 patients with resected pancreatic cancer between gemcitabine and combination therapy gemcitabine and capecitabine (GemCap). The median survival was 25.5 months (95% CI: 22.7–27.9) for gemcitabine and 28.6 months (95% CI: 23.5–31.5) for GemCap. The hazard ratio was 0.82 (95% CI: 0.68–0.98, $P = 0.032$) with a substantial difference in 5-year survival of 28.8 versus 16.3% in the combination group. The ampullary arm of ESPAC-4 (comparing adjuvant gemcitabine vs. gemcitabine plus capecitabine) is currently recruiting and has a target of 346 patients and is anticipated to complete follow-up and report by 2022.

A number of retrospective series examined the benefit for chemoradiotherapy as an adjuvant treatment [46,47]. In a study coordinated by the European Organisation for Research and Treatment of Cancer (EORTC), 218 patients with resected pancreatic and periampullary cancers were randomized to postoperative radiotherapy plus concurrent 5-FU (25 > mg/kg per day by continuous infusion) or observation. There were 104 patients with periampullary cancers (which included cancers of the ampulla, distal common bile duct or duodenum), and there was no difference in the 2-year survival rate (67% radiotherapy vs. 63% observation) or in the incidence of locoregional recurrence in the postoperative radiotherapy group compared to controls. This was contrary to the findings from another series at the Mayo Clinic of

29 out of 125 patients with ampullary cancer who underwent curative surgical resection in addition to 5-FU and concurrent radiotherapy with a median total radiation dose of 50.4 > Gy (range 45.0–54.0 > Gy) while the remainder underwent surgery alone. The 5-year survival figures of 48% versus 11% were in favor of the adjuvant chemoradiation group [19].

Results from the ESPAC-4 ampullary trial will help inform future adjuvant therapy options for this patient group.

### Palliative Therapy

Systemic chemotherapy remains the mainstay to halt disease progression and prolong survival in unresectable and metastatic ampullary carcinoma. Survival figures beyond 3–6 months are dismal without additive palliative therapy. Most of the existing evidence is extrapolated from large studies that contained a mixture of periampullary tumors with ampullary tumors forming a subset. Agents that have been examined in this disease include antimetabolites (fluoropyrimidine and/or gemcitabine) with or without a platinum compound (cisplatin or oxaliplatin) with variability in response rates ranging from 10% to 40% [48,49]. A Phase II study evaluating CAPOX in patients with advanced adenocarcinoma of the small bowel or the ampulla reported a response rate of 33% with improved overall survival (20.4 vs. 15.5 months in patients with metastasis). The primary site of disease was the ampulla of Vater in 12 out of 30 patients [28].

In the ABC-02 trial (see Table 145.2) which randomly assigned 410 patients with locally advanced or metastatic biliary tract cancer to receive combination cisplatin and gemcitabine versus gemcitabine alone [24], there were 206 patients in the gemcitabine group (ampullary: 11 cases) and 204 patients in the cisplatin plus gemcitabine group (ampullary: 9 cases). The median progression-free survival was 8 months in the cisplatin plus gemcitabine versus 5 months in the gemcitabine-only cohort. The overall median survival was 11.7 months versus 8.1 months, respectively.

## Conclusion

Periampullary tumors constitute a diverse group of tumor subtypes. Despite the advances in diagnostics and clinical cancer care their treatment remains challenging for clinicians and oncologists worldwide. The rarity of these tumors, in addition to disparity of the published data, has slowed the advancements made in the field. There is a high unmet need for these patients. Future randomized trials should be of high quality and use efficient novel study designs to ensure that the best clinical evidence is available for these patients.

# Long-Term Survival After Tumor Resection

## 146

## Long-Term Survival After Resection of Periampullary Cancer

*Masayuki Ohtsuka and Masaru Miyazaki*

*Department of General Surgery, Graduate School of Medicine, Chiba University, Chiba, Japan*

### Introduction

Periampullary cancers are grouped as a heterogeneous malignant lesions arising from anatomic sites around the pancreatico-biliary-digestive junction. They consist of pancreatic cancer in the head of the pancreas, ampullary region cancer, distal bile duct cancer, and duodenal cancer. Because of their anatomical proximity, periampullary cancers share similar clinical presentations and treatment strategies. Surgical resection is the most effective treatment option regardless of the site of the origin of these cancers. Pancreaticoduodenectomy represents the surgical procedure of choice for periampullary cancers, although limited resections are indicated for some patients.

The incidences and the long-term survival rates after surgical resection are very different according to the type of cancer. Pancreatic cancer is the most common, and accounts for 80% of all periampullary cancers, and has the poorest prognosis with 5-year survival rate of around 20%. Other cancers are less common than pancreatic cancer. Patients with ampullary region cancer and duodenal cancer are known to have relatively favorable prognosis after surgical resection.

This chapter focuses on the long-term survival after surgical resection in patients with periampullary cancers other than pancreatic cancer.

### Distal Bile Duct Cancer

#### Overall Survival

There are few reports describing the clinicopathologic data of patients with distal bile duct cancer (Table 146.1). According to the Biliary Tract Cancer Registry in Japan [1], 4091 patients with distal bile duct cancer were registered from 2008 to 2013. Of these patients, 3800 (92.9%) underwent surgical resection. On the basis of the Japanese classification of the biliary tract cancers [2], T3a disease was the most frequently seen (53.4%), followed by T2 disease (28.6%). In this patient population, the 5-year survival rate was reported to be 39.1%.

In a multi-institutional study, the Nagoya Surgical Oncology Group [3] reported 370 patients undergoing pancreaticoduodenectomy, including 38 cases (10.3%) of T1 disease, 96 (25.9%) of T2 disease, and 236 (63.8%) of T3 disease, classified by the American Joint Committee on Cancer (AJCC) TNM classification system [4]. They reported that the 3-year, 5-year, and 10-year survival rates were 53.3%, 40.8%, and 28.4%, respectively, with a median survival of 42 months. Another multi-institutional study from France [5] included 55 patients with 4 (7.3%) T1, 15 (27.3%) T2, 28 (50.9%) T3, and 8 (14.5%) T4 diseases. The 5-year survival rate of all patients was 34% with a median survival of 24 months.

In high-volume single-center studies, a Johns Hopkins Medical Institution series in the United States [6] found that the 3-year and 5-year survival rates were 33% and 18%, respectively, with a median survival of 20.3 months in 147 patients. In their series, 88.5% of all cases were classified as T3 or higher. In a Samsung Medical Center series in Korea [7], the 3-year, 5-year, and 10-year survival rates were 55.3%, 48.3%, and 33.7%, respectively, with a median survival of 73.0 months, after pancreaticoduodenectomy in 237 patients. Among these patients, 173 (73.0%) had T3 or T4 diseases. Similarly, in our series consisting of 75 patients including 21 (28%) patients with T2 disease, 46 (61%) with T3a, and 8 (11%) with T3b according to the Japanese classification [2], the 1-year, 3-year, and 5-year survival rates were 85.2%, 63.3%, and 38.2%, respectively, with a median survival of 46.0 months.

### Prognostic Factors

Several reports indicated prognostic factors for patients with distal bile duct cancer (Table 146.2). According to the meta-analysis of 25 studies [8], R1 resection, lymph node metastasis, perineural invasion, lymphatic invasion, vascular invasion, pancreatic invasion, and pathological tumor stage ≥ T3 were significantly associated with shorter overall survival, while sex, age, and blood transfusion have no impact on survival. Of these, R1 resection is one of the strongest prognostic factors, which was also indicated in other studies as a factor influencing survival after pancreaticoduodenectomy in patients with distal bile duct cancer [3,5,7]. Since distal bile duct cancer often spreads along the bile duct, a cancer-positive margin at the stump of the bile duct is sometimes encountered, resulting in a R0 resectability rate of 46–96% [8], which is lower than the frequency for other periampullary cancers.

Another important factor is lymph node metastasis, which was reported at appreciably different frequencies ranging from 22% to 68% [8]. According to the Japanese classification [2], the most frequently involved lymph nodes were nodes on the surface of the head of the pancreas (station nos. 13 and 17), followed by nodes in the hepatoduodenal ligament (station no. 12), nodes along the common hepatic artery (station no. 8) and nodes at the root of the superior mesenteric artery (station no. 14). Among these nodal stations, metastases to station no. 12 [9] or no. 8 [3] were reported to be associated with unfavorable outcome after pancreaticoduodenectomy. The lymph node ratio—the number of lymph nodes with metastases/the total number of removed lymph nodes—may be a possible predictor for survival, but variable results have been reported [10,11].

When the analysis was limited to patients with lymph node metastasis, the number of involved nodes ≥4 was shown to be a strong predictor of survival [3]. However, because of the limited data, further validation is required.

### Recurrence

A few studies have reported on cancer recurrence after pancreaticoduodenectomy. Recurrence occurred in 39–67% of patients [7,12,13] with a mean follow-up of 29–32 months. Mean delay was reported to be 13 months after surgical resection [12]. The frequent form of recurrence was intrahepatic and local recurrence, followed by peritoneal and systemic recurrence [7,12]. Intrahepatic recurrence occurs with higher frequency in patients with distal bile duct cancer than with ampullary region cancer [13].

## Ampullary Region Cancer

### Overall Survival

The survival in patients with ampullary region cancer is favorable (Table 146.3) compared with that in patients with distal bile duct cancer. According to the Biliary

Tract Cancer Registry in Japan [1], 2161 patients were registered from 2008 to 2013. Of these patients, 2053 (95.0%) underwent surgical resection. On the basis of the Japanese classification of biliary tract cancers [2], T2 disease was the most frequently seen (38.5%), followed by T1a disease (17.5%), and tumor stage was most frequently classified as Stage IA (29.1%), followed by Stage IB (27.2%). The overall 5-year survival rate was reported to be 61.3%. This survival rate decreased significantly with increasing degree of pathologic T category and tumor stage: the 5-year survival rates were 92.8% and 85.8% in patients with T1a and T1b diseases, respectively, and 92.2% and 74.7% in patients with Stage IA and Stage IB, respectively. In the database of the Surveillance, Epidemiology, and End Results (SEER) national cancer registry from the United States [14], 3292 patients were registered from 1998 to 2003, and 1301 of them (40%) underwent resection. The 5-year cancer-specific survival after resection was 47.3%. In this database, patients with Stage IIb were most frequently seen, and only 37.5% of patients were classified as Stage I.

In a multi-institutional study from the United States, Japan, and Turkey [15], the 1-year, 3-year, and 5-year survival rates were 85%, 63%, and 49%, respectively in 313 patients. This study included 32 patients (10.2%) with T1N0 and 81 patients (25.9%) with T2N0, according to the AJCC TNM classification system [4].

In high-volume single-center studies, the Johns Hopkins Hospital series [16] revealed that 5-year survival rate was 45.0% in 347 patients. In their series, 21.2% of all cases were classified as Stage I. In the Charité Campus Virchow Universitätsmedizin series in Germany [17], the 1-year and 5-year survival rates were 79% and 40%, respectively, with a median survival of 37 months in 143 patients undergoing pancreaticoduodenectomy. This series included 49 (34%) patients with Stage I. The National Yang Ming University series in Taiwan [18] showed that the 5-year survival rate was 42.7% with a median survival of 45.1 months in 194 patients, including 64 (33%) patients with Stage I.

## Prognostic Factors

Although diverse prognostic factors for resected ampullary region cancer have been described in the literature (Table 146.4), lymph node metastasis has been identified as the strongest prognostic factor. Lymph node metastasis could be found in 24–58% of patients [1,5,14–24]. Once tumor invades the sphincter of Oddi, lymph node metastasis can be found, and the frequency increases

BMI, body mass index; UICC, International Union Against Cancer; PPPD, pylorus-preserving pancreaticoduodenectomy.

with advancing depth of infiltration. The 5-year survival of patients with lymph node metastasis was reported to be 20–46% [1,5,15,16,18–21], while without lymph node metastasis it was 54–85%. Among node-associated variables, some reports indicated that the number of involved nodes was a significant independent prognostic factor, but cut-off point for the number of nodes was variable among studies [5,15,18,19]. Few reports showed the significance of the lymph node ratio [5,10].

The depth of infiltration or T category also influences long-term survival. Patients with T1/2 and Stage I disease have apparently favorable prognosis after pancreaticoduodenectomy, while limited resection such as transduodenal ampullectomy for these patients could not yield similar results [25,26]. In contrast, the survival of patients with pancreatic invasion, especially invasion ≥5 mm in depth, was reported to be significantly worse than that of patients without pancreatic invasion [27].

Ampullary region cancer represents a heterogeneous cancer group with different cell types: intestinal and pancreatobiliary types. Since it was first reported by Kimura et al. [28], several authors have revealed that ampullary region cancers with intestinal type are associated with favorable survival [29,30], although there are some controversial reports [31,32].

### Recurrence

A few studies have reported on cancer recurrence after pancreaticoduodenectomy. Recurrence occurred in 17–38% of patients with a median follow-up of 30–115 months [13,22–24]. Median time from surgical resection to recurrence was reported to be 50.2 months [22]. The most frequent form of recurrence reported was various among the literature, but intrahepatic and local recurrences were found to be relatively frequent [13,23,24]. Preoperative bilirubin, T category, pancreatobiliary cell type, lymph node metastasis [22], venous invasion, and perineural invasion [13] have been reported as factors related to recurrence.

## Duodenal Cancer

### Overall Survival

Duodenal cancer (adenocarcinoma) may be located in any part of the duodenum. In most studies, therefore, duodenal cancers arising in the periampullary duodenum, which has not been clearly defined yet, and in other parts of the duodenum (extra-ampullary duodenum) have been grouped together, although periampullary and extra-ampullary duodenal cancers were reported to have similar long-term survival after resection [33]. These cohorts generally included patients undergoing not only pancreaticoduodenectomy, but also segmental resection of the duodenum chiefly for duodenal cancer arising in the fourth portion of the duodenum.

The survival in patients with duodenal cancer is similar to that in patients with ampullary region cancer (Table 146.5). In a multi-institutional study in the United Kingdom [34], the 1-year, 3-year, and 5-year survival rates were 83.9%, 66.7%, and 51.2%, respectively, with a median survival of 84 months in 143 patients including 8 (5.6%) T1, 12 (8.5%) T2, 50 (35.2%) T3, and 72 (50.7%) T4 diseases.

Several high-volume single-center studies indicated similar survival rates. The Mayo Clinic series in the United States [33] found 5-year and 10-year survival rates of 43% and 39%, respectively, in 99 patients. In this series, the majority of patients had T3 disease and Stage II disease. In the Johns Hopkins Hospital series [35], the 5-year and 10-year survival rates were 48% and 41%, respectively, in 112 patients undergoing pancreaticoduodenectomy. The majority of patients also had T3 disease. The university of Texas M.D. Anderson Cancer Center series [36] found that the 5-year survival rate was 55.9% with a median survival of 149.8 months in 68 patients, including 31 (45.6%) patients with T3 and 32 (47.1%) with Stage III. In the Massachusetts General Hospital series [37], the 3-year and 5-year survival rates were 57% and 42%, respectively, with a median survival of 44 months in 103 patients who most frequently presented with Stage III disease (45%).

### Prognostic Factors

Recently reported prognostic factors are positive surgical margin, lymph node metastasis, AJCC Stage III/IV, poor differentiation, perineural invasion, and lymphovascular invasion (Table 146.6), while patient age, gender, and size of the tumor have not been consistently associated with the outcome. As for other periampullary cancers, lymph node metastasis is recognized as one of the most significant prognostic factors. Noteworthy is the relationship between an increased number of involved nodes and poor survival. The current AJCC TNM classification system [4] stratifies N category as N0 (no regional lymph node metastasis), N1 (metastasis in 1–3 regional lymph nodes), and N2 (metastasis in four or more regional lymph nodes). In fact, the survival rate was reported to decrease with N category [34,35]. For assignment of the N category, however, the number of lymph nodes examined is important. Sarela et al. [38] showed that examination of ≥15 regional lymph nodes improved prognostic discrimination by the N category. They found that the survival difference between pN0 and pN+ was significant in patients with ≥15 nodes, but was lost in those with <15 nodes probably because of a stage-migration effect.

The lymph node ratio might be also a possible prognostic factor. Poultsides et al. [35] demonstrated that the 5-year survival decreased as the lymph node ratio increased from 0 to >0–0.2 to >0.2–0.4 to >0.4.

### Recurrence

Recurrence occurred in 14–45% of patients with a median follow-up of 26–39 months, although some reports did not clearly describe a median follow-up time [34–37,39]. A median time from surgical resection to recurrence was reported to be 14.5 months [37]. The frequent form of recurrence was distant metastases, followed by locoregional recurrence [34,35,37]. Among distant metastases, liver metastasis is the most frequent.

# Transplantation of Pancreatic Islets

*Bernhard J. Hering and Melena D. Bellin*

*University of Minnesota Medical Center, Minneapolis, MN, USA*

## Introduction

Transplantation of allogeneic islets has evolved as an effective treatment for selected patients with type 1 diabetes (T1D) [1]. Transplantation of autologous islets has become an established treatment to mitigate the severity of surgical diabetes in patients with severe chronic pancreatitis (CP) undergoing total pancreatectomy [2,3]. This chapter provides an update on the status of human islet allotransplantation in T1D and islet autotransplantation in severe CP and briefly reviews research priorities in these fields. Excellent and more comprehensive reviews have recently been published by other authors [1,2,4–12] and updated results on clinical islet allotransplantation have been provided by the Collaborative Islet Transplant Registry (CITR) in their latest annual report [13].

## Manufacturing, Release Testing, and Infusion of Allogeneic Human Islets

The preeminent procedures involved in transplantation of allogeneic human islets in T1D are illustrated in Fig. 147.1 and in more detail in Fig. 147.2. The selection of deceased pancreas donors is a critical factor in determining the yield of islets available for transplant [14–16]. Based on characteristics of 1235 deceased pancreas donors and islet yields obtained from their pancreata, a scoring system has been developed to predict postpurification islet yields of >400,000 islet equivalents (IEQ). Adherence to validated principles of donor pancreas procurement [17] and utilization of optimized enzyme blends for pancreatic tissue dissociation [18] increase the yield and transplant rate of human islet products. To advance allogeneic islet products toward licensure in the United States, eight manufacturing facilities participating in the National Institutes of Health-sponsored Clinical Islet Transplantation (CIT) Consortium jointly developed and implemented a harmonized process for the manufacture of allogeneic purified human pancreatic islet product (PHPI) for evaluation in a Phase 3 trial in subjects with T1D [19]. Manufacturing was controlled by a common master production batch record (MBPR), standard operating procedures (SOP) that included acceptance criteria for deceased donor organ pancreata and critical raw materials, PHPI product specifications, certificate of analysis, and test methods. The process was compliant with Current Good Manufacturing Practices and Current Good Tissue Practices. The quality systems and regulatory and operational strategies developed by the CIT Consortium yielded product lots that met the prespecified characteristics of safety, purity, potency, and identity and were successfully transplanted into participating subjects. No adverse events attributable to the product and no cases of primary nonfunction were observed. The CIT MPBR and SOPs are publicly available (referenced in [19]). The most commonly used islet implantation site is the liver with islets being infused intraportally. The portal vein is accessed by percutaneous transhepatic catheterization [20–22] or by minilaparatomy [23,24].

## Selection of Islet Allotransplant Recipients

Transplants of allogeneic islets have been performed in patients with T1D either as islet transplant alone (ITA) in nonuremic recipients, as simultaneous islet kidney

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

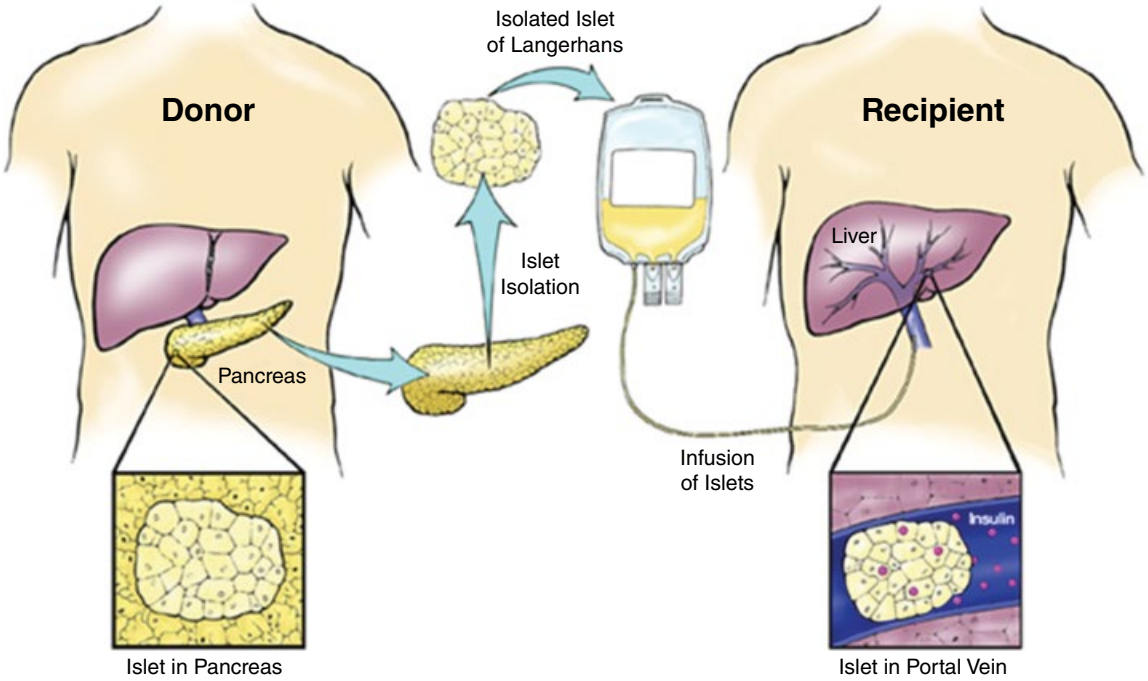

**Figure 147.1** Diagram depicting the standard approach to transplantation of human allogeneic islets. A pancreas is retrieved from a suitable deceased donor. Islets are isolated from the donor pancreas, transferred to a transfusion bag, and infused intraportally into a type 1 diabetic recipient.

(SIK) transplant in uremic recipients, or as islet after (previous) kidney (IAK) transplant in posturemic recipients [25].

As ITA recipients are exposed to chronic and generalized immunosuppression only for the purpose of protecting the islet graft, in each individual ITA candidate the morbidity of diabetes complications must be perceived to be more serious than the risks associated with immunosuppression and the expectation of benefit associated with the islet graft must be high. Most ITA have been performed in patients in whom T1D is complicated by impaired awareness of hypoglycemia (IAH) and recurrent severe hypoglycemic episodes (SHE) [25]. Because of profound neuroglycopenia, severe hypoglycemia is a greatly feared acute complication [26,27] that requires the assistance of another person for recovery [28,29]. IAH is found in up to one-third of adult patients with T1D and increases their risk of SHE sixfold [30]. Recurrent hypoglycemia can have a profound impact on people's confidence, careers, and personal relationships [31], it can disrupt many everyday activities such as driving, work performance, leisure pursuits, and sleep [27,32], and it can cause embarrassment, social ostracism, and employment discrimination [33].

Although several new educational and technological interventions have recently been developed and should always be employed as first-line therapy in patients with SHE [34], not all patients with IAH benefit from these interventions [35]. Despite accepting elevated hemoglobin $A_{1c}$ ($HbA_{1c}$) targets of 8.0% and having access to behavioral therapies and sensor-augmented insulin pumps at a specialist hypoglycemia service, only 50% of patients with T1D and recurrent SHE experienced resolution of SHE, and 30% required pancreas or islet transplantation because of persistent SHE [36]. As will be outlined in more detail later, islet transplantation is very effective in restoring near-normoglycemia, awareness of hypoglycemia, and protection from SHE in patients with T1D and IAH who accept the risks associated with immunosuppression. Accordingly, recently published evidence-informed clinical practice recommendations identify patients in whom T1D is complicated by IAH and recurrent episodes of SHE as candidates for islet or pancreas transplantation under the following condition: SHE persist after completion of a structured stepped care approach or a formalized medical optimization run-in period that provides access to hypoglycemia-specific education including behavioral therapies, insulin analogs, and diabetes technologies under the close supervision of a specialist hypoglycemia service [35]. Recent reports of multicenter trials of ITA in T1D complicated by hypoglycemia provide additional information on patient selection and eligibility [37–39].

SIK and IAK recipients [40–56] are already obligated to immunosuppression because of their concurrent or previous kidney transplant. Therefore, the risks of the

Balamurugan, University of Louisville, and Jeffrey Ansite and Josh Wilhelm, University of Minnesota.

islet transplant procedure, as in ITA recipients, should be minimal by following well-defined precautions (as discussed later). Thus, the risk–benefit ratio of an added islet transplant could be very favorable, especially in those SIK and IAK recipients with T1D, who cannot meet clinically appropriate glycemic goals or continue to experience SHE after completion of a formalized medical optimization program under the guidance of an expert diabetes care team [35]. These recipients may also include patients who are not surgical candidates for or willing to accept the risks of a pancreas transplant [35,54,57].

## Outcomes of Islet Allotransplantation in T1D

### One- and Two-Year Metabolic Efficacy Results in ITA and IAK/SIK Recipients

The achievement of insulin independence in all of seven nonuremic ITA recipients by Shapiro et al. in Edmonton in 2000 marked a major breakthrough in the clinical development of islet transplantation [58]. All patients quickly attained insulin independence after transplantation of a mean ± SD islet mass of 11,547 ± 1604 IEQ/kg body weight. All recipients required islets from two donor pancreases and one required a third transplant from two donors to achieve sustained insulin independence. After a median posttransplant follow-up of 11.9 months (range 4.9–14.9 months), the mean glycosylated hemoglobin values were normal and episodes of hypoglycemic coma were avoided in all recipients. The complications were minor. The high success rate of the Edmonton protocol in restoring insulin independence has been attributed to the infusion of a high islet mass from more than one donor pancreas and the use of a glucocorticoid-free, low-dose tacrolimus and sirolimus maintenance immunosuppressive protocol, which is considerably less diabetogenic than previous protocols [40,41].

The insulin independence rate in the subsequent international multicenter trial of the Edmonton protocol for islet transplantation was 44% (16 of 36 patients) at 1 year posttransplant [59]. The trial confirmed that persistent islet function even without insulin independence provides both protection from severe hypoglycemia and improved levels of glycated hemoglobin [60]. The lower insulin independence rate compared with the initial and follow-up single-center reports by Edmonton [58,60] was in large part explained by the highly variable results achieved among the nine participating centers [59].

Consequently, and as already discussed, the manufacture of islet products for testing in the subsequent CIT trials was controlled by a harmonized process using a common batch record. Adherence to prespecified batch release criteria was demonstrated in qualification runs at each of the selected participating centers [19]. The purpose of the CIT-07 Phase 3 trial, conducted at eight centers in North America, was to demonstrate the safety and effectiveness of transplantation of allogeneic islets in T1D complicated by SHE. Forty-eight adults with T1D for >5 years and persistent IAH and SHE were enrolled. The treatment protocol included three key features that were adopted from a single-center trial performed at the University of Minnesota, in which insulin independence was achieved in all of eight recipients after infusion of a mean (± SD) islet mass of 7271 ± 1035 IEQ/kg body weight prepared from a single deceased donor pancreas [61]. These protocol elements were pretransplant islet culture for 48 hours, potent induction immunosuppression with antithymocyte globulin, and peritransplant administration of the tumor necrosis factor α (TNF-α) inhibitor etanercept, high-dose heparin, and intravenous insulin [39]. Maintenance immunosuppression was with low-dose tacrolimus combined with sirolimus [58]. The primary endpoint of the CIT-07 trial was achievement of $HbA_{1c}$ <7.0% at day 365 and freedom from SHE from day 28 to day 365 after the first of up to three islet transplants.

This composite endpoint, clinically considered more relevant than insulin independence in the study population of patients with T1D and SH and suggested by the Food and Drug Administration (FDA) Center for Biologics Evaluation and Research (CBER) as the primary endpoint for licensure trials in their 2008 guidance on allogeneic pancreatic islet cell products [62], was met in the CIT-07 trial by 87.5% of participants at 1 year and by 71% at 2 years after the first transplant [39]. The Australian multicenter trial reported results on the same composite endpoint; of the 17 recipients with T1D and IAH enrolled in the Australian trial, 14 (82%) met this endpoint [38]. Comparable metabolic goals were achieved by the Integrated UK Islet Transplant Program in its multicenter trial [37]. The CIT-07 trial also demonstrated highly significant improvements in several other measures of glycemic control (e.g., glycemic lability index, mean amplitude of glycemic excursions, time within glucose target range) and also restoration of hypoglycemia awareness, as evidenced by normal posttransplant Clarke and Ryan HYPO scores [39]. The median daily insulin use decreased from 0.49 units/kg at baseline to 0.00 units/kg (range 0.00–0.43 units/kg) at day 365 posttransplant; 52.1% of participants were insulin independent at day 365.

More detailed metabolic studies demonstrated that intraportal islet transplantation can restore partial glucagon secretion, improve epinephrine secretion, restore autonomic symptom perception, and normalize endogenous glucose production in response to

insulin-induced hypoglycemia in patients with long-standing T1D and IAH enrolled in the CIT-07 protocol [63]. Trials performed in Europe showed that, by increasing endogenous glucose production, even partial islet graft function improves hypoglycemia counterregulation [64], explaining in part that minimal islet graft function is sufficient to abrogate hypoglycemia (<54 mg/dL) [65].

IAK and SIK transplantation has been studied in pilot clinical trials by single centers and the French–Swiss GRAGIL Network (Group de Recherche Rhin, Rhône-Alpes et Genève pour la Transplantation d'Ilots de Langerhans) using several immunosuppressive protocols and endpoints [40–56]. These studies suggest that insulin independence and near-normoglycemia can be restored in IAK/SIK recipients at rates comparable to those for ITA recipients. The CIT-06 trial, performed by the CIT Consortium, is the first Phase 3 trial of transplantation of human islets in T1D patients with established kidney transplants [66]. The primary endpoint of the trial is the proportion of subjects with both an $HbA_{1c}$ ≤6.5% or a reduction in $HbA_{1c}$ of ≥1% and absence of SHE at 1 year after the first islet transplant. The results of this trial are expected to be reported in 2018.

The Ninth CITR Annual Report analyzed islet transplants in 819 ITA and 192 IAK/SIK recipients, who received their first infusion between 1999 and 2013 (Scientific Summary, Exhibit D) [13]. In this report, the CITR identified a small number of favorable factors that define the subgroup of recipients with significantly higher prevalence of several clinically relevant metabolic efficacy outcomes (except absence of SHE, which showed remarkably high and sustained prevalence in islet allograft recipients). The favorable factors in ITA recipients were total IEQ ≥325,000, recipient age ≥35 years, induction immunosuppression with T-cell depletion and/or TNF-α inhibition, and maintenance immunosuppression with mammalian target of rapamycin (mTOR) and calcineurin inhibitor (CNI); the favorable factors identified in IAK/SIK recipients were total IEQ ≥325,000 over one or several infusions and insulin administration during organ donor management. When ITA and IAK/SIK recipients met all of the factors uniquely favorable for their subgroup, at 1 year after the last infusion the proportions of both ITA and IAK/SIK recipients with $HbA_{1c}$ <6.5% or drop by 2% were 78.6 and 83.9%, the proportions of recipients free of SH were 92.9 and 96.9%, and the rates of insulin independence were 74.8 and 68.1%, respectively.

## Long-Term Metabolic Efficacy Results in ITA and IAK/SIK Recipients

Although only a minority (~10%) of 63 patients transplanted under the Edmonton protocol maintained insulin independence for 5 years posttransplant, approximately 80% showed sustained partial islet allograft function associated with $HbA_{1c}$ levels of <7.0% and protection from SH for at least 4 years [60]. The French–Swiss GRAGIL Network also reported sustained benefits of islet transplants in a cohort of 44 islet allograft recipients [48]. At 5 years posttransplant, 26% of recipients had remained insulin independent and 60% met the composite endpoint of $HbA_{1c}$ levels of <7.0% and absence of SHE. In an independent study with more than 7 years of follow-up, the Zurich group showed improved glycemic measures after SIK/IAK transplantation compared with intensified insulin therapy [53]. A CITR analysis reported in 2012 showed that, regardless of sustained graft survival, >90% of all T1D islet allograft recipients in their database, of whom >90% had IAH, had remained free of SH through 5 years of follow-up [25]. Of the ITA recipients meeting the four favorable factors identified by CITR (see earlier), 95.5% were free of SHE and 72.9% had $HbA_{1c}$ <7.0% at 5 years after the last islet infusion (Fig. 147.3). Refined peritransplant management including more potent induction immunosuppression was associated with an insulin independence rate of 50% at 5 years after the final islet infusion [67], suggesting that a higher engrafted islet mass [68] could improve the longevity of the graft [69]. Of note, these improved results match long-term insulin independence rates after vascularized pancreas transplantation alone in nonuremic recipients [70]. The maintenance of insulin independence in an exceptional case for >10 years suggests that continued, long-term islet allograft function is an attainable target [71].

## Effects on Chronic Diabetes Complications, Patient Survival, and Quality of Life

Very few studies have examined the effects of islet transplantation on chronic diabetes complications. The Milan group demonstrated in a cohort of IAK recipients followed for 7 years that successful islet transplantation, when compared with controls, was associated with lower cardiovascular mortality and improved endothelial function, kidney graft function, and kidney graft survival rates [50,72]. Sustained islet graft function was also associated with improved cardiovascular function for up to 3 years [73]. In a prospective, crossover cohort study examining the effects of ITA and intensive medical therapy on the progression of microvascular diabetes complications, the rate of decline in glomerular filtration rate (GFR) was slower and the rate of progression of retinopathy was lower after ITA than on medical therapy [74]. Quality of life (QOL) studies using existing questionnaires showed that islet transplants, although having no impact on overall health-related QOL, were associated with improved diabetes-specific QOL, less fear of

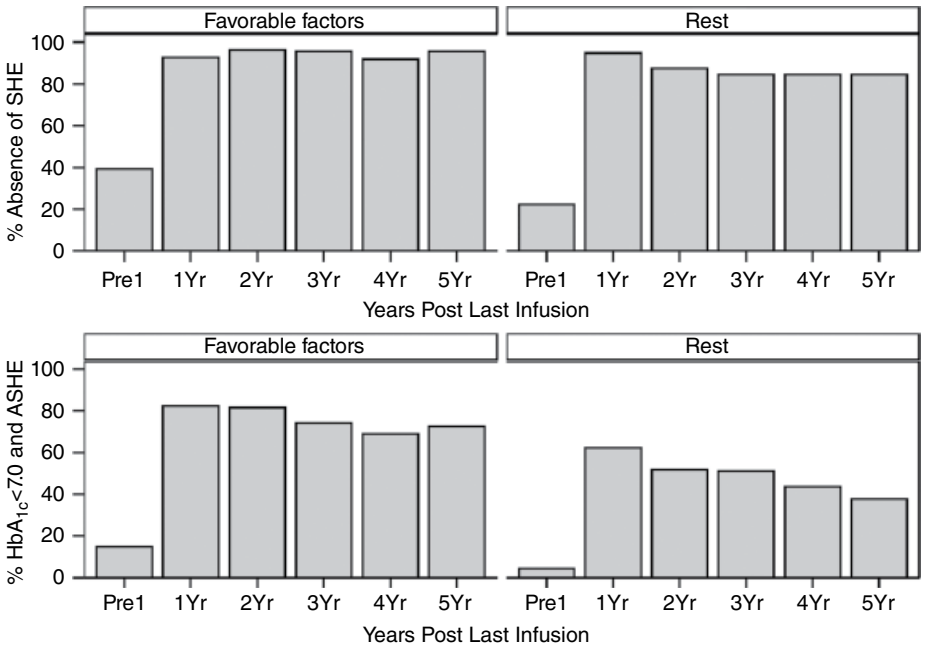

**Figure 147.3** Observed prevalence rates of primary outcomes in T1D ITA recipients reported to CITR. Rates are shown according to subgroups with all four "favorable factors," (i) induction immunosuppression with T-cell depletion and/or TNF-alpha inhibitor, (ii) maintenance immunosuppression with mTOR inhibitor and calcineurin inhibitor, (iii) number of islet equivalents transplanted ≥325,000, and (iv) recipient age ≥35 years (left panels), and less than four favorable factors ("Rest"; right panels). Top row: proportion of recipients with absence of SHE in both subgroups prior to the first islet transplant (Pre1) and at each of the first 5 years after the last islet infusion. Of the 565 recipients analyzed, $n = 148$ met all four favorable factors, whereas $n = 417$ recipients met less than four of the favorable factors ("Rest"). Of those meeting all four favorable factors ($n = 148$), 39.2% (58 of 148) were free of SHE prior to transplantation; whereas 95.5% (42 of 44) of recipients were free of SHE at 5 years post-last islet infusion. Bottom row: proportion of recipients meeting the composite endpoint of $HbA_{1c}$ <7.0% and absence of SHE prior to the first islet transplant and at intervals post-last islet infusion. Of the 619 recipients analyzed, $n = 149$ met all four favorable factors, whereas $n = 470$ recipients met less than four of the favorable factors ("Rest"). Of those meeting all four favorable factors ($n = 149$), 14.8% (22 of 149) met the composite endpoint prior to transplantation; whereas 72.9% (35 of 48) of recipients met the composite endpoint at 5 years post-last islet infusion. *Source:* Courtesy of Franca Barton and Cassandra Ballou, The Emmes Corporation and CITR.

hypoglycemia, a reduction in behaviors adopted in avoiding hypoglycemia, and attenuation in concerns about SHE [75–80]. Importantly, when balancing the outcomes against the immunosuppressant side-effects and the procedure, most recipients reported "no regrets" about undergoing islet transplantation [81].

## Adverse Effects of Islet Transplantation and Immunosuppression

Procedure-related complications of intraportal islet infusion include portal venous thrombosis, transient increase in liver enzymes, puncture of the gallbladder, and bleeding. Portal thrombosis is a preventable complication, provided that therapeutic anticoagulation is maintained and the infused packed cell volume is limited to <5.0 mL [82]. The risk of puncturing the gallbladder injury is minimized by ultrasonic guidance [83]. Postprocedural bleeding can be avoided by effective obliteration of the intraparenchymal catheter tract in the liver [22,84] or by accessing a mesenteric vein via minilaparatomy for intraportal islet infusion [23,24].

Immunosuppression- and immunity-related complications in ITA recipients include nephrotoxicity and sensitization to donor human leukocyte antigen (HLA) antigens. Although the decrease in GFR is common and significant, the GFR typically remains in the normal range. The decline in GFR is explained by an acute CNI effect [85] and is possibly, in part, also associated with correction of hyperfiltration after restoration of near-normoglycemia [86,87]. Whether the decline in GFR is progressive or stable in ITA recipients, as demonstrated in kidney transplant recipients immunosuppressed with CNI [88], remains to be determined. Of note, the rate of decline in GFR was slower in CNI-treated ITA recipients than in control patients on intensive medical therapy [74]. The risk of HLA class I sensitization is significant in ITA recipients in whom immunosuppression is discontinued after complete graft loss; it can be minimized by minimizing the number of islet donors used per recipient and by repeating HLA class I mismatches with

subsequent islet infusions [89,90]. In the CIT-07 Phase 3 trial, six of 48 participants had positive panel reactive antibodies at 2-year follow-up and donor-specific antibodies developed in two patients [39].

Neoplasms were diagnosed in 32 of 864 islet recipients who collectively represent a total of 5762 person-years of observed follow-up [91]. Neoplasms diagnosed were (No. of recipients) basal or squamous cell carcinoma (17), malignant ovarian cysts (6), breast cancer (2), lung cancer (2), thyroid cancer (2), and posttransplant lymphoproliferative disorder (PTLD) (3). The mortality risk is very low in islet transplantation; only three of the 25 deaths in 864 recipients reported to the CITR were definitely related to the transplant or immunosuppression [91].

## Outcomes of Islet Autotransplantation in Chronic Pancreatitis

Total pancreatectomy with islet autotransplantation (TPIAT) is most often utilized in patients with painful and debilitating CP who have not responded to medical, endoscopic, and/or surgical therapies and whose impairment in QOL due to pain is substantial enough to accept the risk of developing postoperative insulin-dependent diabetes and a lifelong commitment to pancreatic enzyme replacement therapy [92]. The criteria for selecting patients with CP for TPIAT have evolved over the years [3]. TPIAT has recently also been considered and performed for an increasing number of other conditions, including benign cystic lesions, pancreatic trauma, and premalignant conditions such as intraductal papillary mucinous neoplasm [2]. TPIAT for malignancy remains highly controversial [93].

Currently, more than 20 academic institutions across the world have active TPIAT programs and the number is rapidly increasing [2,92]. The University of Minnesota, the center with the largest experience (>675 cases since 1977), published a detailed analysis of their first 409 patients [3]. This series included 53 children. Etiologies of chronic pancreatitis were idiopathic, 41%; sphincter of Oddi dysfunction/biliary, 9%; genetic, 14%; divisum, 17%; alcohol, 7%; and other, 12%. The mean age was 35.3 years, 74% were female, and 21% had had earlier operations. Actuarial patient survival post-TPIAT was 96% in adults and 98% in children (at 1 year) and 89% and 98% (at 5 years). Complications requiring relaparotomy occurred in 15.9% and bleeding (9.5%) was the most common complication. IAT function was achieved in 90% (C-peptide >0.6 ng/mL). At 3 years, 30% were insulin independent (25% in adults, 55% in children) and 33% had partial function. Mean $HbA_{1c}$ was <7.0% in 82%. Earlier pancreas surgery lowered islet yield (2712 versus 4077/kg; $P = 0.003$). Islet yield (<2500, 2501–5000, and >5000/kg) correlated with degree of function with insulin-independent rates at 3 years of 12, 22, and 72% and rates of partial function of 33, 62, and 24%, respectively. All patients had pain before TPIAT and nearly all were on daily narcotics. After TPIAT, 85% had pain improvement. By 2 years, 59% had ceased narcotics. All children were on narcotics before and 39% at follow-up; pain improved in 94% and 67% became pain-free. In the SF-36 survey for QOL, there was significant improvement from baseline in all dimensions, including the Physical and Mental Component Summaries, whether on narcotics or not. In a retrospective survey, >95% of the patients stated that they would recommend TPIAT [94].

The University of Minnesota analyzed factors predicting outcomes after TPIAT in their first 581 patients [95]. The duration (mean ± SD) of CP before their TPIAT was 7.1 ± 0.3 years and of narcotic usage 3.3 ± 0.2 years. Pediatric patients had better postoperative outcomes. Among adult patients, the odds of narcotic use at 1 year were increased by previous endoscopic retrograde cholangiopancreatography and stent placement and a high number of previous stents (>3). Independent risk factors for pancreatic pain at 1 year were pancreas divisum, previous body mass index >30, and a high number of previous stents (>3). The strongest independent risk factor for islet graft failure was a low islet yield in IEQ per kilogram of body weight. There was a strong dose–response relationship between the lowest-yield category (<2000 IEQ) and the highest (≥5000 IEQ or more). Islet graft failure was 25-fold more likely in the lowest-yield category. A retrospective review of 75 children undergoing TPIAT at the University of Minnesota [96] showed that pancreatitis pain and the severity of pain statistically improved in 90% of patients after TPIAT and that 41.3% of the children achieved insulin independence. By multivariate analysis, three factors were associated with insulin independence after TP-IAT: (i) male gender, (ii) lower body surface area, and (iii) higher total IEQ per kilogram body weight. Total IEQ (100,000) was the single factor most strongly associated with insulin independence (odds ratio 2.62; $P < 0.001$).

## Research Priorities in Islet Transplantation

Optimizing donor pancreas procurement and transportation, refining islet isolation and release testing, establishing extrahepatic sites and novel islet delivery techniques for enhanced islet engraftment, developing CNI-free immunosuppressive protocols lacking islet toxicity, and incorporating islet imaging and donor-specific immune assays into monitoring will improve the outcomes and utilization of islet allotransplantation [97].

However, the two most impactful research priorities are the generation of an unlimited supply of islet cells for transplant and the development of a maintenance immunosuppression-free rejection and autoimmune recurrence prophylaxis. Although substantial progress has been made in generating functional, insulin-producing stem cell-derived pancreatic islet cells *in vitro* [98,99], important questions remain to be addressed [100]. Remarkable progress has also been made in preclinical studies of porcine islet xenotransplantation [101–103] and in defining the conditions for initiating clinical trials of porcine islet xenotransplantation [104]. Long-term functional supply of allogeneic human islets in an oxygenated immunoisolation device suggests that such technologies could permit testing and possibly drug-free survival of stem cell-derived islet products in humans in the not too distant future [105]. Donor thymus transplantation, mixed xenogeneic chimerism, and other strategies are being developed for tolerance induction to porcine xenografts [106]. The CRISPR/Cas system (clustered regularly interspaced short palindromic repeats/CRISPR-associated system) [107], a novel gene editing platform technology with unmatched precision and efficiency, will accelerate the generation of porcine donors with multiple genetic modifications [108] for the purpose of facilitating xenotransplantation with reduced immunosuppression.

Research gaps and opportunities in TPIAT include selection of the "right" patient, optimal timing of surgery, opportunities to address better pain remission, islet engraftment, and functional survival, unique features of children with CP, psychological comorbidities, standardization of care, and a comprehensive registry that addresses the complexities of CP and TPIAT [92].

## Conclusions

Islet allotransplantation has become a viable treatment option for patients with T1D and IAH in whom optimized medical therapy has been ineffective in preventing SHE [35,39]. Islet transplantation should also be considered in patients with T1D and end-stage renal failure who cannot meet clinically appropriate glycemic goals or in whom SHE persist [53]. TPIAT is now an accepted treatment modality for CP and intractable pain [2]. Although important goals remain to be met, including cost efficiency, durability of graft function, and safety of immunosuppression in allotransplant recipients, real opportunities now exist to overcome these challenges.

## Acknowledgments

This research was supported in part by grants from the National Institutes of Health UO1-AI-065193 (B.J.H.) and K23-DK-084315 (M.D.B.). The authors thank Dr A.N. Balamurugan, University of Louisville, and Jeffrey Ansite and Josh Wilhelm, University of Minnesota, for providing photographs for Fig. 147.2 and Franca Barton and Cassandra Ballou, The Emmes Corporation and CITR, for helpful discussions and for providing Fig. 147.3.

# Transplantation of the Pancreas

*Hans W. Sollinger and Dixon B. Kaufman*

*Division of Transplantation, University of Wisconsin Department of Surgery, Madison, WI, USA*

## Introduction

Over the past 10–15 years, pancreas transplantation has emerged as a standardized, widely accepted option for selected patients with insulin-dependent diabetes mellitus (IDDM) [1]. Several options for pancreas transplant exist: simultaneous pancreas–kidney transplantation (SPK) for patients already in renal failure, pancreas transplantation after a kidney transplant (PAK) for patients who still have problems with blood glucose control or patients who had received a live donor kidney previously, and pancreas transplantation alone (PA) for patients with very brittle diabetes.

From 2010 to 2014, 1-year patient survival for SPK in the United States was reported to be 97.4%, pancreas graft function 91.3%, and kidney survival 95.5%. The improvements were due to fewer technical and immunologic failures. Survival for PAK and PA has also improved dramatically (A.C. Gruessner, International Pancreas Transplant Registry [IPTR], personal communication, 2016).

## Epidemiology and Sequelae of Insulin-Dependent Diabetes Mellitus

According to the Centers for Disease Control Fact Sheet, over 20 million people in the United States, 7% of the population, have IDDM. Type 1 diabetes accounts for about 10% of the prevalence of diabetes, whereas type 2 diabetes accounts for 90% and is caused by impaired insulin action.

IDDM is caused by destruction of the pancreatic β cells by an autoimmune process [2–4]. Without insulin, homeostasis of energy and glucose regulation is severely disturbed, leading to hyperglycemia and ketoacidosis after oral glucose intake. It occurs mostly in young patients, constantly threatening life and impairing quality of life significantly. In the long term, numerous sequelae are linked to diabetes, including nephropathy, neuropathy, retinopathy, and vascular problems, to mention only the most common complications [5]. Overall life expectancy is shortened [6]. The cost for the healthcare system is also significant, mostly in treating advanced diabetic complications [7,8]. Treatment involves insulin injection, aiming to achieve maximum control of glucose levels. On the other hand, achieving tight control of glucose may put the patient at risk of life-threatening hypoglycemia [5]. At present, no insulin therapy, either regular daily injections or artificial insulin pumps, can control glucose levels perfectly. For selected patients, the best option is pancreas transplantation, aiming to restore a functioning feedback mechanism involving glucose measurement and insulin release. Several studies have proved that pancreas transplantation may mitigate the long-term complications of diabetes [9,10]. However, these studies are difficult to interpret as none of them were controlled.

## Historical Aspects

The discovery of insulin in 1920 in Toronto by Banting and Best, an orthopedic surgeon and his medical student, transformed diabetes mellitus from an acutely fatal disease to a chronic illness that may result in kidney failure, blindness, vascular disease, and disabling neuropathy. Transplantation of the vascular pancreas was proposed as a potential cure for this disease, as this operation normalizes blood glucose control without the need for exogenous insulin, normalizes hemoglobin $A_{1c}$ ($HbA_{1c}$) levels, dramatically improves quality of life, and

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

potentially prevents or mitigates secondary complications. The first pancreas transplant was performed on December 16, 1966, by Kelly and Lillehei's group [11]. This was followed by a series of transplants utilizing modified surgical techniques. For more than a decade, the lack of powerful immunosuppressants, antibiotics, and antivirals in a population of severely ill patients yielded very poor results. In 1980, the few centers performing pancreas transplants reported a graft survival at 1 year posttransplant of 20% and patient mortality as high as 40% (D.E.R. Sutherland, IPTR, personal communication, 1982). It was not surprising, therefore, that pancreas transplantation acquired a bad reputation among diabetologists and nephrologists and referrals for this operation were sparse. In 1978, Dubernard and the Lyon group suggested avoiding anastomosis of the pancreatic duct or duodenum altogether and obliterating the pancreatic duct with neoprene, a liquid synthetic rubber that hardened after injection [12]. The technique lost its appeal when it became obvious that pancreaticocutaneous fistulas and infections complicated the postoperative course. The Lyon experience demonstrated that the pancreas must be drained and, in an attempt to avoid contamination by opening bowel, Sollinger and the Wisconsin group first suggested using the urinary bladder as a drainage conduit [13]. This drainage technique proved to be safer and temporarily boosted the enthusiasm for pancreas transplantation. However, in a review of 500 SPKs, we concluded that urologic complications were too significant to continue with bladder drainage [14], and in 1995 we converted to enteric drainage. This technique is now standard in the majority of transplant centers performing pancreas transplantation. About 50% of our patients who had undergone bladder drainage required enteric conversion [15]. For practical purposes, it should be mentioned that enteric conversion is highly successful if performed within 1 year after transplantation. At a later time, the chronically distended duodenal segment is much more prone to anastomotic leakage and we recommend Roux-en-Y diversion.

From December 1966 to December 2014, 48,000 pancreas transplants were reported to the International Pancreas Transplant Registry (A.C. Gruessner, IPTR, personal communication, March 2016). More than 29,000 were reported from the United States. Since 2004, pancreas transplantation has decreased in the United States, whereas other countries have shown a steady increase.

## Indications for Pancreas Transplantation

Our general rule for any type of pancreas transplantation is that the potential beneficial effects of the transplantation must outweigh the possible complications of surgery and the side-effects of immunosuppressive therapy. Patients should be in good general health, since the operation is challenging and has its morbidities. No strict age limit exists, but most transplanted patients are less than 50 years old as complication rates increase with age [16,17]. We recommend 55 years as the upper age limit. Our youngest patient was 11 years old; indeed, younger patients in particular might obtain increased benefit from a transplant, since diabetic comorbidities may reverse better in the young. Obese patients should be encouraged to lose weight before transplantation, since complication rates increase with a body mass index (BMI) >30 [18–20].

SPK is indicated in patients with IDDM and end-stage renal disease (ESRD). Transplantation of the pancreas as a part of an SPK is easily justifiable, as the patient has to undergo immunosuppressive therapy for the kidney transplant in any case. Also, the fact that both organs are transplanted during the same operation makes SPK attractive. Although SPK remains the most frequently performed form of pancreas transplantation, the numbers performed in the United States have decreased since 2004. In the opinion of the authors, this is due to improved medical treatment that delays diabetic end-stage nephropathy (thus causing an increase in the age of potential recipients who develop ESRD), and a progressive increase in donor age making the pancreas organ less suitable for transplant.

The indications for PAK are somewhat controversial. In general, the procedure is reserved for patients who have difficulties controlling diabetes after kidney transplantation. However, in the United States, because of allocation rules in many regions, no preference is given to SPK recipients. Therefore, many patients first receive a live donor or deceased donor kidney followed by a pancreas transplant. Isolated pancreatic grafts are available in larger quantities. There has been controversy regarding the survival benefit of PAK. As a reflection, PAK has decreased by 50% over the past 10 years.

The indications for PA are difficult to standardize. Careful monitoring of long-term survival and immunosuppressive complications is required. In our view, the procedure is indicated only in extremely rare cases. Some surgeons consider the procedure when several severe diabetic complications are present and the diabetes is hyperlabile with severe episodes of hypoglycemia and ketoacidosis in addition to unawareness of hypoglycemia. There is controversy about the degree of difficulty that a patient must experience before he or she qualifies for this operation. At the University of Wisconsin (UW), it is required that the patient be evaluated by an experienced endocrinologist and that at least several types of insulin administration and glucose controls have been attempted. If the patient continues to experience frequent hypoglycemic episodes, the indications for PA are given.

Some centers have performed pancreas transplantation in patients with type 2 diabetes. Hence this indication is becoming more frequent, but the benefits in this scenario still require further study. Most recently, a BMI of 30 or below and a C-peptide level >2 are required for a patient to be listed by the United Network for Organ Sharing (UNOS).

Only a small number of living related pancreas transplants have been performed since 1994 [21]. The procedure bears significant risks for the donor and should be performed only under strict study conditions. The procedure is not performed at our center.

## Preoperative Workup and Cardiac Risk Assessment

The preoperative workup is comparable to a kidney transplant workup and aims to exclude potential risks for the recipient [16]. The workup includes past medical history and a general physical examination, laboratory studies (creatinine, $HbA_{1c}$, C-peptide, etc.), viral serology, immunologic studies, computed tomography (CT) to assess the quality of the iliac arteries, and cancer screening, which includes mammography, PAP smear, prostate-specific antigen, and colonoscopy (in those over 50 years old).

Additionally, patients with diabetes are more prone to have coronary artery disease. Therefore, a thorough evaluation of the status of the coronary arteries is mandatory. Cardiovascular complications are a major cause of both short- and long-term death [22]. Complex algorithms have been published regarding the preoperative cardiac workup for pancreas transplant recipients [23,24]. A review of all studies prompted us to mandate coronary angiography in all patients over 35 years of age and in younger patients with a cardiac history and/or abnormal stress testing.

## Donor Selection and Donor Pancreatectomy

Selection of the pancreas donor is difficult unless the donor is young and slim. The age of the donor is one of the principal factors impacting postoperative pancreas graft survival [25]. The lower age limit at our center is 3 years. In fact, we have shown that pancreatic grafts from younger donors have over 90% success for 10-year patient and graft survival rates [26]. Older donors and obese donors are only accepted if visual inspection of the graft demonstrates a satisfactory graft. Careful evaluation of the graft, considering consistency, fibrosis, steatosis, and status of the arterial vessels, is crucial. In the absence of objective criteria, the donor surgeon's experience is of paramount importance. Grafts from obese donors have a higher rate of thrombosis, fluid collections, abscesses, and anastomotic leaks. The upper age limit at our center is 60 years.

A history of donor pancreatitis or any pancreatic surgery is a contraindication for use. Abdominal trauma may or may not affect the pancreas, hence surgical exploration is justified in an attempt to procure the organ. Elevated glucose levels can be caused by steroid treatment for brain edema or can be stress related, and therefore should not be considered as a contraindication. In questionable cases, one might consider obtaining $HbA_{1c}$ from the donor to rule out latent diabetes. Donors with type 2 diabetes and high C-peptide levels are acceptable unless they are obese. Hyperamylasemia is often encountered in brain-dead donors and therefore is not a contraindication if no other reason is evident. Finally, a pancreas donor risk index (pDRI) has been developed to inform organ acceptance decision making, which considers 10 common donor variables and one transplant factor (ischemia time) as factors associated with an increased risk of allograft failure [27].

## Donor Operation

The medical management of the donor by the anesthetist aims at hemodynamic stability until cross-clamping. Before and during procurement, the urine output is a good measure of sufficient abdominal organ perfusion. Hemodynamic instability enhances the danger of graft pancreatitis and thrombosis and therefore graft loss.

The donor operation is usually a part of multiorgan retrieval. It is preferable that the same team retrieves both liver and pancreas en bloc (Fig. 148.1). This approach is fast and is associated with the least amount of injuries to vascular structures. If divided on the back table or *in situ*, the superior mesenteric artery and splenic artery are handled with care in order to avoid intimal dissection. In the case of an aberrant right hepatic artery, the mesenteric artery is divided distally and the mesenteric origin stays with the liver graft. The splenic artery might retract into the tissue; a marking suture avoids time-consuming back-table exploration. The common bile duct is ligated in order to avoid posttransplant leakage. Dividing the mesentery at the base of the pancreas is crucial. Some surgeons use GIA staplers; however, we prefer double ligation with 2-0 silk. The mesenteric vessels, if not properly ligated, may retract into the pancreatic tissue. Bleeding can occur after reperfusion and the subsequent swelling can lead to venous outflow obstruction, venous thrombosis, and graft loss [28].

If the liver and pancreas teams are separate, then it is the liver team that has priority in deciding where to

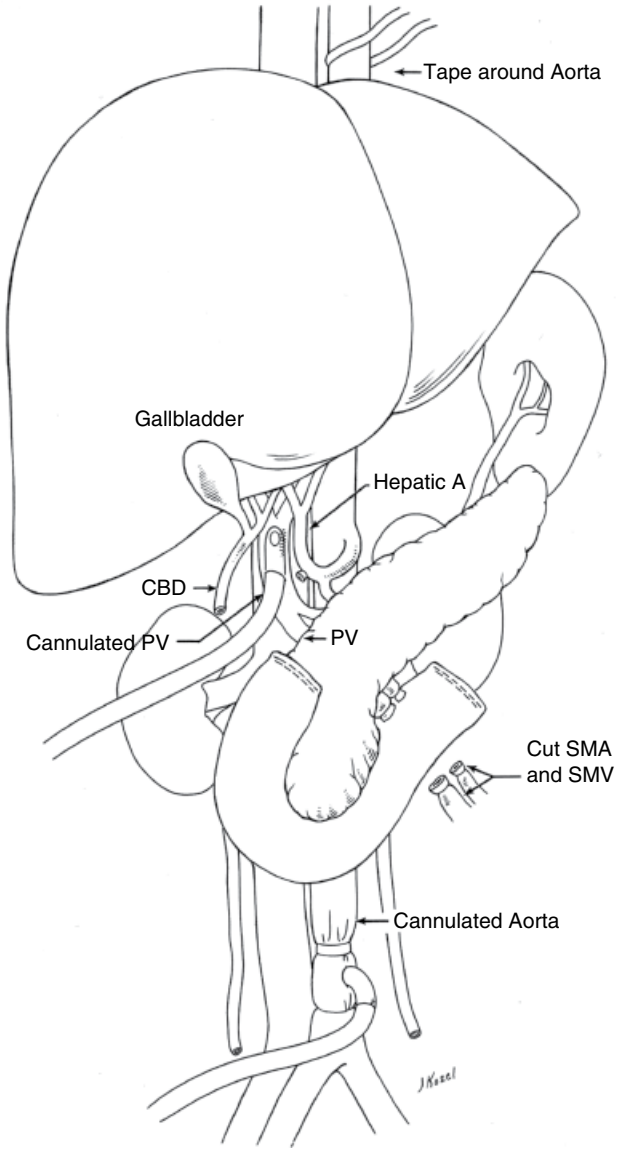

**Figure 148.1** En bloc procurement procedure for liver and pancreas. The abdominal aorta is cannulated distally and prepared for cross-clamping on top. The celiac trunk in dissected to identify the splenic and common hepatic artery. Anatomic variances of the liver arterial supply are identified. The portal vein is cannulated if required. The mesenteric root is divided and the pancreas is mobilized gently, avoiding any tissue trauma, using the spleen as a handle.

transect the portal vein. There is usually enough portal vein to perform a primary anastomosis. Some transplant groups almost routinely use a portal venous interposition graft without any evidence of a higher incidence of pancreas graft venous thrombosis. Transection of the stomach at the antrum and of the proximal jejunum is performed with staplers and leaves sufficient safety margins. Shortening of the intestinal structures is left for the back-table preparation. Instillation of antibiotic solution via the nasogastric tube is optional. Gentle mobilization of the pancreas, not injuring the parenchyma or the capsule, is essential in order to avoid postoperative leakage and pancreatitis. Keeping the pancreas cold with ice during the procurement process is important. Overflushing with preservation fluid leads to graft edema and must be avoided. An arterial graft also has to be procured for the arterial reconstruction. Usually, the bifurcation of the iliac artery is used. Alternatively, the brachiocephalic trunk can be used.

## Deceased Cardiac Death Donors (DCD)

Because of organ shortages and increasing waiting lists, strategies to enlarge the donor pool are under investigation. One option is the utilization of organs from donors after cardiac death. In a study at our center [29], the 5-year patient, pancreas graft, and kidney graft survival rates were similar to those with donation after brain death. Pancreas graft function was unaffected by the mode of procurement, whereas kidney grafts had more delayed graft function but with no sequelae for long-term function [30]. In a follow-up study be Scalea et al. [31], emphasis was placed on the fact that older DCDs carry a higher risk for postoperative dysfunction and careful individual evaluation of each donor is required as outlined in the paper.

## Preservation

The standard preservation fluid for pancreas grafts is the University of Wisconsin (UW) solution developed by Belzer and Southard in 1987. Under clinical conditions, cold ischemia preservation times of up to 40 hours have been reported [32]. Whether UW solution is the gold standard for the pancreas is still a matter of discussion, although large-scale studies by Stuart et al. [33,34] provided solid evidence for its superiority. Another solution, histidine–tryptophan–ketoglutarate (HTK), has been used for heart transplantation since 1986. At present, some large centers in the United States and Europe use HTK as their standard preservation solution for the pancreas and have reported good results.

## Technical Aspects of the Recipient Operation

As discussed in the Introduction, it took several decades to develop a technique for pancreas transplantation that provides reproducibly good results with a minimum of complications.

## Back-Table Graft Preparation

If the procurement is not done by the same team, the transplant surgeon thoroughly inspects the pancreas on the back table. If signs of fibrosis, necrosis, steatosis, or severe trauma are present, the procedure should be aborted. As a first step, the spleen is removed and the vessels are ligated separately. The duodenum is shortened on both sides using GIA staplers and the duodenal segment is inverted with sutures. Excessive tissue, especially lymphatic tissue around the superior mesenteric artery, is removed. The portal vein is lengthened by ligation of smaller branches. Arterial reconstruction is performed by an iliac arterial Y graft by connecting the external iliac artery to the superior mesenteric artery and the internal iliac artery to the splenic artery (Fig. 148.2).

## Recipient Operation

The abdomen is entered via a midline incision. In SPK, the kidney is also usually implanted through a midline incision, although either a separate incision or mobilization of the extraperitoneal space alone has been used to allow extraperitoneal positioning of the kidney graft. In our experience, this has not proven beneficial. The iliac vessels are exposed. In general, the pancreas is implanted on the right side, because venous access is easier. With the bladder draining technique, the head of the pancreas is positioned toward the pelvis (Fig. 148.3), whereas in the current technique with enteric drainage, the head is positioned upwards (Fig. 148.4).

## Vascular Anastomosis

The venous anastomosis is performed first. At the implantation site of the distal vena cava/proximal right common iliac vein, the vein is controlled with a side-biting clamp and the anastomosis is performed end-to-side with 6-0 running Prolene suture. A technical controversy existed about the preferred type of venous drainage. Several authors described drainage into the portal system to one of the mesenteric veins, claiming that the first-pass effect of insulin through the liver leads to a more physiologic insulin distribution. In our view, there is no clear-cut demonstration that there are any metabolic consequences of peripheral venous drainage, and after an initial wave of enthusiasm, more recently reported series have failed to show a benefit for the portal drainage technique [35].

The arterial anastomosis is performed second. The iliac graft extension is sutured to the common iliac artery of the recipient using 6-0 Prolene. The length should be adapted to allow for distension following graft edema. On the other hand, the graft should not be left too long in order to avoid kinking and risk of thrombosis. Thereafter, removal of the vascular clamps is sequential: first the venous clamp, followed by the distal and then proximal arterial clamps, allowing enough time for thorough hemostasis after each step.

## Management of Exocrine Pancreatic Secretion

Many surgical complications originated from the difficulty of securing the drainage of the exocrine pancreas. Bladder drainage techniques evolved from use of a duodenal button to use of a duodenal segment (Fig. 148.3). At the UW, we chose this technique in the early 1980s, as a review of technical failures after enteric anastomosis suggested rejection of the small bowel as the cause. This, of course, occurred before the introduction of cyclosporin and mycophenolate mofetil (MMF). For this reason, a drainage site was chosen in which the anastomosis could be protected for 5–10 days by urinary catheter

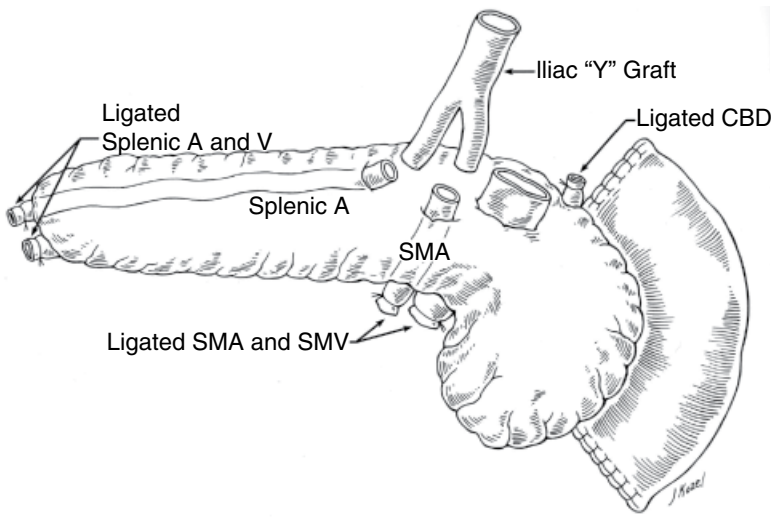

**Figure 148.2** Posterior view of the pancreas graft after back-table preparation. The iliac Y graft is anastomosed to the superior mesenteric and the splenic artery. All the vessels in the mesenteric root at the lower border of the pancreas and the distal splenic vessels are thoroughly tied. The duodenal stumps are stapled and oversewn additionally.

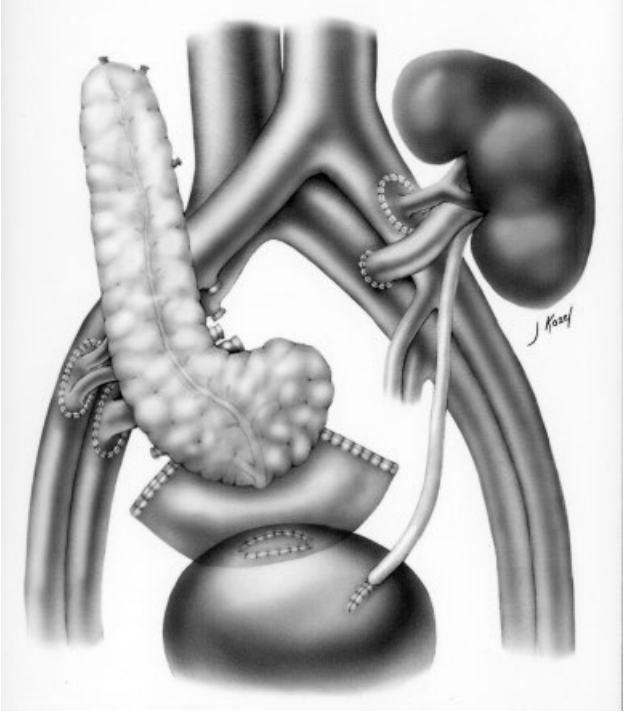

**Figure 148.3** Pancreas transplantation with bladder drainage.

decompression. In our view, duct injection was never acceptable after we visited multiple centers around the world and observed the high complication rates associated with this technique. Bladder drainage uses the bladder as the draining conduit. In the most frequently used technique, a duodenal segment is anastomosed side-by-side to the urinary bladder. This is usually done in two layers. Although this technique is relatively safe, later urinary complications such as frequent urinary tract infections, urethral erosions, and leaks and bleeding from the bladder, and also large loss of bicarbonate, made it clear that this is not an ideal technique [14]. Nevertheless, and to our surprise, this technique is still used by some large centers today. These centers claim that determination of urinary amylase is useful in the early diagnosis of rejection of the pancreas.

Enteric drainage, initially performed by Kelly and Lillehei, was later championed by the Stockholm group. After we had introduced MMF into pancreas transplantation, the incidence of acute rejection decreased by more than 50% [36]. This made us sufficiently comfortable to switch from bladder drainage to enteric drainage in 1995. Our center has now performed 400 bladder-drained and more than 800 enteric-drained transplants, and there is no question that enteric drainage carries a much lower complication rate [35]. In fact, more than 50% of our bladder-drained patients have had to undergo enteric conversion. Early enteric conversion (within 1 year of transplant) is usually well tolerated, whereas late

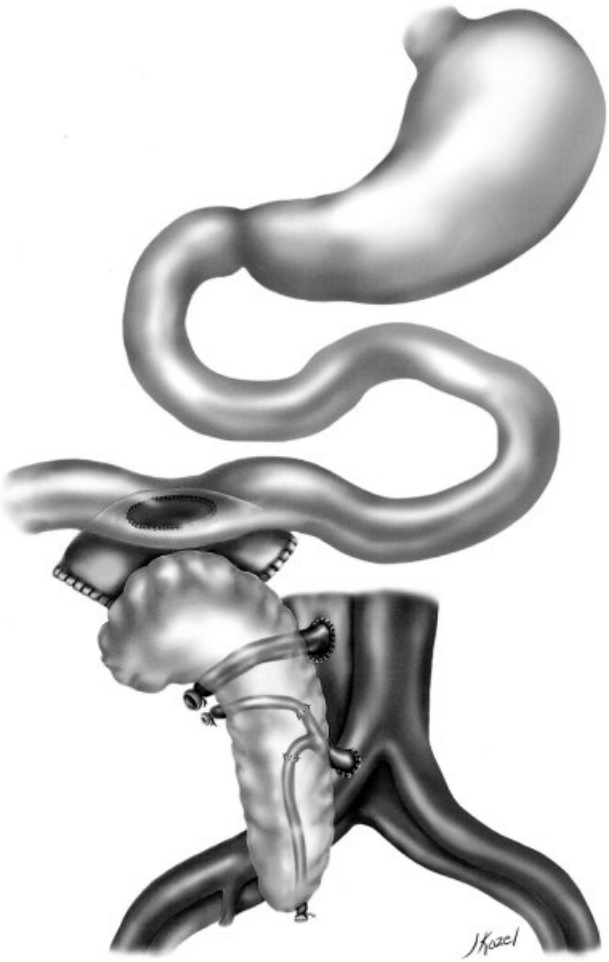

**Figure 148.4** Pancreas transplantation with enteric drainage.

conversions are technically difficult owing to a very thin duodenal segment and anastomotic leakage as high as 50%. We now recommend that every late conversion must be diverted through a Roux-en-Y loop. The indications for enteric conversion are leaks, hemorrhage from the bladder, loss of bicarbonate, and recurrent urinary tract infections.

In enteric drainage, the duodenal segment is anastomosed to the proximal jejunum side-to-side in a two-layer suture (Fig. 148.4). The postoperative complications of enteric drainage are few. Anastomotic leaks are rare; the most common site of a leak is the mesenteric side of the proximal staple line. If, during the retrieval, the length of bowel distal to the pylorus has been cut too close to the pancreas, inversion of the bowel is difficult, resulting in an ischemic corner of bowel that is prone to leak.

According to the IPTR, outside the United States more than 98% of all SPK transplants are managed with enteric drainage, whereas within the United States slightly more cases have used bladder drainage, but these nonetheless constitute only a minority of transplants.

### Postoperative Care

The patient with diabetes who undergoes SPK, PA, or PAK requires meticulous postoperative management. In the postoperative period, the patient is monitored in the recovery unit. The majority of patients do not require admission to an Intensive Care Unit. Pancreas function is monitored by measuring glucose levels, as a rise in glucose indicates graft dysfunction, most likely due to vascular thrombosis in this early stage. If there is a question in this regard, an urgent ultrasound examination is performed. Although there have been reports of successful rescue operations for arterial and venous thrombosis, these cases are rare. Urine output is the measure of kidney function. Conversely, if delayed kidney graft function is present, careful fluid management avoiding fluid overload is mandatory. Overall hemodynamic stability should be achieved in the early postoperative period and, if any signs of intra-abdominal hemorrhage are present, the patient should be brought back to the operating room immediately.

In addition to antibiotic and antiviral prophylaxis, careful immunosuppressive and anticoagulation management is required. Thrombosis of the pancreas is one of the most feared complications. We reported series [1] that demonstrated one of the lowest thrombosis rates. In fact, we believe that the use of heparin will not reduce thrombosis rates, and we have argued that systemic anticoagulation might enhance not only posttransplant bleeding, but also the incidence of thrombosis itself [28]; therefore, we do not use any anticoagulation apart from aspirin (375 mg daily). The use of a nasogastric tube, even after enteric drainage, not only seems to be unnecessary, but also prolongs posttransplant ileus. We therefore do not support the routine use of nasogastric decompression.

### Biopsy of the Pancreas

Biopsy of the pancreas is routinely performed at our center if there is suspicion of allograft rejection. Common indicators are rising amylase and lipase levels or elevated blood glucose values. The biopsies are performed under ultrasound guidance and the complication rate is low. Banff criteria are used for the degree of rejection and the determination of antirejection therapy.

## Current Status and Results of Pancreas Transplantation in the United States

Although the described technical and management innovations have contributed to pancreas transplantation becoming a standardized procedure in the United States, the numbers of both SPK and PTA have declined; the overall decline was 34% between 2005 and 2014. The addition of new patients to the waiting list has also declined. It is possible that improvements in competing therapies or higher standards for donor selection may be responsible. On the other hand, the results of pancreas transplantation have improved. From 2006 to 2014, early graft failures decreased from 12.8 to 8.2%. Kidney graft survival rates for SPK at 1, 5, and 10 years for the recent cohort (2004–2014) were 93, 74 and 47%, respectively. At 10 years, PTA mortality decreased from 46 to 26%. Mortality for all pancreas transplants improved substantially across all groups. The 1-year mortality for SPK decreased from 8% in 1995 to 2% in 2013. There are approximately 14,000 patients in the United States today with a functioning pancreas transplant.

Although this progress is encouraging, pancreas transplantation is available to only 2% of all patients with newly diagnosed type 1 diabetes. Therefore, newer therapies are under investigation. There is particular interest in the areas of stem-cell research and gene therapy.

## Conclusion

A remarkable amount of progress has been made in the field of pancreas transplantation since the first successful procedure in humans in 1966. Pancreas transplantation has evolved from an experimental procedure, with high morbidity and mortality, into an operative procedure with expected excellent outcomes akin to a kidney-alone transplantation. The rise of the field is due to great strides in surgical techniques, immunosuppressive protocols, donor evaluation, preoperative recipient assessment, and postoperative management. The techniques described have been in routine use at our center with excellent results and continue to evolve to make pancreas transplantation a safer and more effective treatment option for patients with diabetes.
