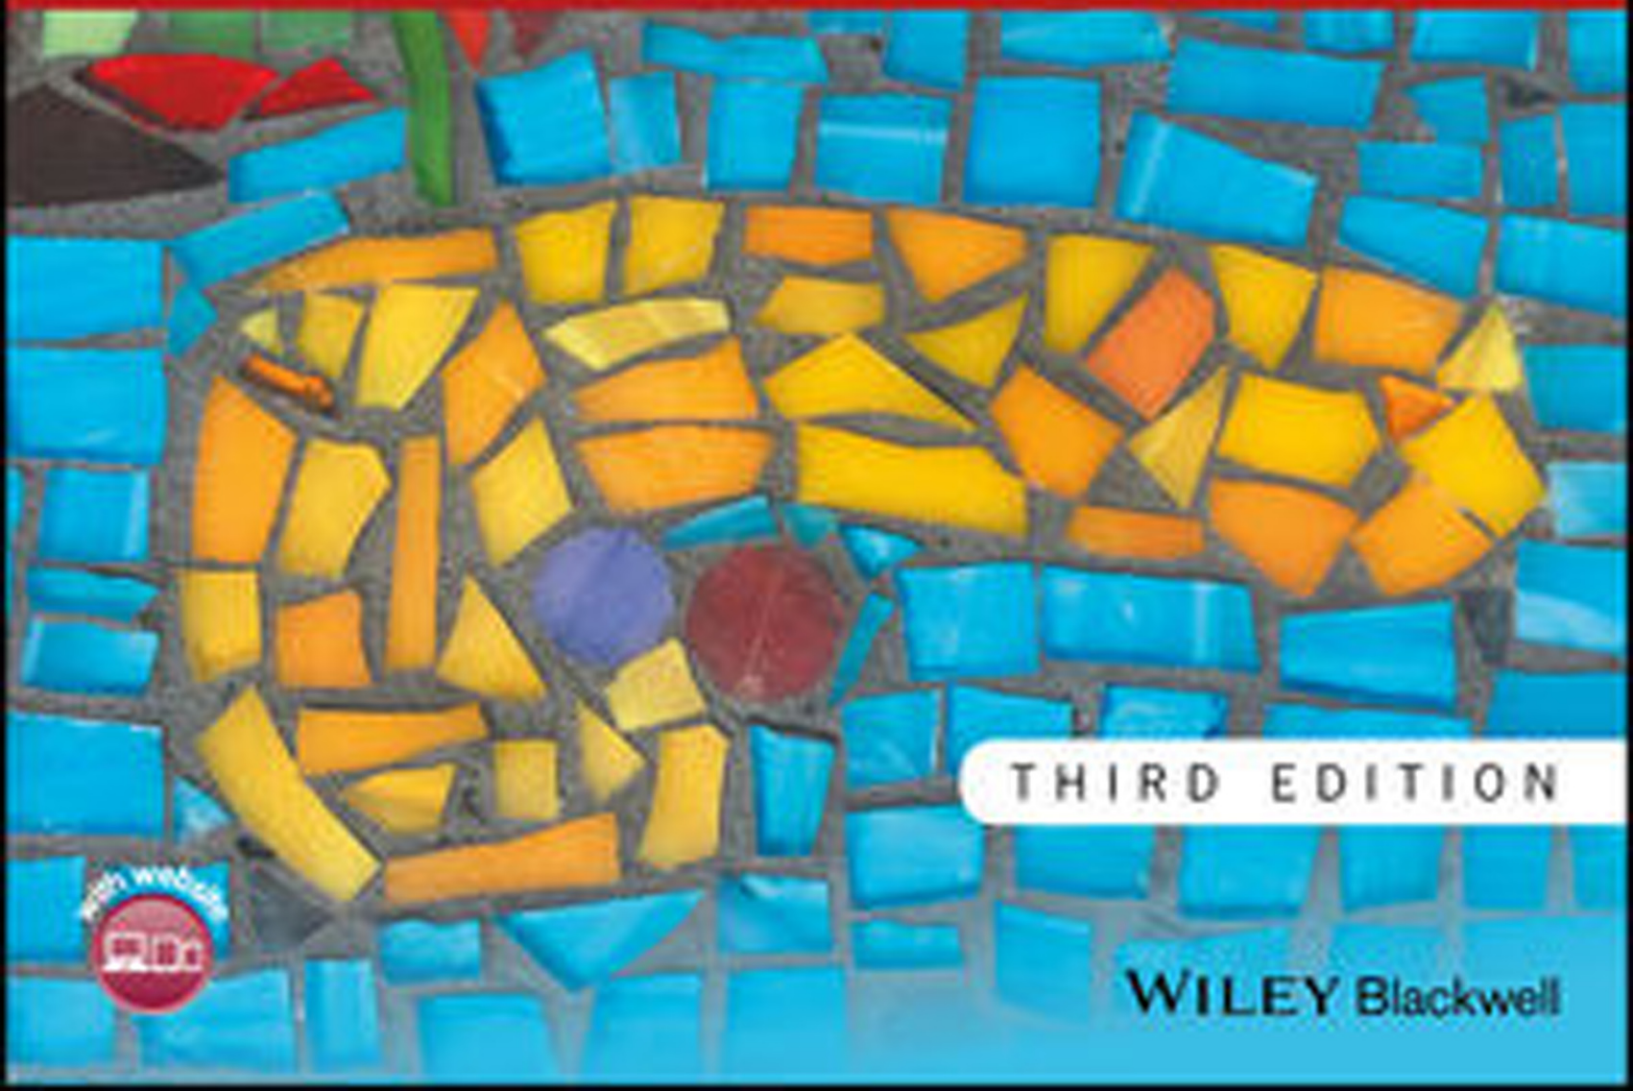
# The PANCREAS

## AN INTEGRATED TEXTBOOK OF BASIC SCIENCE, MEDICINE, AND SURGERY

EDITED BY HANS BEGER, ANDREW WARSHAW, RALPH HRUBAN, MARKUS BÜCHLER, MARKUS LERCH, JOHN NEOPTOLEMOS, TOORU SHIMOSEGAWA AND DAVID WHITCOMB



THIRD EDITION

WILEY Blackwell

# The Pancreas

## An Integrated Textbook of Basic Science, Medicine, and Surgery

**Third Edition**

*Edited by*

**Hans G. Beger MD, FACS(Hon), JSS(Hon), CSS(Hon)**
*Founding Editor, Professor Emeritus of Surgery, c/o University of Ulm, Ulm, Germany*

**Andrew L. Warshaw MD, FACS, FRCSEd(Hon)**
*W. Gerald Austen Distinguished Professor of Surgery, Harvard Medical School, Surgeon-in-Chief Emeritus, Massachusetts General Hospital, Boston, MA, USA*

**Ralph H. Hruban MD**
*Baxley Professor and Director, The Sol Goldman Pancreatic Cancer Research Center, Department of Pathology, The Johns Hopkins University School of Medicine, Baltimore, MD, USA*

**Markus W. Büchler MD**
*Professor of Surgery and Chair, Department of Surgery, University of Heidelberg, Heidelberg, Germany*

**Markus M. Lerch MD, FRCP**
*Professor and Chair, Department of Medicine A, University Medicine Greifswald, Greifswald, Germany*

**John P. Neoptolemos MA, MB, BCHIR, MD, FRCS, FMEDSCI**
*Professor of Surgery, Department of Surgery, University of Heidelberg, Heidelberg, Germany*

**Tooru Shimosegawa MD, PhD**
*Professor, Department of Gastroenterology, Tohoku University Graduate School of Medicine, Sendai, Miyagi, Japan*

**David C. Whitcomb MD, PhD**
*Professor of Medicine, Cell Biology & Physiology, and Human Genetics, Director, UPMC Precision Medicine Service, University of Pittsburgh and UPMC, Pittsburgh, PA, USA*

*Coordinating Editor*

**Christiane Groß**
*German Foundation Battle Against Pancreatic Cancer, c/o University of Ulm, Ulm, Germany*

WILEY Blackwell

This edition first published 2018

## Contributors

***N. Volkan Adsay MD***
Professor, Department of Pathology
Medical College of Wisconsin
Milwaukee, WI, USA

***Ali A. Aghdassi MD***
Department of Medicine A
University Medicine Greifswald
Greifswald, Germany

***Kathryn M. Albers PhD***
Professor, Department of Neurobiology
and Medicine/Gastroenterology, Hepatology,
and Nutrition
University of Pittsburgh
School of Medicine
Pittsburgh, PA, USA

***Guido Alsfasser MD***
Department of General, Thoracic, Vascular,
and Transplantation Surgery
University of Rostock
Rostock, Germany

***Minoti V. Apte MBBS, MMedSci, PhD***
Professor of Medicine and Director
Pancreatic Research Group
South Western Sydney Clinical School
Faculty of Medicine
University of New South Wales, Sydney;
Ingham Institute for Applied Medical Research
Liverpool Hospital, Liverpool, NSW, Australia

***Volker Aßfalg PD Dr. med***
Technical University of Munich
School of Medicine
Klinikum rechts der Isar
Department of Surgery
Munich, Germany

***Kai Bachmann PD Dr.***
Department of General, Visceral
and Thoracic Surgery
University Medical Center Hamburg-Eppendorf
Hamburg, Germany

***Todd H. Baron MD***
Division of Gastroenterology and Hepatology
University of North Carolina
Chapel Hill, NC, USA

***Savio George Barreto MBBS, MS, PhD***
Consultant Surgeon
Gastrointestinal Surgery, Gastrointestinal Oncology,
and Bariatric Surgery
Medanta Institute of Digestive and Hepatobiliary Sciences
Medanta, The Medicity
Gurgaon, India

***Omer Basar MD***
Pancreas Biliary Center, Gastrointestinal Unit
Massachusetts General Hospital; Boston, MA, USA
Professor of Medicine
Department of Gastroenterology
University of Hacettepe
Turkey

***Claudio Bassi MD, FRCS, FACS***
Pancreas Institute
G.B. Rossi Hospital
University of Verona Hospital Trust
Verona, Italy

***Surinder K. Batra PhD***
Department of Biochemistry and Molecular Biology
University of Nebraska Medical Center
Omaha, NE, USA

***Dirk Bausch MD***
Department of Surgery
University of Schleswig-Holstein
Campus Lübeck
Lübeck, Germany

***Hans G. Beger MD, FACS(Hon.), JSS(Hon.), CSS(Hon.)***
Founding Editor;
Professor Emeritus of Surgery
c/o University of Ulm
Ulm, Germany

***Melena D. Bellin MD***
Associate Professor of Pediatric Endocrinology
Department of Pediatrics
Schulze Diabetes Institute;
Director of Research, Islet Autotransplant Program
University of Minnesota Medical Center
Minneapolis, MN, USA

***Vincent Bernard MS***
Graduate Research Assistant
The University of Texas Graduate School of
Biomedical Sciences at Houston;
Sheikh Ahmed Pancreatic Cancer Research Center
The University of Texas MD Anderson Cancer Center
Houston TX, USA

***Georg Beyer MD***
Department of Medicine II
University Hospital Munich, Ludwig-Maximilians-
University, Munich
Department of Medicine A, University Medicine
Greifswald, Greifswald, Germany

***Dieter Birk MD***
Professor of Surgery
Head of the Department of General
and Visceral Surgery, Hospital Bietigheim
Bietigheim-Bissingen, Germany

***Zackary E. Boomsaad MD***
The Physicians' Spine & Rehabilitation
Specialists of Georgia
Atlanta, GA, USA

***Lodewijk A.A. Brosens MD, PhD***
Department of Pathology
University Medical Center Utrecht
Utrecht, The Netherlands

***William R. Brugge MD***
Professor of Medicine, HMS;
Director, Pancreas Biliary Center
Gastrointestinal Unit
Massachusetts General Hospital
Boston, MA, USA

***Markus W. Büchler MD***
Professor of Surgery and Chair
Department of General, Visceral
and Transplantation Surgery
University of Heidelberg
Heidelberg, Germany

***Richard A. Burkhart MD***
Fellow, Surgical Oncology
Department of Surgery
Johns Hopkins University School of Medicine
Baltimore, MD, USA

***John L. Cameron MD, FACS***
Department of Surgery
The Johns Hopkins Medical Institutions
Baltimore, MD, USA

***Rosalie A. Carr MD***
General Surgery Resident
Indiana University School of Medicine
Department of Surgery
Indianapolis, IN, USA

***Suresh T. Chari MD***
Professor of Medicine
Division of Gastroenterology and Hepatology
Mayo Clinic College of Medicine
Rochester, MN, USA

***Madhuchanda Chatterjee MD***
Specialty Doctor in Medical Oncology
Department of Medical Oncology
Clatterbridge Cancer Centre
Bebington, Wirral, UK

***Michael D. Chuong MD***
Department of Radiation Oncology
University of Maryland School of Medicine
Baltimore, MD, USA

***Vito Cincinnati MD***
Department of Hepatology
and Gastroenterology
University Hospital Münster
Münster, Germany

***Thomas E. Clancy MD***
Department of Surgery
Brigham and Women's Hospital
Boston, MA;
Assistant Professor of Surgery
Harvard Medical School
Boston, MA, USA

***Ashley K. Clift BA, MBBS***
Department of Surgery and Cancer
Imperial College London
London, UK

***Amanda B. Cooper MD***
Assistant Professor of Surgery
Department of Surgery
Penn State Milton Hershey Medical Center
Penn State School of Medicine
Hershey, PA, USA

***Emma L. Culver BSc, MBChB, PhD, MRCP***
Translational Gastroenterology Unit
John Radcliffe Hospital, and Nuffield
Department of Medicine
Oxford University
Oxford, UK

***Rohit Das MD***
Division of Gastroenterology & Hepatology
Department of Medicine
University of Pittsburgh Medical Center
Pittsburgh, PA, USA

***Brian M. Davis PhD***
Professor, Department of Neurobiology
and Medicine/Gastroenterology, Hepatology,
and Nutrition
University of Pittsburgh
School of Medicine
Pittsburgh, PA, USA

***Rajinder Dawra PhD***
Department of Surgery
University of Miami
Miller School of Medicine
Miami, FL, USA

***Nicolò de Pretis MD***
University of Verona
Verona, Italy

***Vikram Deshpande MD***
Massachusetts General Hospital &
Harvard Medical School
Boston, MA, USA

***Francesco F. di Mola MD, PhD***
Surgical Oncology
ASL-2 Abruzzo
"SS Annunziata" Hospital
Chieti, Italy

***Pierluigi di Sebastiano MD, FACS***
Surgical Oncology
ASL-2 Abruzzo
"SS Annunziata" Hospital
Chieti, Italy

***Ryuichiro Doi MD, PhD***
Kyoto University Hospital
Kyoto, Japan

***Shinpei Doi MD, PhD***
Associate Professor
Department of Gastroenterology
Teikyo University Mizonokuchi Hospital
Kawasaki, Japan

***J. Enrique Domínguez-Muñoz MD, PhD***
Department of Gastroenterology
and Hepatology
Health Research Institute of
Santiago de Compostela (IDIS)
Spain

***Henning Dralle FACS, FRCS, FEBS***
Head of the Section of Endocrine Surgery
Department of General, Visceral
and Transplantation Surgery
University Hospital Essen
Essen, Germany

***Vikas Dudeja MD***
Department of Surgery
University of Miami
Miller School of Medicine
Miami, FL, USA

***Sinead N. Duggan RD, PhD***
Research Fellow
Department of Surgery
Trinity College Dublin
Ireland

***Tomoki Ebata***
Department of Surgery
Division of Surgical Oncology
Nagoya University Graduate School of Medicine
Nagoya, Japan

***Barish H. Edil MD, FACS***
Associate Professor of Surgery
Department of Surgery
Division of GI, Tumor, and Endocrine Surgery
University of Colorado Anschutz Medical Campus
Aurora, CO, USA

***John F. Eisses MD, PhD***
Department of Pediatric Gastroenterology,
Hepatology, and Nutrition
University of Pittsburgh School of Medicine
Pittsburgh, PA, USA

***Michael Erdek MD***
Division of Pain Medicine
Johns Hopkins University School of Medicine
Baltimore, MD, USA

***Mert Erkan MD***
Department of Surgery
Koc University
Istanbul, Turkey

***Alistair B.J. Escott MBChB, PG Dip Surg Anat***
Research Fellow
Department of Surgery
University of Auckland
Auckland, New Zealand

***Olusola O. Faluyi MBChB (Hons), PhD, MRCP***
Consultant in Medical Oncology and Honorary Lecturer
Department of Medical Oncology
Clatterbridge Cancer Centre
Bebington, Wirral, UK;
Department of Molecular and Clinical Cancer Medicine
University of Liverpool
Liverpool, UK

***Michael B. Farnell MD***
Professor of Surgery
Emeritus
Department of Surgery
Mayo Clinic
Rochester, MN, USA

***Carlos Fernández-del Castillo MD, FACS***
Department of Surgery
Massachusetts General Hospital
Harvard Medical School
Boston, MA, USA

***Elliot K. Fishman MD***
Department of Radiology
Johns Hopkins University
Baltimore, MD, USA

***Zhi Ven Fong MD***
Department of Surgery
The Sol Goldman Pancreatic Cancer Research Center,
Johns Hopkins University School of Medicine
Baltimore, MD;
Department of Surgery
Massachusetts General Hospital
Harvard Medical School,
Boston, MA, USA

***Chris E. Forsmark MD***
Professor of Medicine and Chief
Division of Gastroenterology, Hepatology, and Nutrition
University of Florida
Gainesville, FL, USA

***Ann K. Friedrich MD***
Division of Surgical Oncology
Department of Surgery
University of Massachusetts Memorial Medical Center
Worcester, MA, USA

***Helmut Friess MD***
Professor and Chairman
Department of Surgery
Technical University of Munich
School of Medicine
Klinikum rechts der Isar
Munich, Germany

***Andrea Frilling MD, FACS***
Professor of Surgery
Department of Surgery and Cancer
Imperial College London
London, UK

***Stefan Fritz MD***
Attending Surgeon
Department of General, Visceral,
Thoracic and Transplantation Surgery
Hospital Stuttgart
Stuttgart, Germany

***Luca Frulloni MD, PhD***
University of Verona
Verona, Italy

***Noriyoshi Fukushima MD***
Professor, Department of Pathology
Jichi Medical University, Tochigi, Japan

***Timothy B. Gardner MD, MS***
Associate Professor of Medicine
Section of Gastroenterology and Hepatology
Dartmouth-Hitchcock Medical Center
Lebanon, NH, USA

***Roberto García-Figueiras MD, PhD***
Department of Radiology
University Hospital of Santiago de Compostela
Spain

***Georgios Gemenetzis MD***
Postdoctoral Fellow
Department of Surgery
Johns Hopkins School of Medicine
Baltimore, MD, USA

***Paula Ghaneh MBChB, MD, FRCS***
Professor of Surgery
Department of Molecular and Clinical Oncology
University of Liverpool
Liverpool, UK

***Michael Goggins MD***
Professor of Pathology, Medicine, and Oncology
Divisions of GI Pathology and
Gastroenterology/Hepatology;
Director of the Pancreatic Cancer
Early Detection Research Laboratory
The Sol Goldman Pancreatic Cancer Research Center
Johns Hopkins University School of Medicine
Baltimore, MD, USA

***Fred Gorelick MD***
Professor of Cell Biology and Medicine
Yale University School of Medicine
New Haven, CT, USA

***Miral Sadaria Grandhi MD***
Assistant Professor of Surgery
Rutgers Cancer Institute of New Jersey
Rutgers Robert Wood Johnson Medical School
New Brunswick, NJ, USA

***Thomas Matthias Gress MD***
Department of Internal Medicine
Division of Gastroenterology and Endocrinology
Philipps University
Marburg, Germany

***Tracy C. Grikscheit MD***
Department of Surgery
Children's Hospital Los Angeles
Los Angeles, CA, USA

***Ryan T. Groeschl MD***
Surgical Oncology
Essentia Health
Duluth Clinic
Duluth, MN, USA

***Tommaso Grottola MD***
Surgical Oncology
ASL-2 Abruzzo
"SS Annunziata" Hospital
Chieti, Italy

***Scott R. Gunn MD, FCCM***
Chief of Service
Department of Critical Care Medicine
University of Pittsburgh/UPMC
Pittsburgh, PA, USA

***Rajib Gupta MD***
Clinical Fellow
Department of Pathology
University of Minnesota Medical Center
Minneapolis, MN, USA

***Stephan L. Haas MD, PhD***
Gastrocentrum
Karolinska University Hospital
Stockholm, Sweden

***Aida Habtezion MD, MSc, FRCPC***
Division of Gastroenterology and Hepatology
Stanford University School of Medicine
Stanford, CA, USA

***Thilo Hackert MD***
Attending Surgeon
Department of General, Visceral
and Transplantation Surgery
University of Heidelberg
Heidelberg, Germany

***Walter Halangk PhD***
Department of Experimental Surgery
Otto von Guericke University
Magdeburg, Germany

***Bradley R. Hall MD***
Departments of General Surgery
and Biochemistry and Molecular Biology
University of Nebraska Medical Center
Omaha, NE, USA

***Chris Halloran***
NIHR Liverpool Pancreas Biomedical Research Unit
Department of Molecular and Clinical Cancer Medicine
Institute of Translational Medicine
University of Liverpool;
Royal Liverpool & Broadgreen University
Hospitals NHS Trust
Royal Liverpool University Hospital
Liverpool, UK

***Shin Hamada MD, PhD***
Division of Gastroenterology
Tohoku University Graduate School of Medicine
Sendai, Japan

***Kazuo Hara MD***
Department of Gastroenterology
Aichi Cancer Center Hospital
Nagoya, Aichi, Japan

***Jin He MD, PhD***
Department of Surgery
The Johns Hopkins Medical Institutions
Baltimore, MD, USA

***Max Heckler MD***
Department of Surgery
University of Heidelberg, Heidelberg
Germany

***Bernhard J. Hering MD***
Professor of Surgery and Medicine
Eunice L. Dwan Chair in Diabetes Research
McKnight Presidential Chair
in Transplantation Science;
Executive Director
Schulze Diabetes Institute;
Director, Islet Transplantation
University of Minnesota Medical Center
Minneapolis, MN, USA

***Joseph M. Herman MD, MSc***
Professor, Clinical Research Director
Ad interim Division Head
Division of Radiation Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas, USA

***Masayuki Hijioka MD, PhD***
Department of Medicine and Bioregulatory Science
Graduate School of Medical Sciences
Kyushu University
Fukuoka, Japan

***Susumu Hijioka MD***
Department of Gastroenterology
Aichi Cancer Center Hospital
Nagoya, Aichi, Japan

***Seiko Hirono MD***
Second Department of Surgery
Wakayama Medical University
School of Medicine
Wakayama, Japan

***Morihisa Hirota MD***
Division of Gastroenterology
Tohoku University Graduate School of Medicine
Sendai, Japan

***Melissa E. Hogg MD, MS***
Assistant Professor of Surgery
Department of Surgery
University of Pittsburgh Medical Center
Pittsburgh, PA, USA

***Sebastian Holländer MD***
Department for General, Visceral, Transplant and
Pediatric Surgery
University of the Saarland
Homburg/Saar, Germany

***Ralph H. Hruban MD***
Baxley Professor and Director
Departments of Oncology and Pathology
The Sol Goldman Pancreatic Cancer Research Center
Johns Hopkins University School of Medicine
Baltimore, MD, USA

***Sohail Z. Husain MD***
Department of Pediatric Gastroenterology,
Hepatology, and Nutrition
University of Pittsburgh School of Medicine;
McGowan Institute for Regenerative Medicine
University of Pittsburgh, Pittsburgh, PA, USA

***Norbert Hüser MD***
Technical University of Munich
School of Medicine
Klinikum rechts der Isar
Department of Surgery
Munich, Germany

***Calogero Iacono MD***
Department of Surgery
Unit of Hepato-Pancreato-Biliary Surgery
University of Verona
School of Medicine
Verona, Italy

***Julio Iglesias-García MD, PhD***
Department of Gastroenterology and Hepatology
Health Research Institute of
Santiago de Compostela (IDIS)
Spain

***Tsukasa Ikeura***
Department of Gastroenterology and Hepatology
Kansai Medical University
Osaka, Japan

***Hiroyuki Isayama MD, PhD***
Department of Gastroenterology
Graduate School of Medicine
University of Tokyo
Tokyo, Japan

***Rainer Isenmann MD***
Professor, Department of Surgery
St.-Anna-Virngrund-Klinik
Ellwangen, Germany

***Tetsuhide Ito MD, PhD***
Chief of Neuroendocrine Tumor Centre
Fukuoka Sanno Hospital
Fukuoka;
Professor
International University of Health and Welfare
Fukuoka, Japan

***Takao Itoi MD, PhD, FASGE, FACG***
Department of Gastroenterology and Hepatology
Tokyo Medical University
Tokyo, Japan

***Jakob R. Izbicki MD***
Professor and Chairman
Department of General, Visceral and
Thoracic Surgery
University Medical Center Hamburg-Eppendorf
Hamburg, Germany

***Elizabeth M. Jaffee MD***
The Sidney Kimmel Comprehensive Cancer Center;
Department of Oncology
The Skip Viragh Center for Pancreatic Cancer
Johns Hopkins University School of Medicine
Baltimore, MD, USA

***Robert P. Jones BSc, MBChB, PhD, MRCS***
Honorary Lecturer in Surgery
Department of Molecular and Clinical
Oncology
University of Liverpool
Liverpool, UK

***Jörg Kaiser MD***
Department of General, Visceral
and Transplantation Surgery
University of Heidelberg
Heidelberg, Germany

***Gregory Kaltsas MD, FRCP***
Professor Pathophysiology – Endocrinology
Department of Pathophysiology
National University of Athens
Athens, Greece

***Terumi Kamisawa MD, PhD***
Department of Internal Medicine
Tokyo Metropolitan Komagome Hospital
Tokyo, Japan

***Atsushi Kanno MD***
Division of Gastroenterology
Tohoku University Graduate School of Medicine
Sendai, Japan

***Atsuko Kasajima MD, PhD***
Department of Pathology
Graduate School of Medicine
Tohoku University
Sendai, Japan

***Dixon B. Kaufman MD, PhD, FACS***
Ray D. Owen Professor of Surgery
Chairman
Division of Transplantation
University of Wisconsin Department of Surgery
Madison, WI, USA

***Shigeyuki Kawa MD, PhD***
Department of Internal Medicine
Matsumoto Dental University
Shiojiri, Japan

***Ken Kawabe MD, PhD***
Department of Medicine and
Bioregulatory Sciences
Graduate School of Medical Sciences
Kyushu University
Fukuoka, Japan

***Tobias Keck MD, MBA, FACS***
Chairman of the Department of Surgery
University of Schleswig-Holstein
Campus Lübeck
Lübeck, Germany

***Hideyo Kimura MD, PhD***
Department of Surgery and Oncology
Graduate School of Medical Sciences
Kyushu University
Fukuoka, Japan

***Wataru Kimura MD, PhD***
Professor and Chairman
First Department of Surgery
Faculty of Medicine
Yamagata University
Yamagata, Japan

***Alison P. Klein PhD, MHS***
Professor, Departments of Oncology
and Epidemiology
Sidney Kimmel Comprehensive Cancer Center
Johns Hopkins School of Medicine
Baltimore, MD, USA

***Günter Klöppel MD***
Professor Emeritus of Pathology
Department of Pathology
Consultation Center for Pancreatic
and Endocrine Tumors
Technical University Munich
Munich, Germany

***Kazuhiko Koike MD, PhD***
Department of Gastroenterology
Graduate School of Medicine
University of Tokyo
Tokyo, Japan

***Masaru Koizumi MD, PhD***
Assistant Professor
Department of Surgery
Jichi Medical University
School of Medicine
Tochigi, Japan

***Jennifer LaFemina MD, FACS***
Assistant Professor of Surgery
Division of Surgical Oncology
Department of Surgery
Program Director
General Surgery Residency Program
University of Massachusetts Memorial
Medical Center
Worcester, MA, USA

***Felix Lämmerhirt MD***
Department of Medicine A
University Medicine Greifswald
Greifswald, Germany

***Kok-Onn Lee MD, FRCP***
Professor of Endocrinology
Department of Medicine
National University of Singapore
Singapore

***Linkaku Lee MD, PhD***
Department of Medicine and Bioregulatory Science
Graduate School of Medical Sciences
Kyushu University
Fukuoka, Japan

***Alan K. Lefor MD, MPH, PhD***
Professor, Department of Surgery
Jichi Medical University
School of Medicine
Tochigi, Japan

***Anne Marie Lennon MD, PhD***
Associate Professor of Medicine and Surgery
Benjamin Baker Scholar;
Director of the Multidisciplinary
Pancreatic Cyst Clinic
Johns Hopkins Hospital
Baltimore, MD, USA

***Markus M. Lerch MD, FRCP***
Department of Medicine A
University Medicine Greifswald
Greifswald, Germany

***Brian Lewis PhD***
Associate Professor
Department of Molecular, Cell and Cancer Biology
University of Massachusetts Medical School
Worcester, MA, USA

***Keith D. Lillemoe MD***
W. Gerald Austen Professor of Surgery
Harvard Medical School
Surgeon-in-Chief and Chief of the
Department of Surgery
Massachusetts General Hospital
Harvard Medical School
Boston, MA, USA

***J.-Matthias Löhr MD, PhD***
Professor of Gastroenterology & Hepatology
Karolinska Institutet
Stockholm, Sweden

***Daniel S. Longnecker MD***
Professor, Active Emeritus
Department of Pathology
Geisel School of Medicine at Dartmouth
Hanover, NH, USA

***Mark E. Lowe MD, PhD***
Department of Pediatrics
Division of Gastroenterology, Hepatology and Nutrition
Washington University School of Medicine
St. Louis, MO, USA

***Albert B. Lowenfels MD***
Emeritus Professor of Surgery,
and Professor of Family Medicine
New York Medical College
Valhalla, NY, USA

***Masatoshi Mabuchi MD, PhD***
Assistant Professor
Department of Gastroenterology
Teikyo University Mizonokuchi Hospital
Kawasaki, Japan

***Andreas Machens MD, PhD***
Associate Professor, Department of Visceral,
Vascular and Endocrine Surgery
Medical Faculty
Martin Luther University Halle-Wittenberg
Halle (Saale), Germany

***Deepa Magge MD***
Department of Surgery
University of Pittsburgh
Pittsburgh, PA, USA

***Hiroyuki Maguchi MD***
Director, Center for Gastroenterology
Teine-Keijinkai Hospital
Sapporo, Japan

***Pia Maier***
Gastrocentrum
Karolinska University Hospital
Stockholm, Sweden

***Patrick Maisonneuve MD***
Director, Unit of Clinical Epidemiology
European Institute of Oncology
Milan, Italy

***Anirban Maitra MBBS***
Professor of Pathology, Division of Pathology
The University of Texas MD Anderson Cancer Center
Houston, TX;
Sheikh Ahmed Pancreatic Cancer Research Center
The University of Texas MD Anderson Cancer Center
Houston, TX, USA

***Shounak Majumder MD***
Assistant Professor of Medicine
Division of Gastroenterology and Hepatology
Mayo Clinic College of Medicine
Rochester, MN, USA

***Giuseppe Malleo MD, PhD***
Pancreas Institute, G.B. Rossi Hospital
University of Verona Hospital Trust
Verona, Italy

***Junhao Mao PhD***
Associate Professor
Department of Molecular, Cell and Cancer Biology
University of Massachusetts Medical School
Worcester, MA, USA

***Giovanni Marchegiani MD***
Pancreas Institute, G.B. Rossi Hospital
University of Verona Hospital Trust
Verona, Italy

***Atsushi Masamune MD, PhD***
Division of Gastroenterology
Tohoku University Graduate School of Medicine
Sendai, Japan

***Julia Mayerle MD***
Department of Medicine II
University Hospital Munich
Ludwig-Maximilians-University Munich
Germany

***Christoph W. Michalski MD***
Attending Surgeon, Department of General,
Visceral and Transplantation Surgery
University of Heidelberg
Heidelberg, Germany

***Masaru Miyazaki MD***
Emeritus Professor of Surgery
Graduate School of Medicine
Chiba University
Chiba, Japan

***Nobumasa Mizuno MD, PhD***
Department of Gastroenterology
Aichi Cancer Center Hospital
Nagoya, Aichi, Japan

***Evelina Mocci***
Departments of Oncology and Epidemiology
Sidney Kimmel Comprehensive Cancer Center
Johns Hopkins School of Medicine
Baltimore, MD, USA

***Eyas Mohamed MBChB, MRCS***
Research Fellow
Department of Molecular and Clinical Oncology
University of Liverpool
Liverpool, UK

***Véronique D. Morinville MD***
Associate Professor of Pediatrics
McGill University;
Division of Pediatric Gastroenterology
and Nutrition
Montreal Children's Hospital
Montreal, QC, Canada

***Fuyuhiko Motoi MD***
Department of Surgery
Tohoku University School of Medicine
Sendai, Japan

***Shmuel Muallem PhD***
Chief, Epithelial Signaling and Transport Section
Molecular Physiology and Therapeutics Branch
National Institute of Dental and Craniofacial Research
National Institutes of Health
Bethesda, MD, USA

***Saurabh Mukewar MD***
Instructor of Medicine
Division of Gastroenterology and Hepatology
Mayo Clinic College of Medicine
Rochester, MN, USA

***J.J. Mukherjee MD, FRCP***
Senior Consultant
Division of Endocrinology
Department of Medicine
Apollo Gleneagles Hospital
Kolkata, India

***Adrian G. Murphy MB, BCH, BAO, PhD***
The Sidney Kimmel Comprehensive Cancer Center;
Department of Oncology
The Skip Viragh Center for Pancreatic Cancer
Johns Hopkins University School of Medicine
Baltimore, MD, USA

***Masato Nagino MD, PhD***
Department of Surgery
Division of Surgical Oncology
Nagoya University Graduate School of Medicine
Nagoya, Japan

***Akimasa Nakao MD, PhD, FACS***
Professor Emeritus
Nagoya University;
President
Nagoya Central Hospital
Nagoya, Japan

***Masafumi Nakamura MD, PhD, FACS***
Emeritus Professor of Surgery
Graduate School of Medical Sciences
Kyushu University
Fukuoka, Japan

***Amol K. Narang MD***
Department of Radiation Oncology & Molecular
Radiation Sciences
Johns Hopkins University School of Medicine
Baltimore, MD, USA

***John P. Neoptolemos MB, BChir, MD, FRCS***
Professor of Surgery
Department of Surgery
University of Heidelberg
Heidelberg, Germany

***Avinoam Nevler MD***
Department of Surgery
Jefferson Pancreas, Biliary
and Related Cancer Center
Thomas Jefferson University
Philadelphia, PA, USA

***Michaël Noë MD***
Department of Pathology
University Medical Center Utrecht
Utrecht, The Netherlands

***Johan Offerhaus MD, PhD, MPH***
Department of Pathology
University Medical Center Utrecht
Utrecht
The Netherlands

***Masayuki Ohtsuka MD***
Department of General Surgery
Graduate School of Medicine
Chiba University
Chiba, Japan

***Takao Ohtsuka MD, PhD***
Associate Professor
Department of Surgery and Oncology
Graduate School of Medical Sciences
Kyushu University
Fukuoka, Japan

***Kazuichi Okazaki MD, PhD***
Department of Gastroenterology and Hepatology
Kansai Medical University
Osaka, Japan

***Stephen J. O'Keefe MD, MSC, FRCP***
Division of Gastroenterology,
Hepatology and Nutrition
University of Pittsburgh
Pittsburgh, PA, USA

***Nozomi Okuno***
Department of Gastroenterology
Aichi Cancer Center Hospital
Nagoya, Aichi, Japan

***Chee Y. Ooi MBBS, PhD***
School of Women's and Children's Health
Medicine, University of New South Wales and Sydney
Children's Hospital Randwick
Sydney, Australia

***Chung Owyang MD***
Division of Gastroenterology
Department of Internal Medicine
University of Michigan
Ann Arbor, MI, USA

***Daniel H. Palmer BSc(Hons), MBChB, PhD, FRCP***
Professor of Medical Oncology
and Honorary Consultant
Department of Medical Oncology
Clatterbridge Cancer Centre
Bebington, Wirral;
Department of Molecular and Clinical
Cancer Medicine
University of Liverpool
Liverpool, UK

***Georgios I. Papachristou MD, PhD***
Associate Professor of Medicine
University of Pittsburgh Medical Center
Pittsburgh, PA, USA

***Nickolas Papadopoulos PhD***
Professor, Departments of Oncology and Pathology
The Sol Goldman Pancreatic Cancer Research Center
Johns Hopkins University School of Medicine
Baltimore, MD, USA

***Thomas Pausch MD***
Department of Surgery
University of Heidelberg
Heidelberg, Germany

***Ole H. Petersen CBE, FRS***
MRC Professor, Cardiff School of Biosciences
Cardiff University
Cardiff, UK

***Max S. Petrov MD, MPH, PhD***
Department of Surgery
University of Auckland
Auckland, New Zealand

***Anthony R.J. Phillips BSc, MBChB, PhD***
Director, Applied Surgery and Metabolism Laboratory
School of Biological Sciences and Department of Surgery
University of Auckland
Auckland, New Zealand

***Romano C. Pirola MD, FRACP***
Honorary Professor
Pancreatic Research Group
South Western Sydney Clinical School
Faculty of Medicine
University of New South Wales
Sydney;
Ingham Institute for Applied Medical Research
Liverpool Hospital, Liverpool, NSW, Australia

***Martha Bishop Pitman MD***
Director of Cytopathology
Department of Pathology
Massachusetts General Hospital;
Professor of Pathology
Harvard Medical School
Boston, MA, USA

***Meredith E. Pittman MD***
Department of Pathology
Weill Cornell Medical College
New York, NY, USA

***Henry A. Pitt MD***
Chief Quality Officer
Temple University Health System;
Associate Vice Dean for Clinical Affairs
Lewis Katz School of Medicine at Temple University
Philadelphia, PA, USA

***Stephanie Plagemann***
Department of General, Visceral and Thoracic Surgery
University Medical Center Hamburg-Eppendorf
Hamburg, Germany

***Bertram Poch MD***
Center of Oncologic, Endocrine
and Minimal Invasive Surgery
Donau-Klinikum
Neu-Ulm, Germany

***Siva P. Raman MD***
Department of Radiology
Johns Hopkins University
Baltimore, MD, USA

***Michael G.T. Raraty MBBS, PHD, FRCS***
Royal Liverpool & Broadgreen
University Hospitals NHS Trust
Royal Liverpool University Hospital
Liverpool, UK

***Bettina M. Rau MD***
Professor of Surgery, Head of Department
Department of General,
Visceral and Thoracic Surgery
Municipal Hospital of Neumarkt
Neumarkt, Germany

***Isabel Rauscher MD***
Technical University of Munich
School of Medicine, Klinikum rechts der Isar
Department of Nuclear Medicine
Munich, Germany

***Michelle D. Reid MD***
Associate Professor
Department of Pathology and Laboratory Medicine
Emory University Hospital, Atlanta, GA, USA

***Anja Rinke MD***
Department of Internal Medicine
Division of Gastroenterology and Endocrinology
Philipps University
Marburg, Germany

***Eduardo Rodrigues-Pinto MD***
Division of Gastroenterology and Hepatology
University of North Carolina
Chapel Hill, NC, USA;
Gastroenterology Department
Centro Hospitalar São João
Porto, Portugal

***Lauren M. Rosati BS***
Department of Radiation Oncology & Molecular
Radiation Sciences
Johns Hopkins University School of Medicine
Baltimore, MD, USA

***Klaus Sahora MD***
Department of Surgery
Massachusetts General Hospital
Harvard Medical School
Boston, MA, USA

***Jami L. Saloman PhD***
Research Associate
Department of Neurobiology
University of Pittsburg, School of Medicine
Pittsburg, PA, USA

***Ashok K. Saluja PhD***
Professor and Vice-Chair of Research
Department of Surgery
Director, Sylvester Pancreatic Cancer
Research Institute
University of Miami, Miller School of Medicine
Miami, FL, USA

***Maria Dolors Sans MD***
Department of Molecular and Integrative Physiology
University of Michigan Medical School
Ann Arbor, MI, USA

***Hironobu Sasano MD, PhD***
Department of Pathology,
Graduate School of Medicine
Tohoku University
Sendai, Japan

***Naohiro Sata MD, PhD***
Director, Jichi Medical University Hospital; Chairman
Division of Gastroenterological and General Surgery;
Professor, Department of Surgery
Jichi Medical University, School of Medicine
Tochigi, Japan

***Rebecca Saunders***
NIHR Liverpool Pancreas Biomedical Research Unit
Department of Molecular and Clinical
Cancer Medicine
Institute of Translational Medicine
University of Liverpool
Liverpool, UK

***Jörg Schirra MD***
Department of Medicine II
University Hospital Munich
Ludwig-Maximilians-University Munich
Germany

***Christopher R. Schlieve MD***
Department of Surgery
Children's Hospital Los Angeles
Los Angeles, CA, USA

***C. Max Schmidt MD, PhD, MBA, FACS***
Vice Chairman of Surgery
Academic Affairs; Professor
Surgery, Biochemistry & Molecular Biology
Indiana University School of Medicine;
Director, IU Health Pancreatic Cyst and Cancer Early
Detection Center
Indianapolis, IN, USA

***Lutz Schneider MD***
Associate Professor of Surgery
Department of General, Visceral
and Transplantation Surgery
University of Heidelberg
Heidelberg, Germany

***Richard D. Schulick MD MBA FACS***
The Aragón/Gonzalez-Gíustí Chair Professor &
Chair of Surgery, Department of Surgery
Division of GI, Tumor, and Endocrine Surgery
University of Colorado Anschutz Medical Campus
Aurora, CO, USA

***Andrea Sheel***
NIHR Liverpool Pancreas Biomedical Research Unit
Department of Molecular and Clinical Cancer Medicine
Institute of Translational Medicine
University of Liverpool
Liverpool, UK

***Celeste Shelton MS, CGC***
Genetic Counselor
Departments of Medicine, Division of Gastroenterology
Hepatology and Nutrition, and Human Genetics
University of Pittsburgh
Pittsburgh, PA, USA

***Kyoko Shimizu MD***
Departments of Internal Medicine and Gastroenterology
Tokyo Women's Medical University School of Medicine
Tokyo, Japan

***Tooru Shimosegawa MD, PhD***
Professor, Division of Gastroenterology
Tohoku University Graduate School of Medicine
Sendai, Japan

***Keiko Shiratori MD (Retired)***
Formerly: Departments of Internal Medicine and Gastroenterology
Tokyo Women's Medical University
School of Medicine
Tokyo, Japan

***Shailesh V. Shrikhande MBBS, MS, MD***
Professor and Head
Gastrointestinal and Hepato-Pancreato-Biliary Surgical Oncology
Tata Memorial Centre
Mumbai, India

***Peter Simon MD***
Department of Medicine A
University Medicine Griefswald
Greifswald, Germany

***Hans W. Sollinger MD, PhD, FACS***
Folkert O. Belzer Professor of Surgery
Division of Transplantation
University of Wisconsin Department of Surgery
Madison, WI, USA

***Anna-Katharina Stadler***
Resident Surgeon
Department of General, Visceral
and Transplantation Surgery
Heidelberg University Hospital
Heidelberg, Germany

***Oliver Strobel MD***
Associate Professor of Surgery
Department of General, Visceral
and Transplantation Surgery
University of Heidelberg
Heidelberg, Germany

***Makoto Takaoka MD***
Department of Gastroenterology and Hepatology
Kansai Medical University
Osaka, Japan

***Kyoichi Takaori MD, PhD, FACS, FMAS(H)***
Professor, Division of Hepatobiliary-Pancreatic Surgery and Transplantation
Department of Surgery
Kyoto University Hospital
Kyoto, Japan

***Vernissia Tam MD***
Resident in General Surgery
Department of General Surgery
University of Pittsburgh Medical Center
Pittsburgh, PA, USA

***May C. Tee MD, MPH***
Clinical Fellow, Section of Hepatobiliary,
Pancreatic, and Transplant Surgery
University of British Columbia
Department of Surgery
Vancouver General Hospital
Vancouver, BC, Canada

***Phuong Nguyen Thanh MD***
Senior Consultant
Department of General, Visceral
and Oncological Surgery
Klinikum St. Georg
Leipzig, Germany

***Elizabeth D. Thompson MD, PhD***
Assistant Professor of Pathology
Johns Hopkins University School of Medicine
Baltimore, MD, USA

***Christin Tjaden MD***
Department of General, Visceral
and Transplantation Surgery
University of Heidelberg
Heidelberg, Germany

***James Toouli MBBS, PhD, FRACS***
Professor of Surgery
Department of General and Digestive Surgery
Flinders University
Adelaide, Australia

***Yoshihisa Tsuji MD, PhD***
Associate Professor
Department of Clinical Education
Shiga University of Medical Science
Otsu, Shiga, Japan

***Aliye Uc MD***
Stead Family Department of Pediatrics
Division of Pediatric Gastroenterology
University of Iowa Children's Hospital
Iowa City, IA, USA

***Kazushige Uchida***
Department of Gastroenterology and Hepatology
Kansai Medical University
Osaka, Japan

***Keijiro Ueda MD, PhD***
Department of Medicine and Bioregulatory Science
Graduate School of Medical Sciences
Kyushu University
Fukuoka, Japan

***Shinji Uemoto MD, PhD***
Division of Hepatobiliary-Pancreatic Surgery and
Transplantation, Department of Surgery
Kyoto University Hospital
Kyoto, Japan

***Waldemar Uhl MD***
Department of General and Visceral Surgery
St. Josef-Hospital Bochum
Ruhr-University
Germany

***Alexis Ulrich MD***
Department of General, Visceral
and Transplantation Surgery
University of Heidelberg
Heidelberg, Germany

***Michiaki Unno MD, PhD***
Department of Surgery
Tohoku University School of Medicine
Sendai, Japan

***Laura Vachel PhD***
Epithelial Signaling and Transport Section
Molecular Physiology and Therapeutics Branch
National Institute of Dental and Craniofacial Research
National Institutes of Health
Bethesda, MD, USA

***Gauri Varadhachary MD***
Professor of Medicine
Department of GI Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, TX, USA

***Yogesh Kumar Vashist MD***
Department of General,
Visceral and Thoracic Surgery
University Medical Center Hamburg-Eppendorf
Hamburg, Germany

***Andrew L. Warshaw MD, FACS, FRCSEd(Hon)***
W. Gerald Austen Distinguished Professor of Surgery
Harvard Medical School
Senior Consultant, International and Regional Clinical
Relations, Massachusetts General Hospital
Boston, MA, USA

***George Webster BSc, MD, FRCP***
Department of Hepatopancreatobiliary Medicine
University College Hospital
London, UK

***Frank Ulrich Weiss PhD***
Department of Medicine A
University Medicine Greifswald
Greifswald, Germany

***Jürgen Weitz MD***
Professor and Chairman
Department of Surgery
Dresden University Hospital
Dresden, Germany

***Ulrich F. Wellner MD***
Surgeon, Department of Surgery
University of Schleswig-Holstein
Campus Lübeck, Lübeck, Germany

***Giles F. Whalen MD***
Division of Surgical Oncology, Department of Surgery
University of Massachusetts Memorial Medical Center
Worcester, MA, USA

***David C. Whitcomb MD, PhD***
Giant Eagle Foundation Professor of Cancer Genetics;
Professor of Medicine
Cell Biology & Molecular Physiology
and Human Genetics
Division of Gastroenterology, Hepatology and Nutrition;
Director, UPMC Precision Medicine Service
University of Pittsburgh/UPMC
Pittsburgh, PA, USA

***Indy Wilkinson MD***
Fellow in Pain Medicine
Johns Hopkins University School of Medicine
Baltimore, MD, USA

***John A. Williams MD, PhD***
Professor and Chair
Department of Molecular and Integrative Physiology
University of Michigan Medical School
Ann Arbor, MI, USA

***Jeremy S. Wilson MD***
Professor of Medicine and Clinical Associate Dean
Pancreatic Research Group, South Western Sydney
Clinical School
Faculty of Medicine
University of New South Wales
Sydney;
Ingham Institute for Applied Medical Research,
Liverpool Hospital, Liverpool, NSW, Australia

***John A. Windsor BSc, MBChB, MD, FRACS, FACS, FRSNZ***
Professor of Surgery
Department of Surgery
University of Auckland
Auckland, New Zealand

***Jordan M. Winter MD***
Department of Surgery, Jefferson Pancreas,
Biliary and Related Cancer Center
Thomas Jefferson University
Philadelphia, PA, USA

***Mathias Wittau MD***
Department General and Abdominal Surgery
University of Ulm
Ulm, Germany

***Uwe A. Wittel MD***
Department of General and Visceral Surgery
University Medical Center Freiburg
Freiburg, Germany

***Robert A. Wolff MD***
Professor of Medicine
Department of GI Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, TX, USA

***Christopher L. Wolfgang MD, PhD***
Professor of Surgery, Pathology, and Oncology
Department of Surgery
Johns Hopkins University School of Medicine
Baltimore, MD, USA

***Laura D. Wood MD, PhD***
Assistant Professor of Pathology & Oncology
The Sol Goldman Pancreatic
Cancer Research Center
Johns Hopkins University School of Medicine
Baltimore, MD, USA

***Dhiraj Yadav MD, MPH***
Division of Gastroenterology & Hepatology
Department of Medicine
University of Pittsburgh Medical Center
Pittsburgh, PA, USA

***Natsuyo Yamamoto MD, PhD***
Department of Gastroenterology
Graduate School of Medicine
University of Tokyo
Tokyo, Japan

***Kenji Yamao***
Department of Gastroenterology
Aichi Cancer Center Hospital
Nagoya, Aichi, Japan

***Hiroki Yamaue MD***
Second Department of Surgery
Wakayama Medical University
School of Medicine,
Wakayama, Japan

***Ichiro Yasuda MD, PhD***
Professor, Department of Gastroenterology
Teikyo University Mizonokuchi Hospital,
Kawasaki, Japan

***Charles J. Yeo MD***
Department of Surgery
Jefferson Pancreas, Biliary and Related
Cancer Center
Thomas Jefferson University
Philadelphia, PA, USA

***Yang Yinmo MD***
Department of Surgery
Peking University First Hospital
P.R. of China

***Yukihiro Yokoyama MD, PhD***
Department of Surgery
Division of Surgical Oncology
Nagoya University Graduate School of Medicine
Nagoya, Japan

***Yue Xue MD, PhD***
Assistant Professor
Department of Pathology and Laboratory Medicine
Emory University Hospital, Atlanta, GA, USA

***Giuseppe Zamboni MD***
Professor, Department of Pathology
University of Verona
Ospedale S. Cuore-Don Calabria
Negrar, Verona, Italy

***Zachary Zator MD***
Fellow in Gastroenterology,
Hepatology, and Nutrition
University of Pittsburgh Medical Center
Pittsburgh, PA, USA

***Herbert J. Zeh III MD***
Chief, Division of Gastrointestinal Surgical Oncology
Professor and Watson Family Chair in Surgery
Co-Director
UPMC Pancreatic Cancer Center
Co-Director
Gastrointestinal Oncology Program
Department of Surgery
University of Pittsburgh
Pittsburgh, PA, USA

***Yoh Zen MD, PhD, FRCPath***
Professor, Department of Diagnostic Pathology
Kobe University
Kobe, Japan

***Mei Zeng MD, PhD***
Epithelial Signaling and Transport Section
Molecular Physiology and Therapeutics Branch
National Institute of Dental and Craniofacial Research
National Institutes of Health
Bethesda, MD, USA

***Martin Zenker MD***
Institute of Human Genetics, University Hospital
Magdeburg, Germany

***Lei Zheng MD, PhD***
The Sidney Kimmel Comprehensive Cancer Center;
Department of Oncology
The Skip Viragh Center for Pancreatic Cancer
Johns Hopkins University School of Medicine
Baltimore, MD, USA

***Amer Zureikat MD***
Assistant Professor in Surgery
Division of Surgical Oncology
University of Pittsburgh Medical Center
Pittsburgh, PA, USA

# Preface

The pancreas has long been an underappreciated organ. Although Aristotle first acknowledged the pancreas in *Historia animalium*, written between 347 and 335 BCE, Galen insisted that the only function of the pancreas was to pad the abdominal vessels, and so the organ was ignored. It took more than a thousand years for Wirsung to describe, in 1642, the ductal morphology of the gland, as well as the communications of the pancreatic duct with the lumen of the small intestine. Today, we recognize the critical importance of the gland, and understanding the pancreas, its normal and abnormal functions and its morphological pathology has become an international focus of established scientists. The understanding of functions and dysfunctions of the exocrine and endocrine pancreas is derived from molecular biological data on the actions of compounds in subcellular compartments and intracellular transcription pathways. In clinical medicine, new and improved technical devices enable the gastroenterologist and the gastrointestinal surgeon to identify lesions by high-resolution imaging techniques, imaging of metabolic processes, and intrapancreatic ductal investigations. In the last 20 years, the spectrum of diseases of the pancreas has been extended by recognition of new and increasingly identified common disorders of the pancreas such as cystic neoplasms and autoimmune pancreatitis. In pancreatology only ductal pancreatic cancer remains largely an uncontrollable mystery disease.

Medical science is not uniform around the world. However, the impact of information technology, international data exchange, and global communication networks have resulted in a broad, increased level in the understanding and practice of pancreatology. The synergistic interaction of basic scientists, pathologists, gastroenterologists, and gastrointestinal tract surgeons in the field of investigative and clinical pancreatology has led to better understanding of pancreatic diseases through combining the knowledge of each to achieve the best management. Decision making is increasingly based on the evidence of data from clinical trials on treatment. New technical devices—endoscopic visualization of cellular abnormalities, laparoscopic minimal invasive surgical approaches, and robotic surgery—have led to the establishment of a local, parenchyma-sparing surgical approach for neoplastic and inflammatory pancreatic diseases. Although care of patients cannot be made a global affair, this book brings the most recent knowledge on the pancreas from international experts to readers everywhere.

The goal of this third edition of *The Pancreas: An integrated textbook of basic science, medicine, and surgery* is to provide the clinician with the most current data-based synthesis of understanding of pancreatic diseases, functional assessment, diagnostic and technical devices, and treatment options. All chapters are written by leading international experts on the topic. A major part of this edition has been contributed by international basic scientists, who provide an understanding of the molecular basis of pancreatic functions and diseases. The editors acknowledge and are deeply indebted to all authors who have contributed to this edition. Their diligent efforts have provided state-of-the-art knowledge, particularly in regard to clinical decision making based on evidence.

*Hans G. Beger, Ulm*
*Andrew L. Warshaw, Boston*
*Ralph H. Hruban, Baltimore*

## Abbreviations

| | |
|---|---|
| 4EBP1 | initiation factor 4E binding protein 1 |
| 5-FU | 5-fluorouracil |
| 5-HIAA | 5-hydroxyindoleacetic acid |
| 5-HT | 5-hydroxytryptamine; serotonin |
| 25(OH)D | 25-hydroxyvitamin D |
| α-gal | alpha-galactosylated |
| α-GI | alpha-glucosidase inhibitor |
| αSMA | alpha smooth muscle actin |
| ABP | acute biliary pancreatitis |
| ACC | acinar cell carcinoma |
| ACE | angiotensin-converting enzyme |
| ACG | American College of Gastroenterology |
| ACh | acetylcholine |
| ACP | alcoholic chronic pancreatitis |
| ACS | abdominal compartment syndrome |
| ACS | American Cancer Society |
| ACTH | adrenocorticotropic hormone |
| ADH | alcohol dehydrogenase |
| ADM | acinar-to-ductal metaplasia |
| ADP | adenosine diphosphate |
| ADPKD | autosomal dominant polycystic kidney disease |
| AFIP | Armed Forces Institute of Pathology |
| AFP | alpha-fetoprotein |
| AGA | American Gastroentrological Association |
| AHPBA | American Hepato-Pancreato-Biliary Association |
| AID | autoinhibitory domain |
| AIDS | acquired immune deficiency syndrome |
| AIH | autoimmune hepatitis |
| AJCC | American Joint Committee on Cancer |
| AIP | autoimmune pancreatitis |
| ALDH | acetaldehyde dehydrogenase |
| ALI | acute lung injury |
| ALT | alanine transaminase |
| ALT | alternative lengthening of telomeres |
| ANC | acute necrotic collection |
| anti-SSA | anti-Sjögren syndrome A |
| anti-SSB | anti-Sjögren syndrome B |
| AP | acute pancreatitis |
| AP-1 | activator protein-1 |
| APA | American Pancreatic Association |
| APACHE | acute physiology and chronic health evaluation |
| APBDU | anomalous pancreaticobiliary ductal union |
| APC | activated protein C |

| | |
|---|---|
| APC | antigen-presenting cells |
| APFC | acute pancreatic fluid collection |
| ARDS | acute respiratory distress syndrome |
| ARF | acute renal failure |
| Arg | arginine |
| ARP | acute recurrent pancreatitis |
| ARTN | artemin |
| ARX | aristaless-related homeobox |
| ASA | acetylsalicylic acid |
| ASCO | American Society of Clinical Oncology |
| AST | aspartate transaminase |
| ATIII | antithrombin 3 |
| ATMDS | alpha-thalassemia myelodysplastic syndrome |
| ATP | adenosine triphosphate |
| ATRX | alpha-thalassemia/mental retardation X-linked |
| AUROC | area under the receiver operating characteristic curve |
| BAPTA-AM | 1,2-bis(*o*-aminophenoxy)ethane-*N*,*N*,*N*′,*N*′-tetraacetic acid |
| BCAA | branched-chain amino acid |
| BD-IPMN | branch-duct intraductal papillary mucinous neoplasm |
| BE | balloon enteroscopy |
| BHOB | β-hydroxybutyrate |
| BilIN | biliary intraepithelial neoplasia |
| BMI | body mass index |
| BMP | bone morphogenic protein |
| *BRCA1* | breast cancer 1 gene |
| *BRCA2* | breast cancer 2 gene |
| BRPC | borderline resectable pancreatic cancer |
| BR-PDAC | borderline resectable pancreatic ductal adenocarcinoma |
| BSA | body surface area |
| BSG | British Society of Gastroenterology |
| BUN | blood urea nitrogen |
| BWS | Beckwith–Wiedemann syndrome |
| CA 19-9 | carbohydrate antigen 19-9 |
| CA | carbonic anhydrase |
| CA | celiac axis |
| cADPR | cyclic ADP-ribose |
| CAP | College of American Pathologists |
| CAPS | Cancer of the Pancreas Screening programs |
| CARS | compensatory anti-inflammatory response syndrome |
| CAS | celiac artery stenosis |
| CASR | calcium-sensing receptor |
| CBCT | cone beam computed tomography |
| CBD | common bile duct |
| CBER | Center for Biologics Evaluation and Research |
| CBP | CREB-binding protein |
| CCK | cholecystokinin |
| CDX | caudal-related homeobox transcription factor |
| CEA | carcinoembryonic antigen |
| CE-CT | contrast-enhanced computed tomography |
| CEL | carboxyl ester lipase |
| CF | cystic fibrosis |
| CFRD | cystic fibrosis-related diabetes mellitus |
| CFTR | cystic fibrosis transmembrane conductor regulator |
| CG | celiac ganglion |
| CGRP | calcitonin gene-related peptide |
| ChA | chromogranin A |

| | |
|---|---|
| CHI | congenital hyperinsulinism |
| Chr | chromosome |
| CI | confidence interval |
| CIT | Clinical Islet Transplantation |
| CITR | Collaborative Islet Transplant Registry |
| *CLDN2* | claudin 2 gene |
| CNI | calcineurin inhibitor |
| CNS | central nervous system |
| CONKO | Charité Onkologie |
| COX-2 | cyclooxygenase 2 |
| CP | chronic pancreatitis |
| CPA1 | carboxypeptidase A1 |
| CPB | celiac plexus block |
| CPN | celiac plexus neurolysis |
| CPNT | cystic pancreatic neuroendocrine tumor |
| CRAC | $Ca^{2+}$ release activated $Ca^{2+}$ |
| CREB | cAMP response element binding |
| CRF | corticotropin-releasing factor |
| CRH | corticotropin-releasing hormone |
| CRP | C-reactive protein |
| CRT | chemoradiation therapy |
| CSF-1 | colony-stimulating factor 1 |
| CSF-1/R | colony stimulating factor-1/receptor |
| CT | computed tomography |
| CTC | circulating tumor cells |
| ctDNA | circulating tumor DNA |
| CTGF | connective tissue growth factor |
| CTL | cytotoxic T-lymphocytes |
| CTLA-4 | cytotoxic T-lymphocyte associated protein-4 |
| CTRC | chymotrypsin C or chymotrypsinogen C |
| CTSB | cathepsin B |
| CTSI | CT severity index |
| Cy | cyclophosphamide |
| CYP2E1 | cytochrome P450 2E1 |
| DAMP | damage-associated molecular pattern molecule |
| DAXX | death domain-associated protein |
| DBC | determinant-based classification |
| DBDC | distal common bile duct carcinoma |
| DBE | double-balloon enteroscopy |
| DBTC | dibutyltin chloride |
| DCD | deceased cardiac death donor |
| DEN | direct endoscopic necrosectomy |
| DGE | delayed gastric emptying |
| DKA | diabetic ketoacidosis |
| DM | diabetes mellitus |
| DMV | dorsal motor nucleus |
| DNA | deoxyribonucleic acid |
| DOPA | dihydroxyphenylalanine |
| DOTA | 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid |
| DOTA-NOC | DOTA-Nal-octreotide |
| DOTA-TATE | DOTA-Tyr-octreotate |
| DOTA-TOC | DOTA-Tyr-octreotide |
| DP | distal pancreatectomy |
| DPDS | disconnected pancreatic duct syndrome |
| DPP-4 | dipeptidyl-peptidase-4 |
| DPPHR | duodenum-preserving pancreatic head resection |

| | |
|---|---|
| DPPHR-P | duodenum-preserving partial head resection |
| DPPHR-S | duodenum-preserving total head resection plus segment resection of duodenum and CBD |
| DPPHR-T | duodenum-preserving total head resection but conserving duodenum and CBD |
| DRG | dorsal root ganglion |
| DSS | disease-specific survival |
| DTPA | diethylenetriaminepentaacetic acid |
| DWI | diffusion-weighted imaging MRI |
| DXA | dual X-ray absorptiometry |
| E8.5 | embryonic day 8.5 |
| EBL | estimated blood loss |
| EBRT | external beam radiation |
| ECG | electrocardiogram |
| ECM | extracellular matrix |
| ED | emergency department |
| EGF | epithermal growth factor |
| eIF2α | eukaryotic initiation factor 2 alpha |
| eIF4F | eukaryotic initiation factor 4F |
| eIF4G | eukaryotic initiation factor 4G |
| ELISA | enzyme-linked immunosorbent assay |
| EMT | epithelial mesenchymal transition |
| ENETS | European Neuroendocrine Tumor Society |
| EORTC | European Organization for Research and Treatment of Cancer |
| EPI | exocrine pancreatic insufficiency |
| EPO | erythropoietin |
| ER | endoplasmic reticulum |
| ERCP | endoscopic retrograde cholangiopancreatography imaging |
| ERK | extracellular regulated kinase |
| ERP | endoscopic retrograde pancreatography |
| ES | endoscopic sphincterotomy |
| ESDO | European Society of Digestive Oncology |
| ESGE | European Society of Gastrointestinal Endoscopy |
| ESMO | European Society for Medical Oncology |
| ESPAC | European Study Group for Pancreatic Cancer |
| ESR | erythrocyte sedimentation rate |
| ESRD | end-stage renal disease |
| ESWL | extracorporeal shock wave lithotripsy |
| EUROPAC | European Registry of Hereditary Pancreatitis and Familial Pancreatic Cancer |
| EUS | endoscopic ultrasound |
| EUS-AG | EUS-guided antegrade stenting |
| EUS-BD | endoscopic ultrasonography-guided biliary drainage |
| EUS-CDS | EUS-guided choledochoduodenostomy |
| EUS-CGN | EUS-guided celiac ganglia neurolysis |
| EUS-CPN | endoscopic ultrasound celiac plexus neurolysis |
| EUS-FNA | endoscopic ultrasound guided fine-needle aspiration |
| EUS-HGS | EUS-guided hepaticogastrostomy |
| EUS-RV | EUS-rendezvous technique |
| FAEE | fatty acid ethyl ester |
| FAP | familial adenomatous polyposis |
| FCεR | high-affinity IgE or Fc epsilon receptor |
| FCPD | fibrocalculous pancreatic diabetes |
| fcSEMS | fully covered self-expandable metal stents |
| FDA | Food and Drug Administration (USA) |
| FDG-PET | [$^{18}$F]fluoro-2-deoxy-D-glucose positron emission tomography |
| FDP | [$^{18}$F]fluorodipalmitin |
| FE-1 | fecal elastase-1 |
| FFA | free fatty acid |

| | |
|---|---|
| FGF | fibroblast growth factor |
| FIBS | fibroinflammatory biliary stricture |
| FNA | fine-needle aspiration |
| FNB | fine-needle biopsy |
| FOLFIRINOX | 5-fluorouracil [5-FU], oxaliplatin, irinotecan, and leucovorin |
| FPC | familial pancreatic cancer |
| Ga | gallium citrate |
| GAP-43 | growth-associated protein-43 |
| G-CSF | granulocyte colony-stimulating factor |
| GDA | gastroduodenal artery |
| GEL | granulocytic epithelial lesion |
| GEP-NET | gastroenteropancreatic neuroendocrine tumor |
| GFAP | glial fibrillary acidic protein |
| GFR | glomerular filtration rate |
| GH | growth hormone |
| GHRH | growth hormone-releasing hormone |
| GI | gastrointestinal |
| GIP | gastric inhibitory peptide |
| GIP | glucose-dependent insulinotropic polypeptide |
| GITSG | Gastrointestinal Tumor Study Group |
| GJ | gastrojejunostomy |
| GLP-1 | glucagon-like peptide 1 |
| Gly | glycine |
| GM-CSF | granulocyte macrophage-colony stimulating factor |
| GNAS | guanine nucleotide binding protein alpha stimulating |
| GNPNA | *N*-glutaryl-L-phenylalanine-*p*-nitroanilide |
| GRAGIL | Group de Recherche Rhin, Rhône-Alpes et Genève pour la Transplantation d'Ilots de Langerhans |
| GRF | growth hormone-releasing factor |
| GTX | gemcitabine, docetaxel, and capecitabine |
| GWAS | genome-wide association studies |
| H2R | histamine 2 receptor |
| H&E | hematoxylin and eosin (histologic stain) |
| $HbA_{1c}$ | hemoglobin $A_{1c}$ |
| HB-EGF | heparin-binding EGF-like growth factor |
| HBV | hepatitis B virus |
| hCG | human chorionic gonadotropin |
| hENT1 | human equilibrative nucleoside transporter 1 |
| HES1 | hairy and enhancer of split 1 |
| HGD | high-grade dysplasia |
| HGF | hepatocyte growth factor |
| HIF | hypoxia-induced factor |
| HIV | human immunodeficiency virus |
| HJ | hepaticojejunostomy |
| HLA | human leukocyte antigen |
| HMG-CoA | 3-hydroxy-3-methylglutaryl-coenzyme A |
| HNF | hepatocyte nuclear factor |
| HNPCC | hereditary nonpolyposis colorectal cancer syndrome |
| HPF | high power field |
| HR | hazard ratio |
| HTG | hypertriglyceridemia |
| HTK | histidine–tryptophan–ketoglutarate |
| HTP | hydroxytrytophan |
| HUS | hemolytic uremic syndrome |
| IAH | impaired awareness of hypoglycemia |
| IAK | islet after kidney |
| IAP | International Association of Pancreatology |

| | |
|---|---|
| IAPN | intra-ampullary papillary tubular neoplasm |
| IBD | inflammatory bowel disease |
| IC | immune complex |
| IC | invasive carcinoma |
| ICDC | International Consensus Diagnostic Criteria for AIP |
| ICGC | International Cancer Genome Consortium |
| ICU | intensive care unit |
| IDCP | idiopathic duct-centric pancreatitis |
| IDDM | insulin-dependent diabetes mellitus |
| IDDS | intrathecal drug delivery systems |
| IEQ | islet equivalent |
| IFN-γ | interferon γ |
| Ig | immunoglobulin |
| IgE | immunoglobulin E |
| IGF | insulin-like growth factor |
| IGF-1 | insulin-like growth factor 1 |
| IgG | immunoglobulin G |
| IgG4-MOLPS | IgG4-related multiorgan lymphoproliferative syndrome |
| IgG4-RD | IgG4-related disease |
| IL | interleukin |
| IL-10 | interleukin 10 |
| IL-1β | interleukin 1β |
| IL-6 | interleukin 6 |
| IL-8 | interleukin 8 |
| IMRT | intensity modulated radiation therapy |
| iNOS | inducible nitric oxide synthase |
| IOPN | intraductal oncocytic papillary neoplasm |
| IORT | intraoperative radiation therapy |
| IOU | intraoperative ultrasound |
| $IP_3$ | inositol 1,4,5-trisphosphate |
| IPHM | inflammatory pancreatic head mass |
| IPMN | intraductal papillary mucinous neoplasm |
| IPTR | International Pancreas Transplant Registry |
| IQR | interquartile range |
| IR | insulin receptor |
| IRE | irreversible electroporation |
| IRG | immunoreactive gastrin |
| IRI | immunoreactive insulin |
| ISGPF | International Study Group on Pancreatic Fistula |
| ISGPS | International Study Group of Pancreatic Surgery |
| IT | intrathecal |
| ITA | intraductal tubular adenoma |
| ITA | islet transplant alone |
| ITC | intraductal tubular carcinoma |
| ITPN | intraductal tubulopapillary neoplasm |
| ITU | intensive therapy unit |

## Anatomy of the Pancreas

The pancreas is a unique exocrine and endocrine organ located in the retroperitoneal region of the upper abdominal cavity. In humans, when fully formed, the organ has a distinct head, body, and tail, with the head of the pancreas contacting the duodenal region of the intestines (the main pancreatic duct drains into the duodenum) and the tail of the pancreas abutting the spleen. The greatest mass of the organ is present in the head, which is composed of tissue derived from two independent anlagen (see later). In other mammals, such as dogs and mice, the organ has a far less distinct structure and is identified as an amorphous pink tissue adjacent to the mesentery that runs along the upper intestinal wall.

The cells of the pancreas are arranged into distinct lobules composed primarily of the digestive enzyme-producing cells of the exocrine pancreas, which are arranged into acini (so-called acinar cells), the ductal structures that conduct these digestive enzymes to the intestines, and distinct clusters of endocrine cells, the islets of Langerhans, that secrete hormones and function to regulate glucose uptake and release and serum glucose levels. There are five recognized cell types within the islets, the α, β, δ, ε, and PP cells, which produce the hormones glucagon, insulin, somatostatin, ghrelin, and pancreatic polypeptide, respectively. The majority of the pancreatic tissue mass (more than 90–95%) is present within the exocrine compartment of the organ, with the islets of Langerhans, scattered throughout the tissue. The pancreas also has connective tissue, derived from the embryonic mesenchyme, which forms the septa that separate the many lobules of the organ. Mesenchyme-derived stromal cells are also present in the interlobular regions surrounding the pancreatic ducts, blood vessels, and nerves. In the following sections, we explore how these disparate cell types come together to form the pancreas.

## Organogenesis in the Region of the Pancreas

Around day 14, the embryonic bilaminar germ disk is composed of a layer of epiblast and a layer of hypoblast. At this time, a faint groove appears along the longitudinal midline of the germ disk that develops into a structure called the primitive streak [1]. Around day 15, epiblast cells near the primitive streak undergo a morphologic change and migrate through the primitive streak into the space between the epiblast and hypoblast in a process known as gastrulation (Fig. 1.1). Some of the ingressing epiblast cells invade the hypoblast, which is eventually replaced by a new layer of epiblast-derived cells known as the definitive endoderm. Additional migrating epiblast cells occupy the space between the epiblast and the definitive endoderm to form a third layer of cells called the intraembryonic mesoderm (Fig. 1.1). As cells of the germinal disk migrate anteriorly to form a head process and lateral regions roll underneath to form an approximately cylindrical body shape, the endoderm is rolled into a tube that projects into the developing head region of the embryo surrounded by the mesoderm layer. This is the primitive digestive tube. The pancreas is specified by two separate outgrowths that arise on the dorsal and ventral surfaces of the primitive digestive tube. The epithelial cells of the pancreas originate from the interior lining of the primitive gut tube, which consists of a single layer of endoderm. A layer of

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

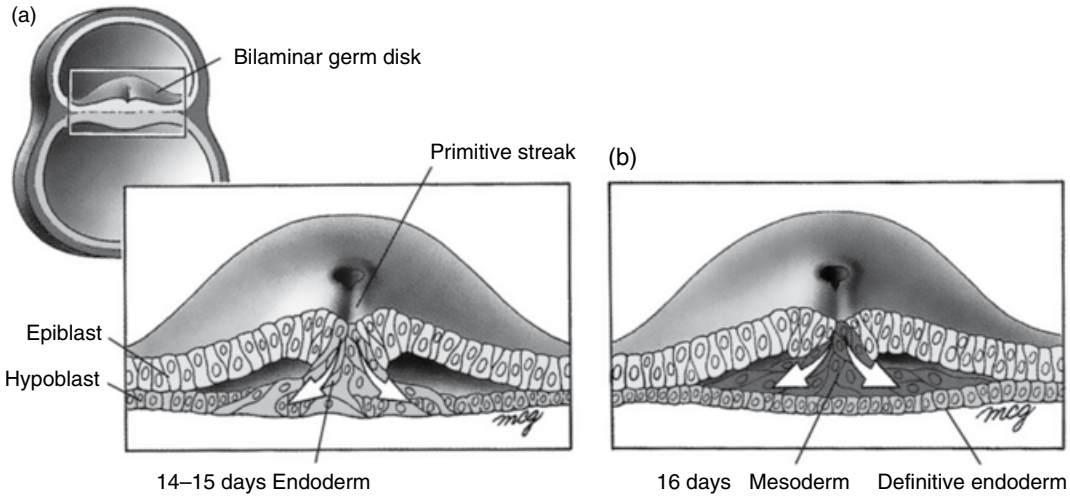

**Figure 1.1** Germ disks sectioned through the region of the primitive streak, showing gastrulation. (a) On days 14 and 15, the ingressing epiblast cells replace the hypoblast to form the definitive endoderm. (b) The epiblast that ingresses on day 16 migrates between the endoderm and epiblast layers to form the intraembryonic mesoderm. Source: Larsen 2001 [1]. Reproduced with permission of Elsevier.

mesenchyme, from which the muscle and connective tissue of the gastrointestinal organs are derived, surrounds the endoderm.

The anterior regions of the endoderm form the foregut; regions posterior to the foregut form the midgut and hindgut. The most anterior regions of the foregut give rise to the esophagus and stomach. Just posterior to the foregut, the endoderm is continuous with the yolk sac, which extends outside the embryo, in a region known as the anterior intestinal portal. Endodermally derived cells close to the anterior intestinal portal specify the pancreas. The duodenum and liver are also specified by foregut endoderm in this region.

Thus, many gastrointestinal tissues are specified at the same time from a fairly restricted region of the gut endoderm. How are each of these organs specified in the appropriate anatomic location, and how do they differentiate properly into mature functional organs? The epithelial organs of the developing embryo originate as buds from the endoderm as the appropriate temporal and spatial cues are received. Thus, proper initiation and location of endodermally derived organs are regulated by the activation status of important signal transduction pathways involved in animal development, including the hedgehog, notch, and fibroblast growth factor signaling pathways.

## Early Pancreatic Development

During the fourth week of gestation, two buds appear on the dorsal and ventral sides of the foregut near the anterior intestinal portal. These epithelial buds indicate the specification of the pancreas. These buds initially grow and differentiate independently, but later fuse to form a single organ. The anlage on the dorsal side, the dorsal pancreatic bud, appears first and gives rise to the dorsal pancreas. The cells of the dorsal pancreas will give rise to the head, body, and tail of the mature pancreas. The second pancreatic anlage appears shortly after the appearance of the dorsal pancreatic bud. This bud, which appears on the ventral side of the gut tube, is appropriately called the ventral pancreatic bud and develops into the ventral pancreas, which forms part of the head of the pancreas. Both pancreatic buds develop simultaneously, and the proliferating epithelial cells grow as projections into the surrounding mesenchymal tissue. During this time, the development of the intestines, and importantly the duodenum, continues. Rotation and asymmetric growth of the duodenum move the originally ventral part to a dorsal location, carrying with it the ventral pancreas and the primordial common bile duct. As the duodenum begins to rotate into its appropriate anatomic location, the ventral pancreas also rotates around the gut tube such that the ventral and dorsal pancreata lie adjacent to each other. These pancreatic rudiments then fuse to form a single organ. While both developing pancreatic buds independently form pancreatic ducts, the lumens of which are continuous with the lumen of the primitive gut, after they fuse their primary ducts anastomose to form the main pancreatic duct (Fig. 1.2). The region of the primary duct of the ventral pancreas proximal to the duodenum fuses with the primary duct of the dorsal pancreas and becomes the primary drainage into the duodenum, entering the duodenum immediately adjacent to the common bile duct. The proximal region of the primary duct of the dorsal pancreas sometimes remains as an accessory drainage but often regresses.

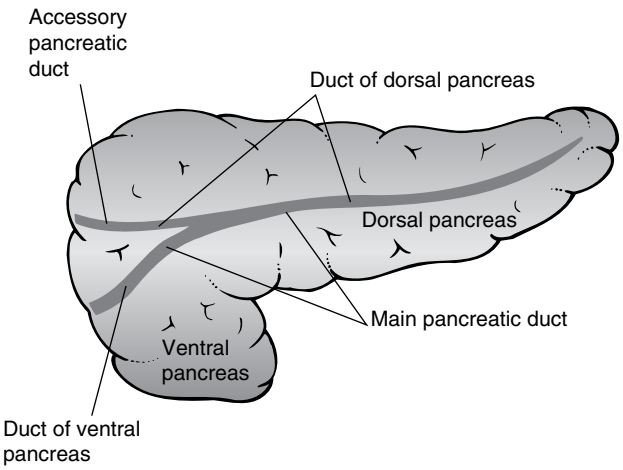

**Figure 1.2** Contributions of the dorsal and ventral pancreas to the definitive organ. The ventral pancreas becomes most of the head. The dorsal pancreas becomes the remainder of the head, plus the body and tail. The duct of the dorsal pancreas contributes a large part of the main pancreatic duct plus the accessory duct. The duct of the ventral pancreas becomes the part of the main duct nearest the duodenum.

The ducts sometimes fail to fuse, in which event two independent duct systems drain into the duodenum.

### Signaling Governing Early Pancreatic Development

Early pancreatic development and establishing pancreatic identity are governed by the interplay between several critical transcription factors and intercellular signaling pathways. PDX1 and PTF1A are among the earliest transcription factors expressed in the pancreatic progenitor populations, and their functions are critical for pancreatic development [2–5]. In mice, PDX1 expression is first detected in the primitive gut tube at embryonic day 8.5 (E8.5), demarcating the prospective pancreatic domain, which is then followed by PTF1A expression in pancreatic endoderm at E9.5 [5–7]. Mice lacking either transcription factor display pancreatic agenesis [2,3,5,8].

In addition to the transcription factors, several key intercellular signaling pathways between gut endoderm and mesenchyme, including the hedgehog and fibroblast growth factor (FGF) pathways, play important roles in establishing the pancreatic identity and controlling the expression of these transcription factors. Research studies have shown that sonic hedgehog (SHH) is excluded from the prospective pancreatic region, but is present in the region of foregut that becomes the duodenum, and ectopic expression of SHH in the pancreas induces an intestinal fate, suggesting that SHH signaling may specify a duodenal versus pancreatic fate in the posterior foregut [9,10]. Another well-understood pathway mediating the mesenchymal–epithelial interaction is the FGF signaling pathway, in particular the FGF10–FGFR2 ligand–receptor pair. During early pancreatic development, FGF10 is highly expressed in the primitive mesenchyme, whereas its receptor FGFR2 is present in the pancreatic epithelium [11]. Mouse genetic experiments demonstrated that FGF10 provides the pro-proliferative signal to promote the expansion of the progenitor pool in the pancreatic epithelium [11]. In addition, FGF10 signaling from the mesenchymal cells is critical for maintaining the epithelial expression of SOX9 [12]. SOX9 is another transcription factor critical for early pancreatic development, and it exerts its function in part by controlling the expression of the FGF10 receptor FGFR2 [12,13]. Together, the complex regulatory loop between these signaling pathways and transcription factors in the epithelium and mesenchyme coordinates early organ growth and the establishment and maintenance of pancreatic identity.

## Differentiation of Pancreas Cell Types

The acinar, ductal, and endocrine cells of the pancreas are all produced through the proliferation and differentiation of the epithelial cells of both pancreas primordia. The cells appear homogeneous during the early stages of development as they proliferate and grow into the surrounding mesenchyme as finger-like projections. The epithelial cells form undifferentiated tubules that branch and anastomose as they penetrate into the mesenchyme to generate a tubular network, which resembles an immature (and nonfunctional) duct system. The acinar cells appear as clusters of cells at the ends of branches of this tubular network. The endocrine cells appear as cells that delaminate from the tubular epithelium and reaggregate in isolated clusters embedded within the developing parenchyma. The existing cells within these small isolated endocrine clusters proliferate, and these clusters therefore expand to form the islets.

Apparent differentiation of pancreas epithelial cells into endocrine cells can be identified beginning at 12 weeks of gestation with the detection of endocrine granules. Most of the endocrine differentiated cells identified at this time express glucagon and are therefore believed to be α cells. Importantly, lineage-tracing experiments performed in mice demonstrated that these early α cells do not act as endocrine progenitors, as β cells, the predominant cell type in the mature islet, are derived from glucagon-negative cells [14]. Differentiation of acinar cells is detected at approximately 16 weeks, as identified by the appearance of zymogen granules. Interestingly, not all enzymes are elaborated at once—detection of

trypsinogen does not occur until approximately 22 weeks. The digestive enzyme-positive cells arise as clusters from the undifferentiated tubules, the expansion of which is rapid such that the acinar cells become the dominant population within the organ. Although they are not yet mature acinar cells, the cells in the acinar clusters display some of their hallmark features, including basolaterally located nuclei. As differentiation continues, the cells become arranged in recognized acini and defined lobules surrounded by connective tissue. The ductal system arises after maturation of the immature tubular network. The specific morphologic changes that accompany this change are unclear, although some work suggests that WNT signaling is involved in this transition [15].

## Transcriptional Mechanisms Underlying Pancreatic Cell Fate Decision

Much information about pancreatic cell fate determination and cell type differentiation has been obtained from studies in animal models. Elegant genetic and cell-based experiments in mice have identified a gene regulatory network controlled by many transcription factors to specify different cell lineages in the developing pancreas.

### Development of the Endocrine Lineage

Endocrine cell specification begins with the expression of NGN3, a bHLH (basic helix loop helix) transcription factor, in a subset of progenitor cells within the trunk region of the pancreatic bud [16–18]. The NGN3-expressing cells eventually give rise to all endocrine cell types: insulin-producing β cells, glucagon-producing α cells, somatostatin-producing δ cells, ghrelin-producing ε cells, and pancreatic polypeptide-producing PP cells [16–18]. NGN3 initiates endocrine lineage specification by inducing the expression of downstream transcription factors, including NeuroD, NKX2.2, PAX4, and ARX. Among them, NKX2.2, NeuroD, and PAX4 play key roles in the specification of β cells [19–21]. Mutant mice lacking any of these transcription factors display a phenotype of dramatic or total loss of β cells [19–21]. Further studies revealed that the opposing actions of PAX4 and ARX determine the fate choice between α and β cells. During endocrine differentiation, loss of ARX leads to a complete loss of α cells, but a concomitant increase in β and δ cells [22], whereas loss of PAX4 results in an opposite phenotype with loss of β and δ cells and expansion of α cells [20,22]. It is believed that this effect on cell fate choice is mediated by the reciprocal transcriptional repression between these factors.

### Differentiation of Acinar Cells

Pancreatic acinar cells are primarily derived from precursor cells in the tip region, and their differentiation is coordinated by the transcription factor PTF1A, a master regulator of pancreatic development. Prior to exocrine differentiation, PTF1A forms a complex with the bHLH transcription factor RBP-Jk, and is required for activation of RBP-Jl, an acinar-specific paralog of RBP-Jk [23,24]. The more active RBP-Jl then replaces RBP-Jk to form the complex with PTF1A, thereby directly inducing the expression of many acinar-specific genes, including secretory peptides and digestive enzymes [23,24]. Interestingly, PDX1, another factor important for early pancreatic morphogenesis, is also involved in acinar differentiation. Although not essential for initial acinar specification, it appears that PDX1 is required for terminal differentiation of acinar cells [25]. Other transcription factors, such as NR5A2 and MIST1, are also required for acinar differentiation and homeostasis, likely through the interaction with the PTF1A/RBP-Jk/l complex [26,27].

### Ductal Cell Differentiation and Lineage Plasticity

In comparison with the endocrine and exocrine lineages, how ductal cells undergo differentiation remains poorly understood. It appears that, during development, NGN3-positive cells in the trunk region of the pancreatic bud give rise to endocrine cells, whereas NGN3-negative trunk epithelial cells contribute to the ductal system [28,29]. A number of transcription factors, such as SOX9, PROX1, HES1, and HNF6, are expressed in the ductal lineage and play various roles in ductal differentiation, including primary cilia formation in the ductal epithelial cells [30–33]. Although the three lineages (endocrine, exocrine, and ductal) are specified during early development, the adult pancreatic cells from different lineages show remarkable plasticity and trans-differentiation capacity in pancreatic injury, pancreatitis, and tumorigenesis, which may shed light on the mechanisms underlying these pancreatic pathologies.

## Development and Disease

Molecules important in the development of the pancreas are also causally associated with pancreatic disorders. Several of the signaling pathways involved in normal pancreas development, such as the notch, hedgehog and WNT signaling pathways, are commonly activated in

pancreatic ductal adenocarcinomas [34–38]. Aberrant activation of WNT signaling drives the development of other pancreatic tumor types such as acinar carcinomas, pancreatoblastoma, and mucinous cystic neoplasms [39–42].

In diabetes, mutation of the transcription factor PDX1, which is important for pancreas specification and for proper β-cell maturation and function, is a cause of maturity-onset diabetes of the young (MODY) [43]. Other transcription factors that are critical for β-cell development (as determined by genetic studies in the mouse), such as hepatocyte nuclear factor 1α (HNF1α), HNF1β, HNF4α, and NeuroD, are all also mutated in additional MODY complementation groups [43]. More recently, scientists have utilized our growing understanding of normal pancreas development to promote the differentiation of induced pluripotent stem cells into insulin-producing cells in a new potential therapeutic approach for diabetes [44,45].

Collectively, these findings illustrate the importance of key regulators of pancreas development and differentiation in pathologic disease states and how knowledge of normal pancreas development may drive new therapeutic strategies for pancreatic diseases.

## Introduction

This chapter reviews the anatomy, histology, and ultrastructure of the pancreas, including the exocrine and endocrine portions. The exocrine pancreas produces and secretes digestive enzymes into the duodenum and includes acinar cells and ducts with associated connective tissue, vessels, and nerves that comprise more than 95% of the pancreatic mass. The endocrine pancreas (islets) makes and secretes insulin, glucagon, somatostatin, and pancreatic polypeptide into the blood. The islets comprise 1–2% of pancreatic mass.

When the anatomic terms *anterior* and *posterior* are used in this chapter, they pertain to relationships in the human, standing erect. Similarly, *superior* and *inferior* mean toward the head and toward the feet, respectively. We will adopt the convention that *right* and *left* (unqualified) indicate the subject's right-hand and left-hand sides. However, when describing the location of structures within an image, *image right* and *image left* are used to denote relationships without reference to the subject's right or left side.

The organization and content of this chapter are based in part on a recent Pancreapedia chapter on pancreatic anatomy and histology [1].

## Gross Anatomy

The pancreas (meaning all flesh) lies in the posterior portion of the upper abdomen behind the stomach. It is largely retroperitoneal and is covered by peritoneum on the anterior surface of the head and body and is surrounded by fat in this region. It is customary to refer to various portions of the pancreas as head, body, and tail. The head abuts the C-shaped second portion of the duodenum in the right upper quadrant of the abdomen. The tail emerges into the peritoneal cavity (covered by peritoneal serosa) and extends to the hilum of the spleen in the left upper quadrant. The pancreas weighs about 100 g and is 14–25 cm long [2]. Figure 2.1 shows a human pancreas that has been dissected to isolate it from surrounding fat and adjacent organs and Fig. 2.2 depicts a pancreas that has been dissected to reveal the pancreatic and common bile ducts.

The pancreas is intimately associated with several adjacent organs. Relationships of the pancreas to surrounding organs and structures are depicted in Figs 2.3, 2.4, 2.5, and 2.6. As noted above, as the duodenum exits the stomach it loops around the head of the pancreas. The tail of the pancreas lies near the hilum of the spleen. The body of the pancreas lies posterior to the pyloric region of the stomach.

The portion of the pancreas that lies anterior to the aorta is somewhat thinner in the anterior–posterior axis than the adjacent portions of the head and body of the pancreas. This region is designated as the neck and marks the junction of the head and body (Fig. 2.1b). The proximity of the neck of the pancreas to major blood vessels posteriorly, including the superior mesenteric artery, superior mesenteric-portal vein, inferior vena cava, and aorta, limits the option for a wide surgical margin during pancreatectomy (Fig. 2.5).

There is no anatomic landmark for the junction between the body and tail of the pancreas [3]. Hellman defined the tail as one-fourth of the pancreas from the

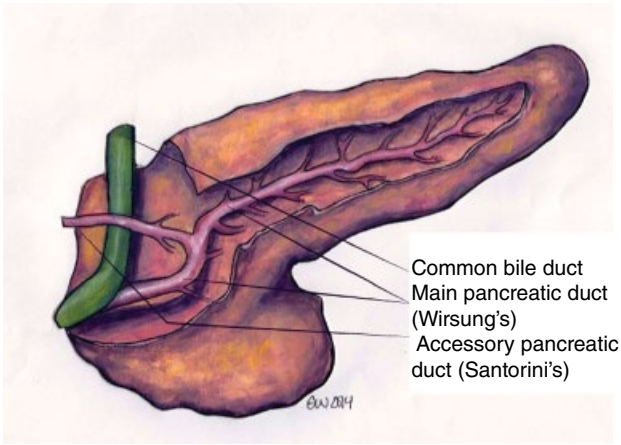

**Figure 2.2** A pancreas dissected to reveal the pancreatic ducts and common bile duct as it traverses the head of the pancreas, ending as it joins the main pancreatic duct near the ampulla of Vater. Interlobular branches of the main duct are depicted but smaller ducts (intralobular ducts and ductules) are not. Eponyms identify the anatomist, embryologist, or physician who is credited with first describing a structure. Wirsung and Santorini were such scientists. *Source:* Drawing by Emily Weber.

tip of the tail to the head [4] whereas Wittingen and Frey defined the junction between the body and tail as the point where the gland sharply narrows [5]. This point is difficult to define in some pancreases.

The common bile duct passes behind the upper portion of the head and then runs through the pancreas to join the main duct in the duodenal wall (Figs 2.2, 2.5, and 2.7b). The accessory pancreatic duct drains into the duodenum at the minor papilla in most humans, and the main pancreatic duct enters the duodenum at the major papilla (Fig. 2.3). See Chapter 3 for discussion of pancreas divisum and other anomalies with possible clinical significance.

Typically, the bile duct and main pancreatic duct join into a "common channel" referring to the fused portion of the bile and pancreatic ducts proximal to its entry into the duodenal lumen. The common channel varies in length from a few millimeters to about 1 cm. A long common channel due to junction of the bile and pancreatic ducts proximal to the duodenal wall is regarded as an anomaly [6]. Less often, there is no common channel because the

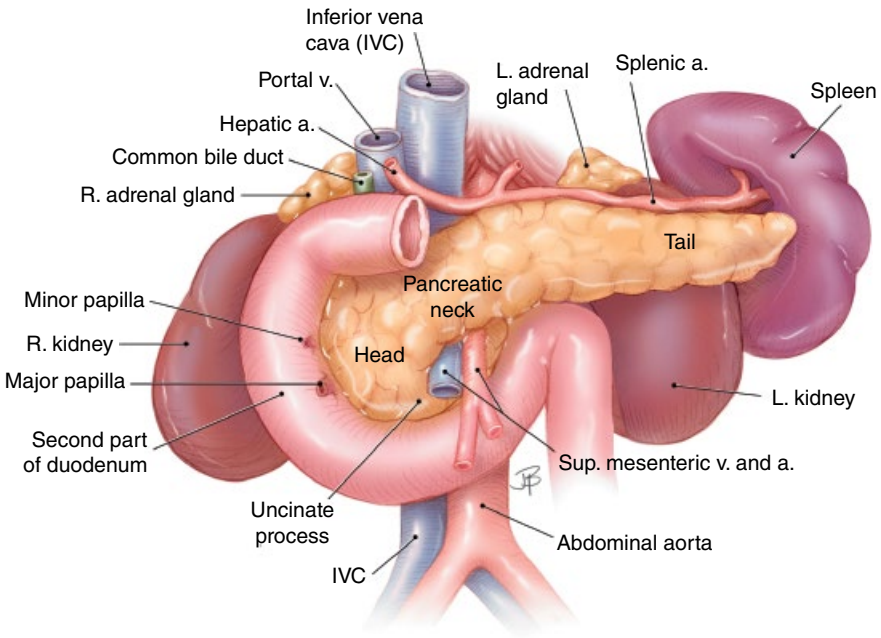

**Figure 2.3** Relationships of the pancreas to surrounding organs. This two-dimensional drawing depicts structures that lie in several different planes; for example, the kidneys lie lateral to the spine and posterior to the pancreas. The superior mesenteric artery and vein lie anterior to the aorta and inferior vena cava. *Source:* Drawing by Jennifer Parsons Brumbaugh, in Hruban RH, Pitman MB, Klimstra DS. Tumors of the pancreas. AFIP Atlas of Tumor Pathology, 4th series, fascicle 6. Washington, DC: American Registry of Pathology, 2007: Chapter 1. Reproduced with permission.

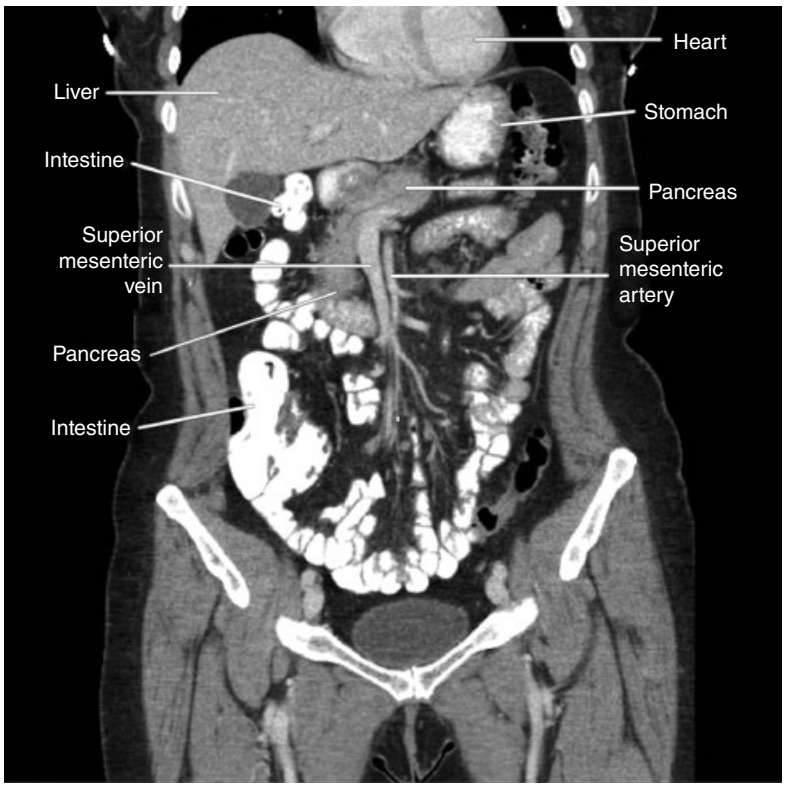

**Figure 2.4** Frontal CT scan in the plane of the head and body of the pancreas. The technology dictates that all structures shown lie in the same plane. The tail of the pancreas is not shown because it lies posterior to the depicted plane. *Source:* Image provided by Jason Ferreira.

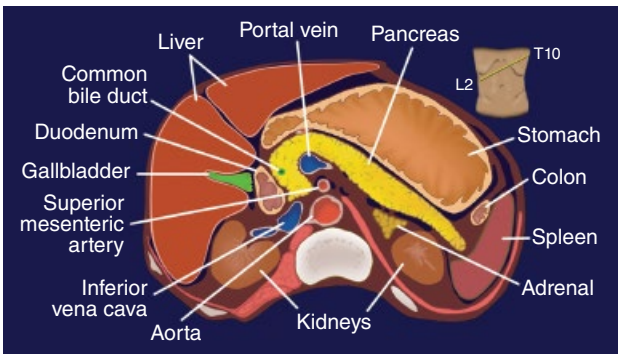

**Figure 2.5** Diagram of the upper abdomen at the level of the pancreas based on a CT scan. Note that the plane of the image is angled upward on the left as indicated, upper image right. The vertebral column is unlabeled bottom center. *Source:* Image contributed by Fred Gorelick.

ducts open separately into the duodenum at the major ampulla. The common channel has received much attention because stones in the biliary tract (gallstones) may lodge in the common channel, causing obstruction of both pancreatic and biliary duct systems. Such an obstruction is frequently the cause of acute pancreatitis.

The arterial blood supply to the pancreas is through branches of the celiac trunk and the superior mesenteric artery (Fig. 2.7). Both arise from the abdominal aorta and have multiple branches that supply several organs. Anastomosis of their branches provides collateral circulation that generally assures a secure arterial blood supply to the pancreas. Most of the arteries are accompanied by veins that drain into the superior mesenteric, portal, and splenic veins as they pass behind the pancreas, as shown in Fig. 2.7b. The superior mesenteric vein becomes the portal vein when it joins the splenic vein (Fig. 2.7b).

The typical locations of lymph nodes surrounding the pancreas are shown in Fig. 2.8. There is significant individual variation in the location of lymph nodes, so the locations shown are a generalization. In general, two systems of lymph nodes drain the organ: one surrounding the edges of the pancreas (Fig. 2.8a), and the other associated with the anterior surface of the aorta and celiac trunk (Fig. 2.8b). Various node groups have been assigned "station numbers" that may be used to designate their location [1,2,7]. These are rarely used in Western literature and are not illustrated here. Lymphatics arise in the interstitium of the pancreas and course with blood vessels and nerves draining to the nodes and then to the thoracic duct.

A rich plexus of autonomic nerves lies behind the head, neck, and body of the pancreas connecting to the celiac ganglia that lie along the aorta (Fig. 2.9).

## Histology and Ultrastructure

### Overview

The exocrine pancreas is a network of tubules composed of acinar and duct cells that synthesize, secrete, and carry digestive enzymes into the intestine. The small tubules in the lobular tissue are largely composed of acinar cells. The acinar tubules connect to the smallest terminal portions of the duct system that are commonly called ductules, although intercalated duct has also been used to denote these components of the duct system. In this chapter, we will use *ductule* to denote these small terminal portions of the duct system that link the acinar tubules to larger ducts, including small intralobular ducts. At the level of gross anatomy, the acinar tubules, ductules, and small ducts appear as solid lobular tissue as seen in Fig. 2.1c. The following descriptions include both histology and ultrastructure for each major cell type.

### Acinar Tissue

An acinus is a cluster of acinar cells that contain zymogen granules, the storage compartment for pancreatic digestive enzymes. For many years, it was considered that acinar tissue was composed of clusters of acini arranged like grapes at the ends of a branching duct system. However, more recent studies have demonstrated that pancreatic acini and tubules are arranged as an anastomosing tubular network [8]. The duct cells at the interface of acinar tubules and ductules are referred to as centroacinar cells and these cells may also be

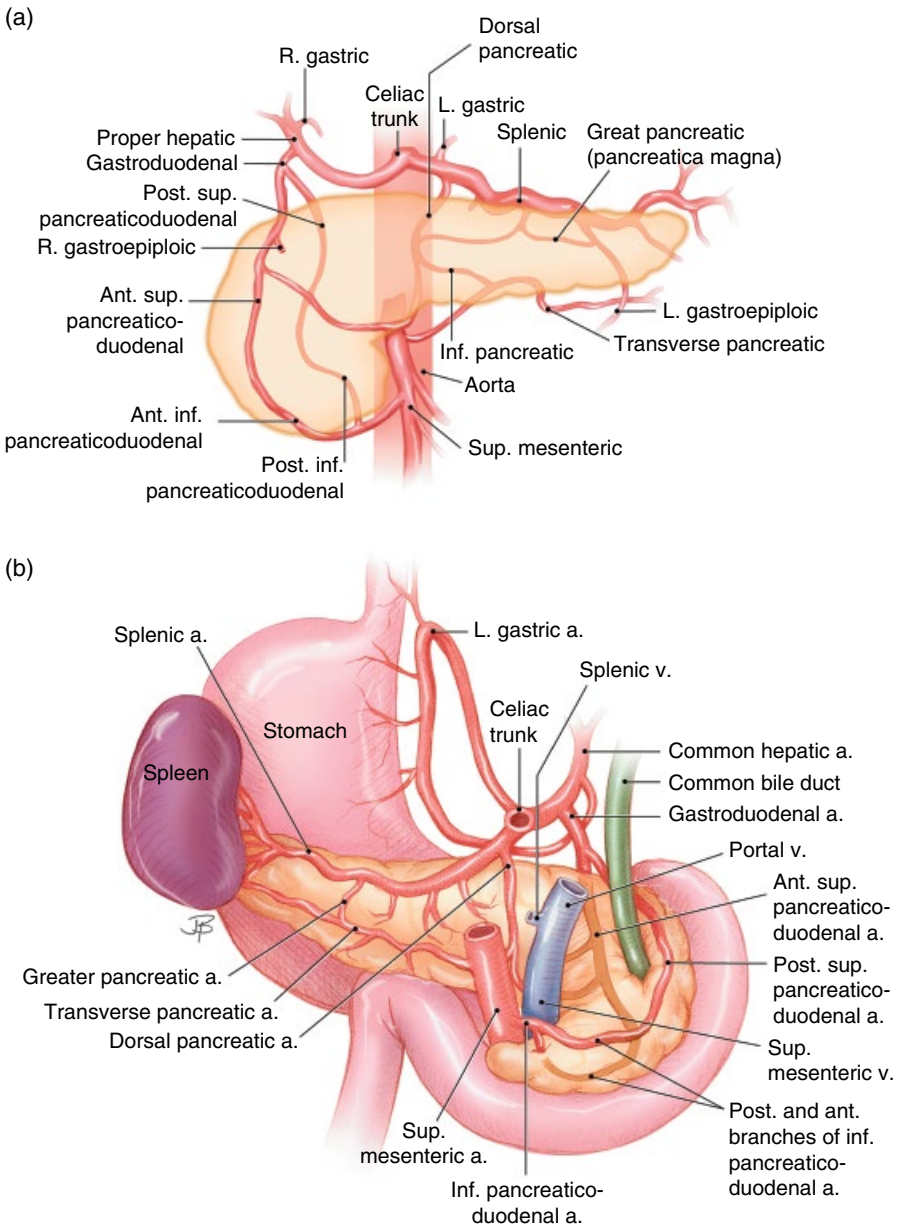

**Figure 2.7** The arterial blood supply of the pancreas. Image (a) is visualized from the front and (b) is seen from the back. *Source:* Drawing by Jennifer Parsons Brumbaugh, in Hruban RH, Pitman MB, Klimstra DS. Tumors of the pancreas. AFIP Atlas of Tumor Pathology, 4th series, fascicle 6. Washington, DC: American Registry of Pathology, 2007: Chapter 1. Reproduced with permission.

interspersed within acini. An acinus may occur as a culde-sac at the end of a tubular network and also as an intermediate structure with ductules on either side. Recognizing this pattern provides a basis for understanding the changes that the pancreas undergoes with the development of cancer and pancreatitis [9,10]. The tubular complexes that are observed as a result of these diseases are contributed to by the transition of acinar cells into ductular-like cells, a process sometimes referred to as acinar to ductal metaplasia [11].

At the histologic level in sections stained with hematoxylin and eosin (H&E), individual acinar cells have bluish cytoplasm in the basal (perinuclear) region, reflecting the high content of RNA (Fig. 2.10). Central to the nucleus, the cytoplasm is eosinophilic (pink), reflecting the higher content of protein in the Golgi and zymogen granules. Many acinar cells are binucleate [12,13]. Although the detailed histologic analysis of binucleation is based on the rat pancreas, the observation also appears to pertain for the humans but is of unknown significance.

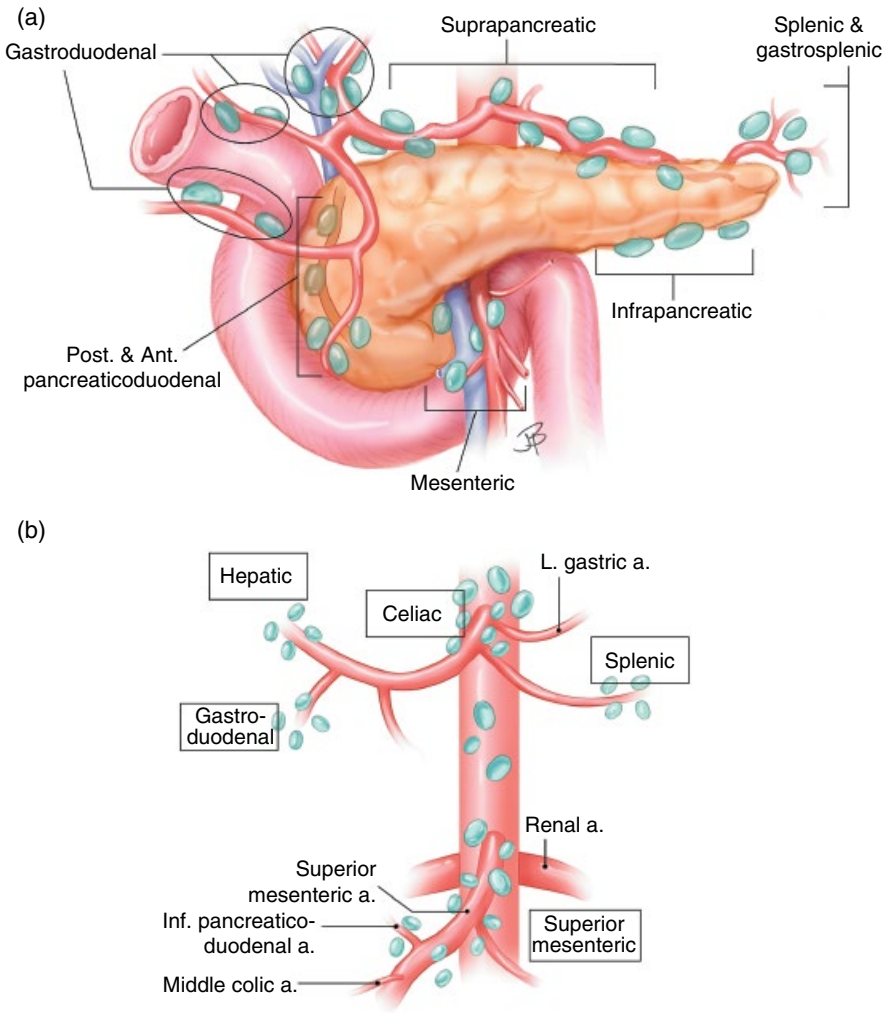

**Figure 2.8** Lymph nodes draining the pancreas. There is considerable individual variation in the location and size of lymph nodes, so this drawing is somewhat schematic. Both (a) and (b) are anterior views; (b) includes some nodes that lie posterior to the pancreas. *Source:* Drawing by Jennifer Parsons Brumbaugh, in Hruban RH, Pitman MB, Klimstra DS. Tumors of the pancreas. AFIP Atlas of Tumor Pathology, 4th series, fascicle 6. Washington, DC: American Registry of Pathology, 2007: Chapter 1. Reproduced with permission.

The acinar cell ultrastructure reflects cell function, that is, the synthesis and secretion of digestive enzymes, and it will be described in the context of this function. The basal cell membrane has an extracellular basement membrane that abuts the interstitial space where capillaries and nerve endings lie (Fig. 2.11). The lateral cell membranes are closely apposed to the cell membranes of adjacent acinar or centroacinar cells and these membranes are linked by linear tight junctions (Figs 2.12 and 2.13). The most distinctive feature of the luminal membrane is the formation of microvilli, which are narrow, finger-like extensions into the lumen (Fig. 2.13).

The basal and perinuclear cytoplasm of acinar cells contains abundant rough endoplasmic reticulum (RER) that forms flattened cisternae with a smooth luminal side, whereas the external surface is studded with ribosomes (giving rise to the "rough" designation). The RER is folded into stacks that generally lie in the plane of the adjacent cell membrane (Fig. 2.12).

Mitochondria are scattered throughout the cytoplasm of the acinar cells but their density is highest in the basal and central portion of the cell (Fig. 2.12). They are sparse in the cytoplasm adjacent to the luminal surface.

On the luminal side of the nucleus, small membrane-bound transport vesicles appear to bud from the RER and then to lie free in the cytoplasm. Central to this region are small stacks of flattened smooth-walled vesicles called the Golgi that appear to arise from the fusion of multiple transport vesicles. At the luminal side of the Golgi, the vesicles begin to round up and progressively to contain homogeneous densities. These are nascent

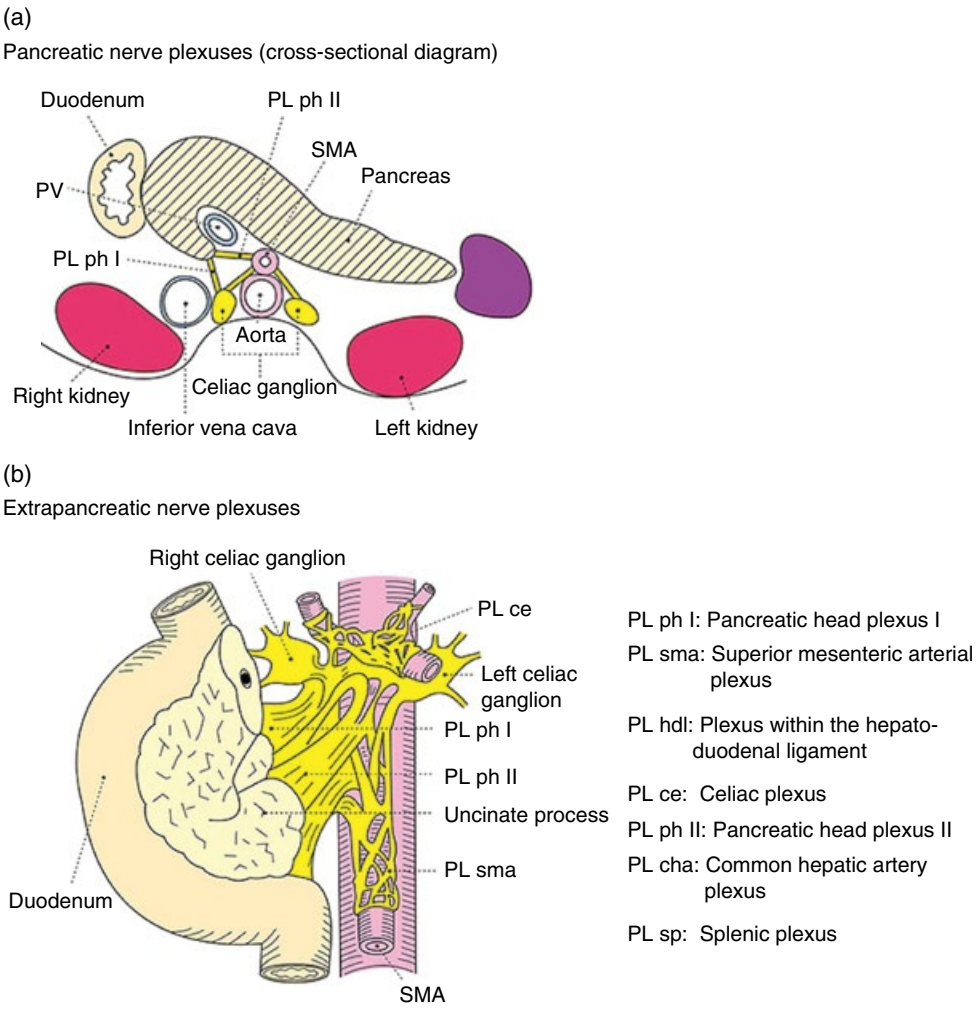

**Figure 2.9** Nerves (yellow) serving the pancreas. The cross-sectional image (a) emphasizes the location of the celiac ganglia of the autonomic system lateral to the aorta while (b) emphasizes the rich nerve plexus that connects these ganglia to the pancreas. SMA, superior mesenteric artery; PL, plexus. *Source:* Classification of Pancreatic Carcinoma, 2003 [7], Fig. 3a and 3b. Reproduced with permission of the Japan Pancreas Society.

zymogen granules (also termed immature zymogen granules or condensing vacuoles) and they progressively lose membrane as contents condense to become mature zymogen granules.

The apical cytoplasm near the acinar lumen is occupied by variable numbers of mature zymogen granules. These are usually spherical (appearing round in cross-section) with a single bilayer membrane surrounding homogeneous dense content (see Figs 2.12, 2.13, 2.18, and 2.22). Fusion of the membranes of zymogen granules and adjacent lumenal cell membrane is observed prior to secretion of the zymogen into the lumen. See Longnecker [1] for additional electron micrographs that illustrate acinar cell ultrastructure.

Acinar cell cytoplasm may contain fat or autophagic vacuoles (sometimes called residual bodies) that are walled-off areas of damaged cytoplasm (Fig. 2.12).

## Duct System

The components of the duct system are the main pancreatic duct (duct of Wirsung); its major branches, called interlobular ducts, that drain into the main duct throughout the pancreas as depicted in Fig. 2.2; smaller intralobular ducts; and ductules that link acinar tubules to the smallest intralobular ducts. The small intralobular ducts and ductules are ordinarily seen only at the level of light and electron microscopy. The accessory duct (duct of Santorini; Fig. 2.2) that connects the main duct to the duodenum at the minor papilla in some humans (Fig. 2.3) is of variable importance and is similar in structure to the main duct, although typically it is slightly smaller.

Enzymes from acinar cells are released into a bicarbonate-rich solution that is secreted by the centroacinar and ductal cells and flows from the acini and acinar

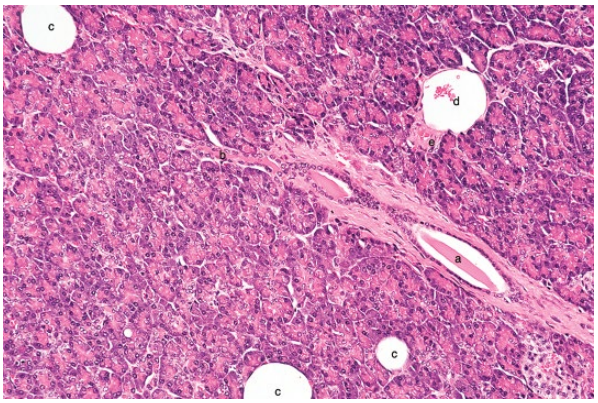

**Figure 2.10** Pancreatic lobular tissue with acinar cells, small duct, ductule, and small islet. This H&E-stained section is largely composed of acini and acinar tubules cut in cross-section or tangentially. A small intralobular duct (a) is shown image right and at its upper end it gives rise to a ductule (b) with virtually no connective tissue evident in its wall. Liquid content of the duct and ductule is homogeneous and pink (eosinophilic). Large, clear spaces are fat cells (c). A small vein (d) and artery (e) are at image right above center. A small islet is near the lower image right corner. *Source:* Hruban RH, Pitman MB, Klimstra DS. Tumors of the pancreas. AFIP Atlas of Tumor Pathology, 4th series, fascicle 6. Washington, DC: American Registry of Pathology, 2007. Reproduced with permission.

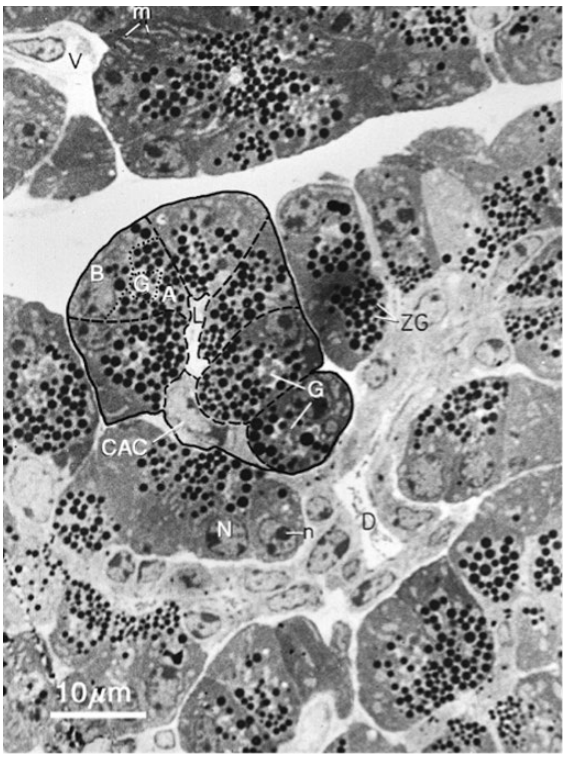

**Figure 2.11** Pancreatic tissue with acinar, centroacinar, and ductal cells. The acinar cells are easily identified because of the darkly stained zymogen granules (ZG) and are larger than centroacinar and ductal cells. The basal portion (B) of the acinar cells lies next to the interstitial space that contains vessels (V), nerves, and connective tissue. Nuclei (N) with nucleoli (n) are in the basal portion of the acinar cells. The golgi (G) lies at the junction of the basal and apical (A) portions of the cell. Centroacinar cells (CAC) have pale cytoplasm with no secretory granules. A small ductule (D) extends from image right to below center. Mitochondria (m) are identified at the top of the field. This is a 1 µm thick section of plastic embedded tissue prepared for electron microscopy that was stained with toluidine blue. *Source:* Micrograph contributed by James Jamieson.

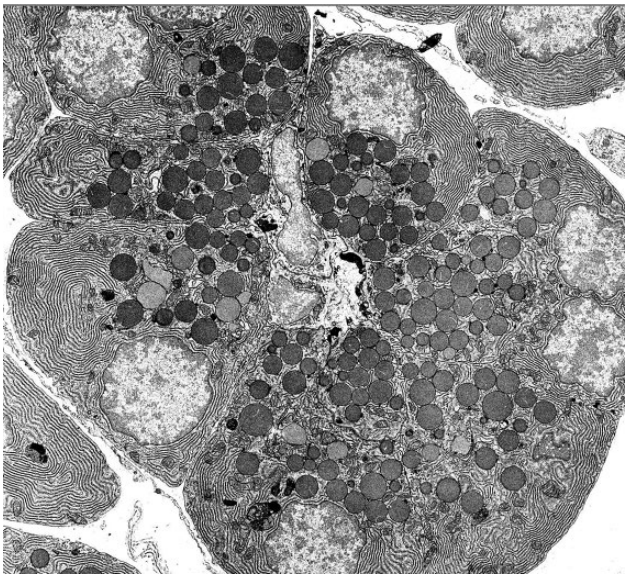

**Figure 2.12** Acinar cells with RER, mature, and immature zymogen granules. Two centroacinar cells are near the center. The acinar cell at 3 o'clock, image right, is binucleate. Numerous mitochondria are present in the acinar cells and lower centroacinar cell. There are several electron-dense residual bodies in the acinar cells. It appears that two have been extruded into the interstitial space at the top of the image and others are being extruded into the acinar lumen near the center of the image. *Source:* Micrograph contributed by James Jamieson.

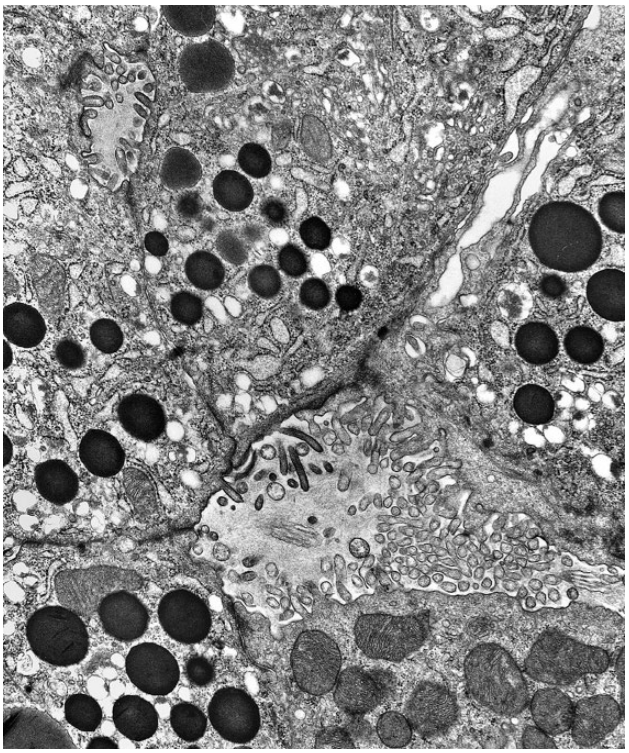

**Figure 2.13** Apical portions of several acinar cells border two luminal spaces, lower image right and upper image left. A centroacinar cell with numerous mitochondria borders the lumen, lower image right. Microvilli protrude into the lumens from the luminal aspect of the acinar and centroacinar cells. Zymogen granules are prominent in all acinar cells. *Source:* Micrograph contributed by James Jamieson.

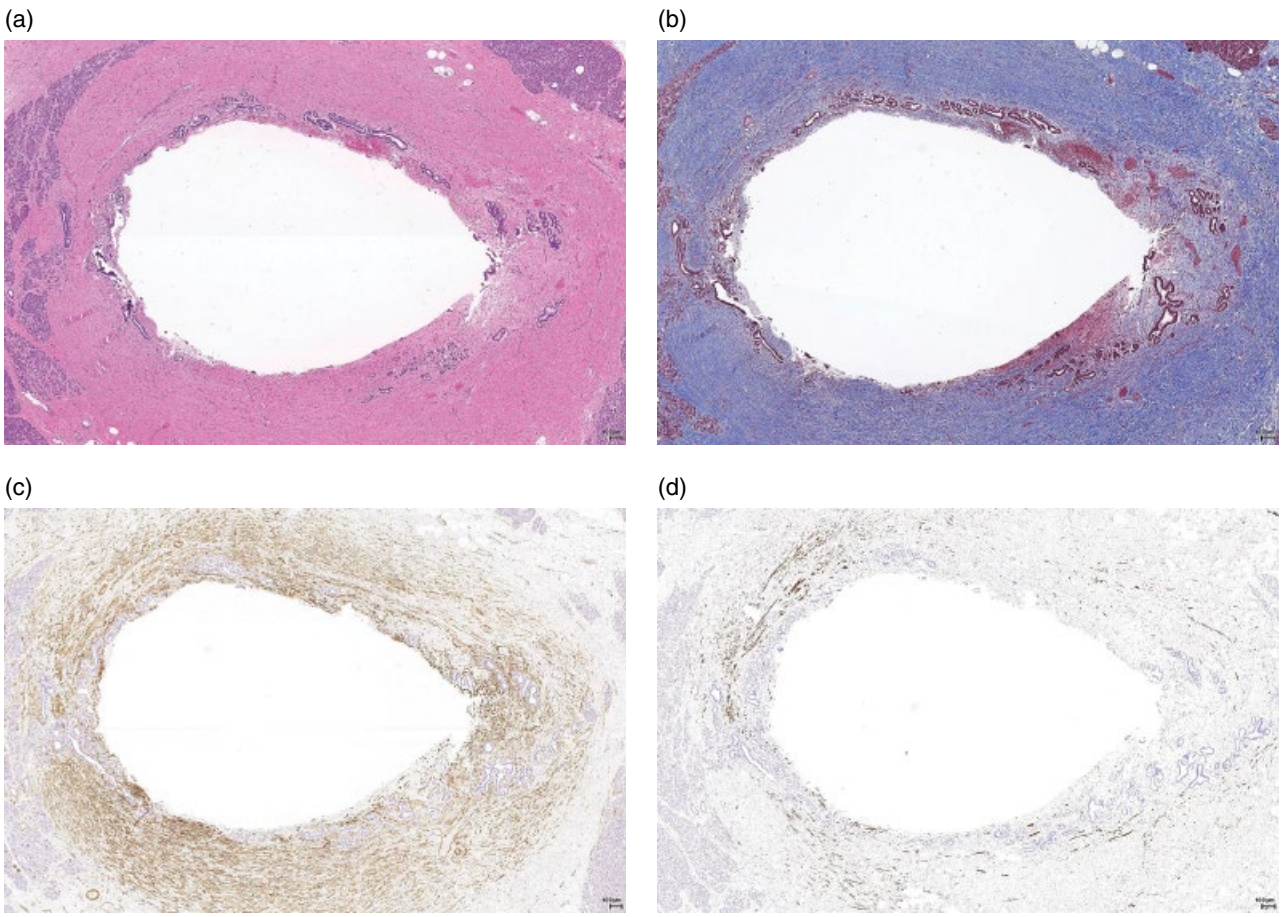

**Figure 2.14** Serial cross-sections of main pancreatic duct (a) (H&E stain) stained to demonstrate collagen (b) (trichrome stain), myofibroblasts (c) (immunoperoxidase stain to demonstrate smooth muscle actin, a marker for myofibroblasts), and smooth muscle (d) (immunoperoxidase stain to demonstrate desmin, a marker for smooth muscle). The lining epithelium has been lost, probably reflecting preoperative ERCP and stenting of the pancreatic duct. The patient underwent a Whipple procedure because of chronic pancreatitis. There are many myofibroblasts and fewer smooth muscle cells in the wall of the main duct. *Source:* Micrographs contributed by Arief A. Suriawinata.

tubules into the ductules that join to form the intralobular ducts, then into the interlobular ducts and main duct, and finally into the duodenum at the major or minor papillae. Ducts are illustrated in Figs 2.10, 2.11, 2.14, 2.15, and 2.16.

The integrity of the duct system is of key importance in preventing entry of the exocrine enzymes into the interstitial space, where they may be activated and cause tissue damage manifested as pancreatitis. As ductules anastomose to form intralobular ducts, the duct walls begin to develop a connective tissue wall (Fig. 2.10) that becomes progressively thicker as the smaller ducts join to form larger ducts and the main pancreatic duct. The main and interlobular ducts have thick, dense, collagenous walls that contain myofibroblasts and smooth muscle cells (Fig. 2.14). The connective tissue component of the duct wall becomes progressively thinner and contains fewer myofibroblasts and smooth muscle cells as the ducts branch and become narrower in the lobules (Fig. 2.15). The smallest intralobular ducts lack smooth muscle cells. Intercellular tight junctions, also called zonula occludens, between duct cells, centroacinar cells, and acinar cells play a major role in preventing leakage of the duct system. Kern provided excellent images and discussion of these tight junctions [14].

The lumen of the duct system is normally lined by a single layer of cuboidal epithelial cells that have a single nucleus and a smaller amount of cytoplasm than acinar cells (Figs 2.10, 2.15, and 2.16). The cytoplasm is pale pink and homogeneous in H&E-stained sections. The duct lumen may contain homogeneous material reflecting the protein content of the secretions (Figs 2.10 and 2.16). Sometimes epithelial cells may be shed into the lumen.

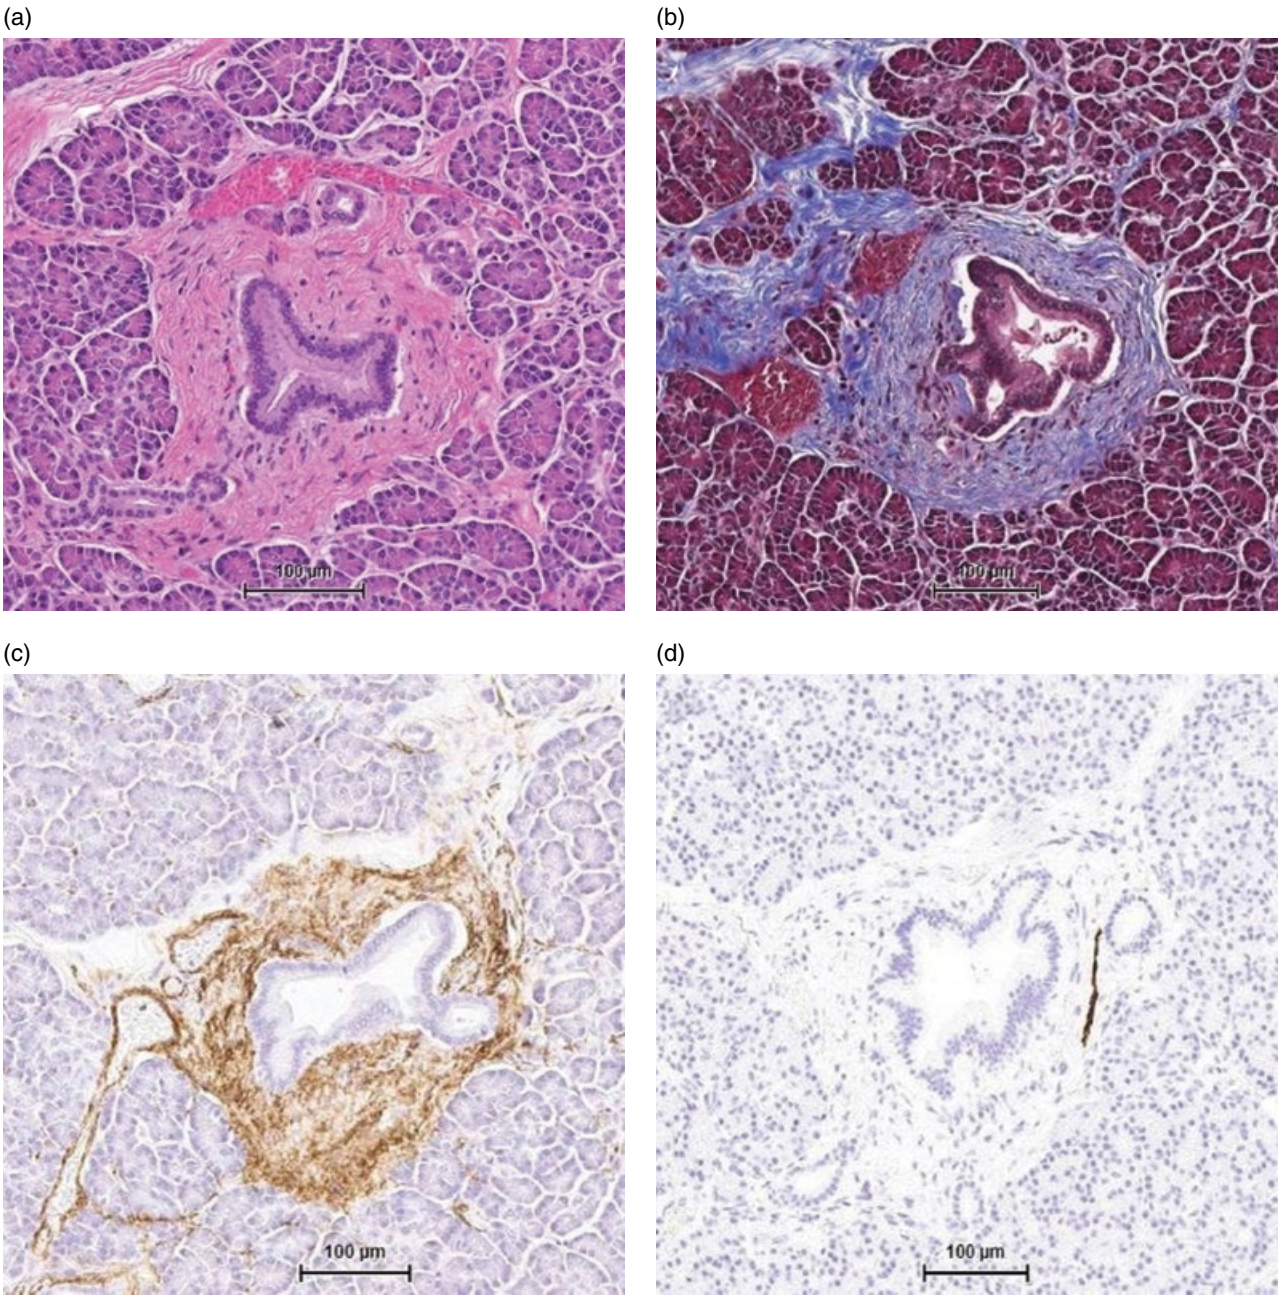

**Figure 2.15** Serial cross-sections of a small intralobubular duct surrounded by acinar tissue from the same patient as in Fig. 2.14. (a) H&E stain. Note the origin of a ductule branching into acinar tissue at 7 o'clock. (b) Trichrome stain with blue-staining collagen. There is fibrosis around acinar lobules (upper image left). (c) Immunoperoxidase stain with antibody to smooth muscle actin (SMA) to demonstrate the abundant myofibroblasts. (d) Immunoperoxidase stain with antibody to desmin to demonstrate smooth muscle cells. There is little staining. *Source:* Micrographs contributed by Arief A. Suriawinata.

Ductal epithelium may undergo squamous metaplasia or mucinous metaplasia. In the latter process, the ducts are lined by tall columnar cells with abundant pale apical cytoplasm that contains mucin. This type of change is characteristic of low-grade PanIN lesions.

At the ultrastructural level, duct cells have a simple structure compared with acinar cells. RER is sparse but mitochondria are numerous, and there are no secretory granules. The luminal surface gives rise to numerous microvilli, similar in appearance to those arising from

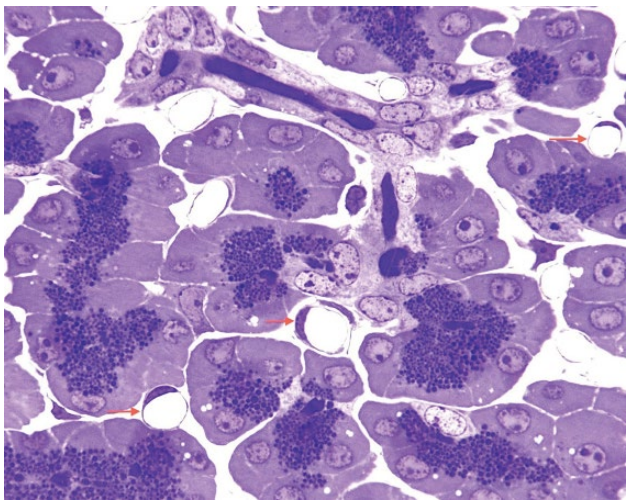

**Figure 2.16** Pancreas ductule (top center) branches (upper image right) to reach several acini or acinar tubules (upper image right and near the center). Blue zymogen granules are conspicuous in the acinar cells and the liquid content of the ductule is also dark blue. Ductal and centroacinar cells have pale cytoplasm. The presence of numerous round empty capillaries (arrows) in the interstitial spaces indicates that the pancreas was perfused with fixative. Toluidine blue stain, 1 μm thick plastic embedded tissue. *Source:* Micrograph contributed by James Jamieson.

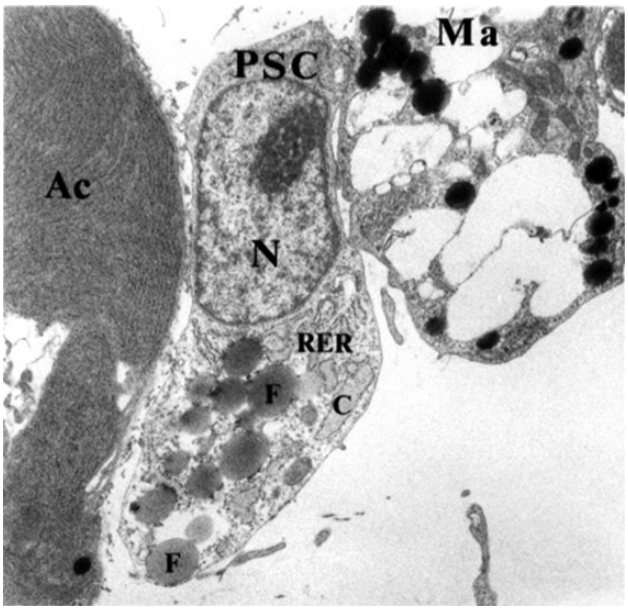

**Figure 2.17** Pancreatic stellate cell (PSC) from a patient with acute pancreatitis. The PSC is near a macrophage (Ma), image right, and an acinar cell (Ac), image left. Fat droplets (F) and RER are conspicuous in the PSC cytoplasm below the nucleus (N). Original magnification 6000×. *Source:* Bachem et al. 1998 [16].

acinar cells (Fig. 2.13). Ductal cells have single cilia, although they are difficult to detect without special tissue preparation and labeling [15].

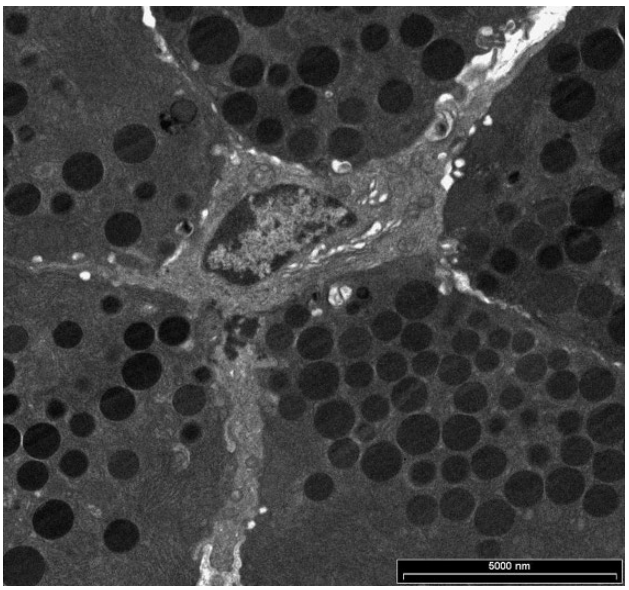

**Figure 2.18** A pancreatic stellate cell (PSC) *in situ* is surrounded by multiple acinar cells containing zymogen granules. Extensions of PSC cytoplasm between acinar cells are conspicuous, upper image right and lower image left. The dark, irregular cytoplasmic inclusions at the origin of the latter interstitial extension may represent lipid droplets—a characteristic of PSC. *Source:* Contributed by the Pancreatic Research Group, UNSW, Australia, with special thanks to Dr Murray Killingsworth.

### Interstitial Tissue

The interstitium contains capillaries, arteries, veins, lymphatics, nerve fibers, fat cells, and stellate cells. The stellate cells are undifferentiated connective tissue cells with characteristic structure (Figs 2.17 and 2.18) that are activated by inflammation to form fibroblasts and contribute to fibrosis associated with chronic pancreatitis and some neoplasms [16] (see Chapter 10).

## Endocrine Pancreas

The pancreatic islets (islets of Langerhans) collectively comprise the endocrine pancreas that synthesizes and secretes insulin, glucagon, pancreatic polypeptide, and somatostatin. Most islets are too small to be seen by gross examination, hence they were not depicted in Figs 2.1 to 2.7. Islets vary greatly in size and ~70% are in the size range 50–250 μm in diameter in humans, with an average in the range 100–150 μm [17]. Small islets are dispersed throughout the acinar lobules (Fig. 2.19) and most larger islets lie along the main and interlobular ducts of the pancreas. Most islets are spherical or ellipsoid, but they can be irregular in shape—sometimes reflecting the presence of an adjacent structure, often a

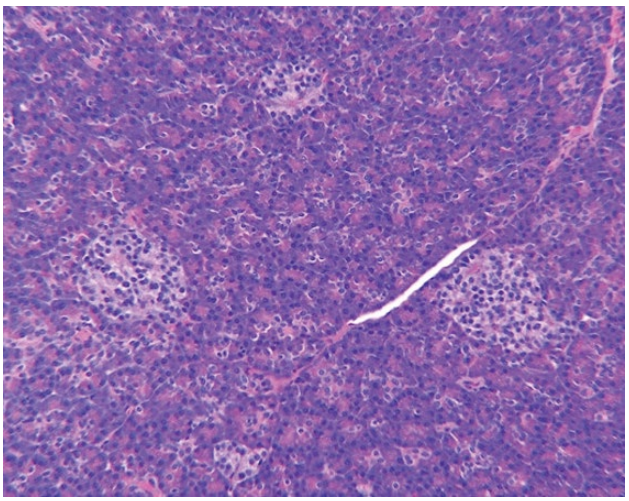

**Figure 2.19** Pancreatic lobules with acinar cells and four islets at 12, 3, 6–7, and 9 o'clock. The islets are paler than the surrounding acinar tissue. The upper and lower islets are small and the lateral islets are medium size. H&E stain.

duct, or limitation by a tissue plane. Several reports provide support for the presence of a higher population density of islets in the tail of the pancreas than in the head and body [5,18], although another study found no difference [19]. In adult humans, the number of islets is estimated to be $5 \times 10^5$–$10^6$ [20], whereas there are far fewer in smaller animals [21]. Islets comprise 1–2% of the pancreas in adults of most mammalian species. In addition to the islets, isolated islet cells may be found dispersed in the acinar lobules or in association with ducts.

Several of the images of islets are from sections that have been immunostained using antibodies to specific islet peptide hormones to demonstrate various islet cell types, including β cells (insulin), α cells (glucagon), δ cells (somatostatin) (Fig. 2.20), and pancreatic polypeptide (PP) (Fig. 2.21). In the portion of the pancreas derived from the dorsal pancreatic anlage, the majority of islet cells are β cells (75–80%), followed by α cells (about 15%), δ cells (about 5%), and very few PP cells. Most PP cells are in the portion of the pancreas derived from

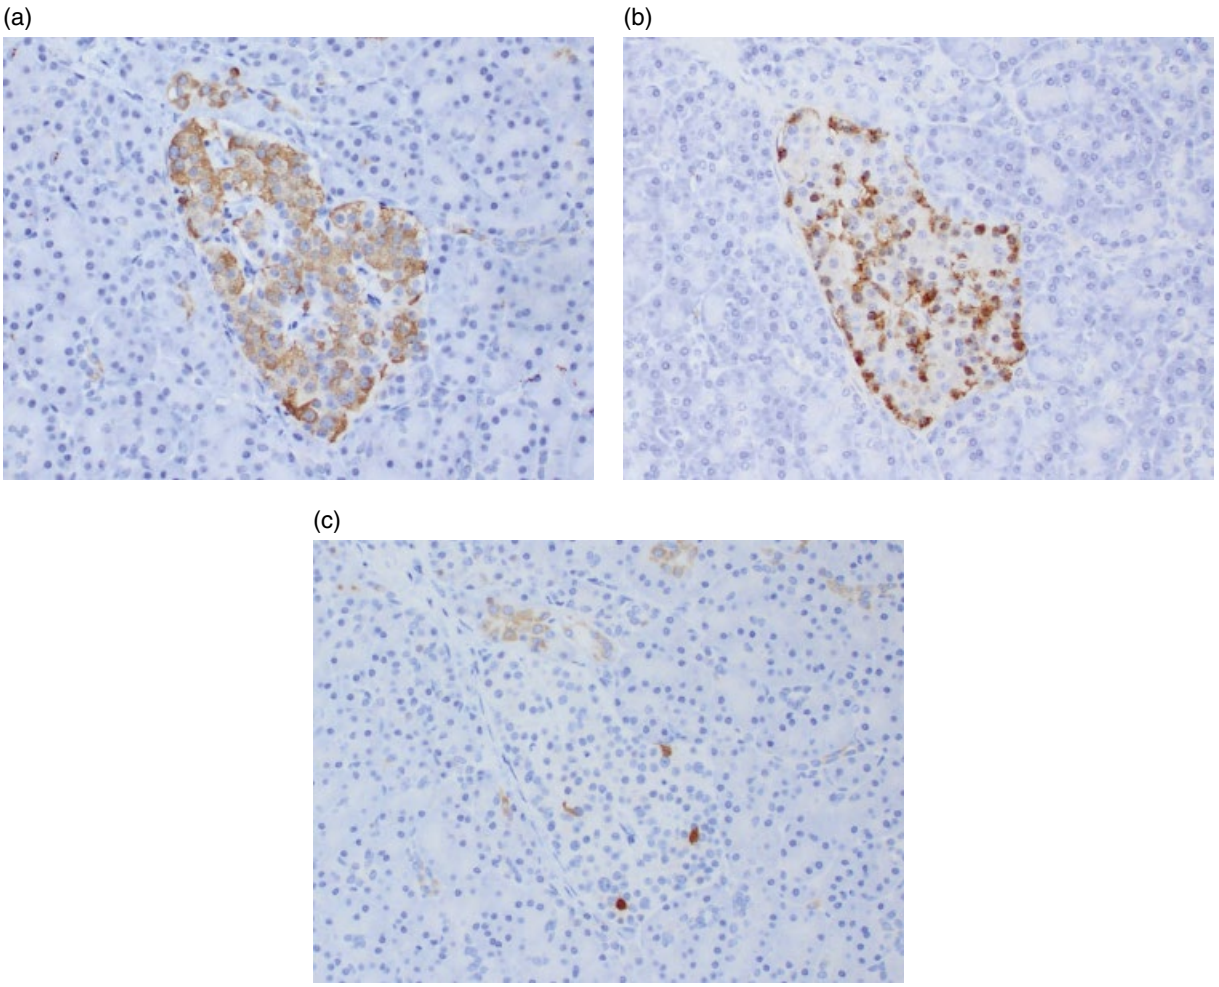

**Figure 2.20** Serial sections of a human islet immunostained using antibodies to insulin (a), glucagon (b), and somatostatin (c). The presence of the hormones is indicated by brown staining. The predominance of insulin secreting β cells is obvious. In (b) and (c), the location of α cells and δ cells is primarily at the border of groups of β cells. *Source:* Photos provided by Arief A. Suriawinata.

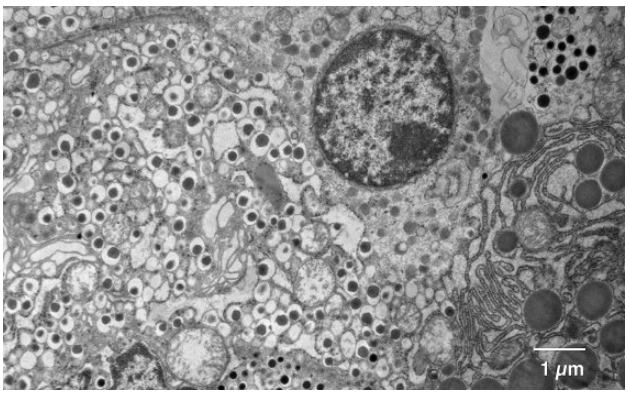

**Figure 2.22** Mouse islet with β-cell cytoplasm containing insulin granules (image left), a δ cell with nucleus and less dense secretory granules (right of center), and α-cell cytoplasm with glucagon granules (upper image right corner) and at the bottom margin near the center. In murine species, β-cell granules have a wide halo surrounding the dense core. Acinar cell cytoplasm with zymogen granules, RER, and mitochondria is present (lower image right). *Source:* Micrograph contributed by Fred Gorelick.

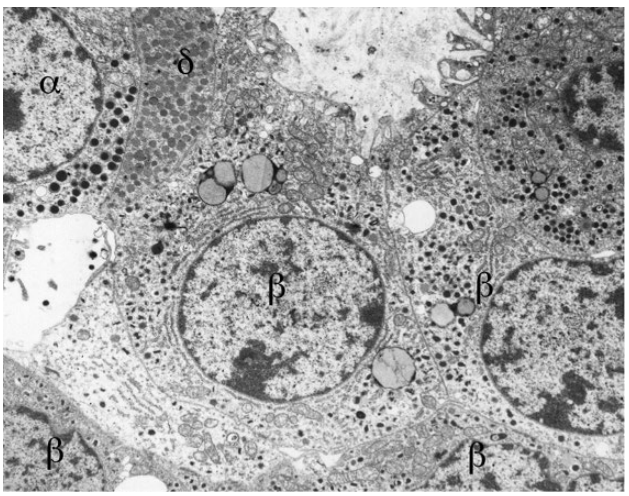

**Figure 2.23** Human islet from transplant isolation with α, β, and δ cells labeled. The α-cell granules are typically slightly larger than β-cell granules; δ-cell granules are typically less densely stained than the granules in α and β cells. The cytoplasm of several islet cells contains lipid—most notably in the central β cell where lipid bodies lie at 4 and 11–12 o'clock around the nucleus. *Source:* Micrograph contributed by Susan Bonner-Weir.

the ventral pancreatic anlage, namely the uncinate process, that is reported to comprise about 10% of the pancreas [22,23]. In the uncinate process, islets contain few α cells and many more PP cells. Stefan et al. presented data from a study of 13 nondiabetic human pancreases, showing that the PP cells comprise 54.3–93.7% of the volume of islets in the uncinate region, displacing most α cells and some β cells [23]. They provided data that indicated that PP cells were the second most prevalent endocrine cell type overall in the pancreases of their 13 subjects.

At the ultrastructural level, islet cells contain numerous mitochondria, a modest amount of RER, and small secretory granules (islet hormones). The granules vary in size and density with cell type and hormone and show some variation between species (Figs 2.22 and 2.23).

Capillaries in the islets connect with capillaries serving the adjacent acinar cells before draining into veins. These proximal acinar cells are exposed to higher concentrations of islet hormones than the majority acinar cells that are more distant from islets. The proximal acinar cells sometimes are larger and contain more zymogen than more distant acinar cells, and they form a halo around the islets. This unique feature of islet–acinar blood supply has been referred to as an insulo-acinar portal system [24].

## Acknowledgments

The authors thank Dale Bockman for reviewing the section that reflects his work on microanatomy of the acinar lobules. Figures 2.2, 2.3, 2.7, 2.8, 2.9, 2.11, 2.16, 2.20, and 2.23 have been published previously online in a Pancreapedia chapter on anatomy and histology of the pancreas [1]. The authors thank the contributors of many of the images as listed in the captions.

## Introduction

The development of the pancreas from dorsal and ventral buds, which physiologically fuse to form one organ and a common ductal system, explains a number of developmental disorders that can lead to anatomic abnormalities of either the pancreas or its ducts. Most anomalies of the pancreas are discovered incidentally either at endoscopy, during diagnostic imaging, particularly magnetic resonance cholangiopancreatography (MRCP), or at autopsy. Some of them may cause clinically relevant problems. Clinical symptoms are related either to damage caused by proteolytic processes or inflammation (pancreatitis), displacement or compression of neighboring organs, or to an abnormal (mostly decreased) quantity of secretory and incretory products. However, owing to the high functional reserve of both the endocrine and the exocrine parts of the pancreas, deficiencies in hormone or zymogen production do usually not become clinically apparent until more than 90% of the respective cells have lost their function. Pancreatic anomalies and functional defects can also be part of complex disorders that affect multiple organ systems or of metabolic abnormalities that cause abnormal development of the pancreas as part of a multiorgan process, or that merely increase the lifetime risk for developing pancreatitis or pancreatic diabetes. This chapter reviews some of the congenital developmental and inherited disorders that can affect the endocrine and exocrine pancreas.

## Primary Malformations

### Pancreatic Agenesis and Hypoplasia

Primary agenesis of the pancreas represents a very rare disorder of pancreatic development. Its exact incidence is not known. Complete absence of the pancreas not only manifests postnatally with diabetes mellitus and malabsorption, it is also consistently associated with intrauterine growth retardation, which appears to relate to the fact that insulin is a major intrauterine growth factor. In most cases, the condition is rapidly fatal [1]. Pancreatic agenesis may occur as a monogenic condition (OMIM 260370). Mutations in the gene for insulin promoter factor-1 *IPF1* (also known as *PDX1*) and mutations in a distal enhancer of the *PTF1A* gene have been found in families with autosomal recessive inheritance of isolated pancreatic agenesis [2,3]. *PTF1A* encodes pancreas transcription factor 1α, which is known to play a pivotal role in mammalian pancreatic development [4]. Recessive mutations of *PTF1A* itself are responsible for a syndromic disorder comprising pancreatic and cerebellar agenesis (OMIM 609069) [5]. The association of congenital heart defects with variable pancreatic defects ranging from agenesis to hypoplasia has been found to be caused by dominant mutations of the *GATA6* gene (OMIM 600001) [6]. All of these human genetic disorders are extremely rare. In mice, a lack of *TCF2*/*vHNF1* also leads to pancreas agenesis [7,8].

In contrast to complete agenesis, pancreas hypoplasia or partial agenesis is unlikely to be symptomatic because

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

of the high functional reserves of both the endocrine and the exocrine pancreas. Partial agenesis of the pancreas mostly affects the dorsal part (also known as congenitally short pancreas), probably reflecting the fact that dorsal pancreas formation relies on different genes and signaling events from those of the ventral pancreas [9]. With this entity, only a pancreatic head is seen on imaging techniques and the body and tail of the organ are missing. Agenesis of the dorsal pancreas has been found to be associated with diabetes and pancreatitis [10,11]. The short pancreas can occur as solitary finding or in association with polysplenia syndrome [12]. Since most of the islet cells are located in the missing distal pancreas, patients with this anomaly have an increased risk of diabetes mellitus [13]. Magnetic resonance imaging (MRI) can assist in establishing the diagnosis.

## Annular Pancreas

Annular pancreas means the complete encirclement of the second part of the duodenum by a ring-like band of pancreatic tissue that may lead to partial or complete duodenal obstruction. Annular pancreas has an estimated incidence of one in 20,000 and is found in 8–21% of patients with neonatal duodenal obstruction. The exact pathogenesis of annular pancreas is not known. Several hypotheses have been proposed to account for annular pancreas, including gut rotation defects, increased outgrowth of both the dorsal and ventral pancreas, persistence of the left ventral bud, or a combination of these events.

Annular pancreas is often associated with other congenital anomalies, including intestinal atresias, malrotation, tracheoesophageal fistula, heart defects, and others. A considerable number of affected individuals have chromosomal disorders, particularly Down syndrome (11–16%) [14,15]. This suggests that annular pancreas represents an early embryologic malformation. Agenesis of the dorsal pancreatic anlage [16] (congenital short pancreas) may also be associated with annular pancreas.

Although most cases of annular pancreas are sporadic, there have been some instances of familial recurrence with different patterns of transmission [17,18], suggesting that this anomaly may also be caused by a monogenic defect. One such disorder associated with annular and/or hypoplastic pancreas is Mitchell–Riley syndrome (OMIM 615710), which includes severe neonatal diabetes, intestinal malrotation, and gallbladder agenesis, among other characteristics. Recessive mutations in the *RFX6* gene, encoding a transcription factor that directs islet cell differentiation, have recently been reported to cause Mitchell–Riley syndrome [19].

Another syndrome involving annular pancreas formation is associated with mutations in the *FOXF1* gene, which are otherwise associated with severe vascular abnormalities of the lungs (OMIM 265380) [20,21].

In mice, homozygous inactivation of Indian hedgehog (*Ihh*) results in 42% annular pancreas, and inactivation of sonic hedgehog (*Shh*) may also lead to annular pancreas in certain genetic backgrounds [22,23]. In addition to the hedgehog pathway, tetraspanin (Tm4sf3) appears to have a fundamental regulatory role in pancreatic development. Experimental deletion of tetraspanin promotes a phenotype similar to pancreas divisum (see later), whereas its overexpression induced the formation of an annular pancreas [24].

Annular pancreas may present at any age, but roughly half of the patients are symptomatic during the first year of life with duodenal obstruction [14]. The earliest presentation may be prenatal with polyhydramnios and may be confirmed by fetal ultrasonography. In infants, the diagnosis is often made by abdominal ultrasound or a "double bubble" sign on plain abdominal radiography in an upright position; owing to post-duodenal obstruction, not only the stomach but also the upper duodenum is filled with gas—hence the double bubble on plain X-ray film. Patients in whom annular pancreas becomes symptomatic later in life may suffer from recurrent vomiting, chronic gastric distension, pain resulting from mild pancreatitis, or peptic ulcers [25–27]. Upper gastrointestinal studies or even contrast-enhanced computed tomography (CT) or MRI, which allows direct visualization of the ring, may help with the diagnosis. Patients are sometimes diagnosed by endoscopic retrograde cholangiopancreatography (ERCP) (Fig. 3.1), albeit this invasive technique is now rarely used for diagnostic purposes. The differential diagnosis of duodenal obstruction should include duodenal atresia and intestinal volvulus.

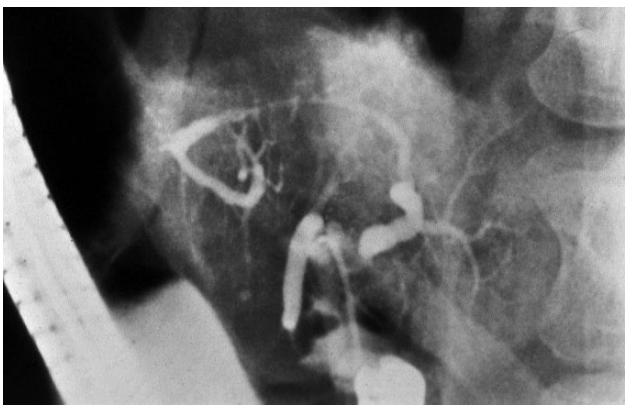

**Figure 3.1** ERCP of pancreas annulare in an adult. Note the ring-shaped pancreatic duct encircling the duodenum.

Surgical management of symptomatic annular pancreas is performed by duodenoduodenostomy as a bypass operation with an excellent long-term prognosis [14]. Resection of the ring is not recommended because of the risk of pancreatic peritonitis, postoperative pancreatitis, fistulae, and late fibrosis.

## Pancreas Divisum

In pancreas divisum, there is absent or incomplete fusion between the dorsal duct of Santorini and the ventral duct of Wirsung [13], resulting in the majority of the gland draining via the smaller duct of Santorini into the minor papilla. The pancreatic head and the processus uncinatus with less tissue mass and secretory load then drain via the duct of Wirsung through the larger papilla of Vater. Multiple variants of the divisum have been described anatomically or on the basis of ERCP findings [28]. Pancreas divisum is the most common anatomic variant of the pancreas [13]. Its estimated incidence varies from approximately 4–14% in autopsy series to 2–7% in ERCP studies and with a reported 9.6% in a population-based secretin-stimulated MRCP study [29]. Diagnosis of pancreas divisum relies on ERCP or MRCP to visualize the duct of Santorini draining the pancreas (Fig. 3.2).

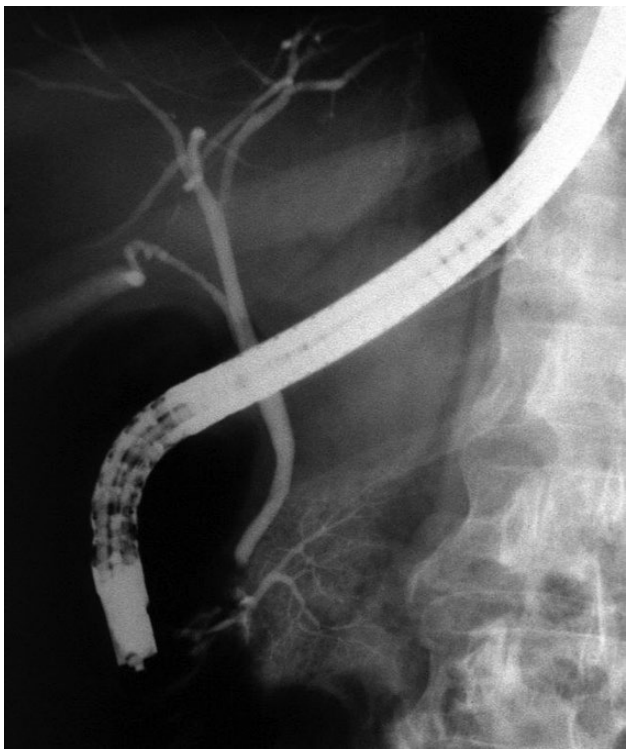

**Figure 3.2** Pancreas divisum on ERCP. Whereas the intra- and extrahepatic bile ducts are of regular size and proportions, the pancreatic duct is short and tender (already overfilled with contrast medium) and supplies only the head of the pancreas.

It has been suggested that the small accessory duct may lead to functional obstruction and a propensity to pancreatitis, but a causal relationship remains controversial. Since the prevalence of a pancreas divisum is identical in the healthy control population and patients with chronic pancreatitis, it is no longer regarded as a risk factor for pancreatitis [30]. Recent evidence even suggests that the prevalence of *SPINK1* and *CFTR* mutations, which are frequently associated with idiopathic pancreatitis, are just as common among chronic pancreatitis with pancreas divisum as without pancreas divisum [31]. This suggests that chronic pancreatitis with pancreas divisum is essentially idiopathic pancreatitis with the same genetic risk factors, of which mutations in the *CFTR* gene are the most conspicuous [31–33]. Although drainage is usually satisfactory, it can, in patients with chronic pancreatitis, add to the problem of impaired ductal flow. In these circumstances, the question arises of whether endoscopic sphincterotomy and stent insertion at the minor papilla are of benefit for the patient or can affect the natural history of chronic pancreatitis [34–36].

## Ectopic Pancreas

Ectopic pancreatic tissue is an aberrant focus of normally developed pancreatic tissue that lacks anatomic and vascular continuity with the main organ and can be found in various locations. Autopsy studies suggest that ectopic pancreatic tissue is fairly common (prevalence from 1% to over 13%), but its clinical manifestation is very rare [37]. Most ectopic pancreatic tissue is discovered endoscopically in the stomach (particularly antrum), duodenum (Fig. 3.3), jejunum, or a Meckel diverticulum. Ectopic pancreatic tissue is mostly located in the submucosa but in some instances it can be found in the muscularis or serosa. Other locations include the ileum, liver, spleen, biliary tract, mesentery, or umbilicus [13].

The exact mechanisms leading to ectopic formation of pancreatic tissue have remained elusive. A key regulator for the appropriate localization of pancreatic stem cells in the forgut appears to be Hes-1 [38]. Ectopic pancreatic tissue has been observed in knockout mice for the homeobox gene *cdx2*. Inhibition of *Shh* signaling also leads to ectopic pancreas in chickens [39].

Although ectopic pancreatic tissue can undergo similar changes to the orthotopic pancreas, particularly cystic degeneration, ectopic pancreatitis [40], and even pancreatic cancer formation [41], in most cases ectopic pancreas remains asymptomatic. In many cases it is an incidental finding during surgery or endoscopy for another indication. If patients with ectopic pancreatic tissue become symptomatic, this may be due to the mass effect, which can cause either obstruction of the intestinal passage (mainly in the prepyloric localization) [42] or

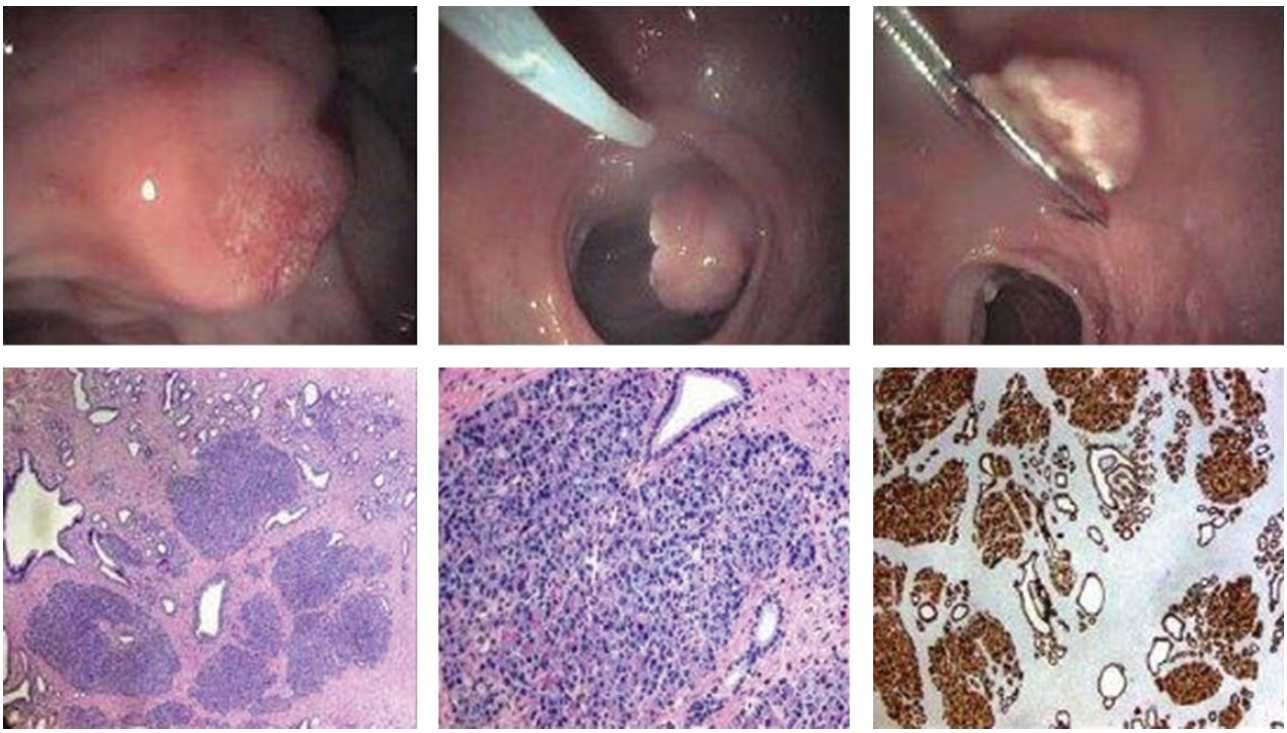

**Figure 3.3** Ectopic pancreas 4 cm distant from the duodenal papilla under endoscopic vision and during endoscopic snare dissection (top images) and histologically (bottom panels, at bottom right cytokeratin staining). Note the complete absence of endocrine cells on histology, which corresponds to a type II ectopic pancreas according to Heinrich (1909), that is, composed only of exocrine cells. *Source:* Histology courtesy of M. Androshchuk and G. Lorenz, Greifswald.

bowel intussusception, gastrointestinal hemorrhage secondary to mucosal ulcerations close to the pancreatic tissue [43], pain secondary to pancreatitis [40], and exceptional malignant transformation [41,44].

Diagnosis is made endoscopically or radiographically in antral localization. In other localizations, diagnosis is made at the time of surgery. The definite diagnosis relies on histology. Treatment of symptomatic ectopic pancreas is either surgical or endoscopic.

## Ductal Anomalies

Variability in the development of the dorsal and ventral ductal systems can give rise to a number of anatomic variations. Most of them are incidental findings at endoscopy/ERCP or by MRI/MRCP during systematic studies [29]. Ductal abnormalities that have been implicated in the pathogenesis of clinical disease include fusion failure of the dorsal and ventral ductal systems, which results in a ductal pattern known as pancreas divisum (see earlier), and the pattern of the junction with the common bile duct known as "common channel syndrome."

Common channel syndrome (pancreaticobiliary maljunction) results from an abnormally long common pancreatobiliary channel due to a junction of the ventral pancreatic duct with the common bile duct outside the duodenum wall [45]. This may permit the reflux of pancreatic enzymes into the common bile duct. Pancreaticobiliary reflux has been confirmed by dynamic MRCP after secretin stimulation [46] but does not appear to play a role in pancreatitis associated with gallstone disease [47]. Reflux of pancreatic juice into the bile duct may result in bile duct cyst formation. Reflux of bile into the pancreas, on the other hand, is much less likely to occur since pancreatic secretory pressure exceeds bile duct secretory pressure consistently. Ductal content flowing in either direction may result in pancreatitis or choledochal cyst formation. Common channel syndrome can be found in the majority of children with choledochal cyst [48]. The diagnosis of a choledochal cyst is mostly made by abdominal ultrasonography. Visualization of the common channel relies on invasive procedures, such as ERCP, percutaneous transhepatic cholangiography, or noninvasive MRCP. Treatment of a choledochal cyst is surgical. Endoscopic sphincteroplasty may be curative in common channel syndrome without choledochal cyst but with pancreatic ductal ectasia [45].

## Congenital Pancreatic Cysts

The great majority of cysts in the pancreas are (a) multiple cysts, (b) pseudocysts (no true epithelial lining), and

(c) a complication of chronic pancreatitis. True single congenital cysts of the pancreas are extremely rare. However, in population-based MRCP studies, small cysts (<1 cm) of unknown etiology (but most likely dysontogenetic) are fairly common and affect one-quarter of healthy volunteers [29]. Larger congenital cysts have a female predominance and may present as an asymptomatic palpable mass, or with epigastric pain, jaundice, and vomiting related to compression of surrounding visceral structures [49]. These cysts are most commonly located in the tail and body of the pancreas and are typically unilocular cysts with thin-walled cavities ranging in size from microscopic to up to 5 cm in diameter [50]. Ductal communication is rare. These cysts are usually anechoic on ultrasound and are low-attenuation cystic structures on CT or MRI examination with no wall enhancement. Associated congenital anomalies may include renal tubular ectasia, polydactyly, anorectal malformations, polycystic kidneys, and asphyxiating thoracic dystrophy [50]. Multilocular cysts may also be part of von Hippel–Lindau disease and autosomal dominant polycystic kidney disease (see below), but in both conditions pancreatic cysts are rarely congenital. Most congenital cysts with the symptoms mentioned and clinical manifestation are diagnosed in children. When they are found in adults, the differential diagnosis of chronic pancreatitis-associated cysts on the one hand, and cystic tumors of the pancreas (cystic adenomas and carcinomas, also more common in females) on the other, becomes an important and sometimes difficult differential diagnosis [51].

Gastrointestinal duplication cysts are abnormalities of the developing foregut that have, in contrast to the pseudocysts seen in chronic pancreatitis (Fig. 3.4), alimentary tract epithelial lining. A majority of these cysts contain gastric mucosa or pancreatic tissue, and digestive secretions can facilitate hemorrhage within the cyst. Juxtapancreatic duplication cysts typically originate from the stomach or duodenum and may compress the pancreas. Rarely, the cysts may be sequestered within the pancreas itself [49]. Communication between the cyst and the pancreatic duct is uncommon and, if present, rather pathognomonic for pancreatitis-associated pseudocysts.

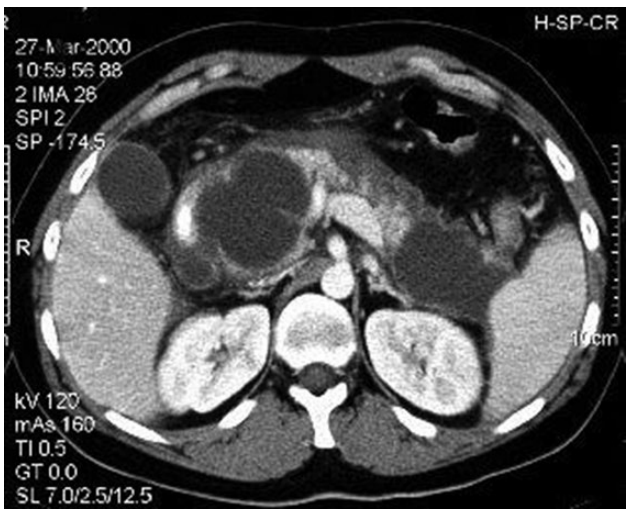

**Figure 3.4** Large cysts in the head and tail of the pancreas in a patient with chronic pancreatitis.

## Congenital Secretory Insufficiency (Excluding Cystic Fibrosis)

Congenital exocrine pancreatic insufficiency is rare. Cystic fibrosis, which leads to progressive destruction of the pancreas and may result in clinical symptoms of secretory insufficiency from birth, accounts for the majority of cases with congenital exocrine pancreatic insufficiency [52]. Mutations in the *CFTR* gene that do not cause cystic fibrosis (including lung disease) but raise the susceptibility for developing pancreatitis have been shown to partially impair pancreatic exocrine secretion [53]. Pancreatic disease in cystic fibrosis is discussed separately in Chapter 47.

Congenital pancreatic secretory insufficiency, if complete, manifests from birth with loose and voluminous stools, steatorrhea, failure to thrive, and hypoproteinemia. However, as the functional capacity of the exocrine pancreas is good, exocrine failure may not become manifest unless more than 90% of the exocrine cells have been destroyed [54].

Congenital exocrine pancreatic insufficiency without diabetes is not due to a primary malformation of acinar cells, because in the absence of acinar tissue endocrine cells do not develop properly. Instead, congenital secretory insufficiency of the pancreas reflects either isolated enzyme deficiencies or early-onset degeneration of acinar cells resulting in fibrosis or lipomatosis of the organ. Owing to the destructive nature of the disorder in the latter group, progression to combined insufficiency is common. Some of the disorders associated with congenital secretory insufficiency are discussed in the following.

### Isolated Enzyme Deficiencies

Isolated deficiencies of several pancreatic zymogens have been described, but all of them are extremely rare. The enzymes affected include lipase, colipase, trypsinogen, and amylase [55].

When lipid digestion is involved, the leading symptoms are chronic diarrhea and steatorrhea, which are readily detected with or without malnutrition. Congenital absence of pancreatic lipase was described as a familial trait with probable autosomal recessive inheritance (OMIM 614338) [56]. Colipase deficiency was reported

in two brothers [57] and the combined defect of both lipase and colipase in another family and one isolated case [58,59]. Mutations in *PNLIP*, the gene encoding pancreatic lipase, have been reported in two families with autosomal recessive inheritance of pancreatic triglyceride lipase deficiency [60,61]. Pancreatic amylase deficiency may lead to diarrhea induced by a diet that is rich in starch, but the functional capacity of the carbohydrate-digesting enzymes is rather high, and therefore amylase deficiency may remain compensated [62,63]. Children with trypsinogen deficiency were reported to present with growth failure, diarrhea, hypoproteinemia, and edema [64]. Enterokinase deficiency, although enterokinase is not an enzyme of the pancreas itself, presents as a pancreatic protease defect, because this enzyme is critical for the activation of pancreas-derived zymogens in the duodenum [65,66]. Mutations in the proenteropeptidase gene *PRSS7* have been reported as the molecular basis of this condition in one family (OMIM 226200) [67]. All these isolated enzyme deficiencies have in common the extreme paucity of reported cases and—apart from very few exceptions—the lack of molecularly proven defects (Table 3.1). This may indicate that alternative sources of lipolytic, proteolytic, and glycolytic activity exist that can compensate for isolated deficiencies. In all conditions of isolated pancreatic enzyme deficiency, enzyme replacement therapy is very effective.

## Shwachman–Diamond Syndrome

After cystic fibrosis, Shwachman–Diamond syndrome (SDS) (OMIM 260400) is the second most common inherited cause of exocrine pancreatic insufficiency. It has an approximate incidence of one in 50,000 in the North American population. Manifestations outside the pancreas sometimes concern skeletal features (e.g., metaphyseal dysplasia) but most often involve hematologic abnormalities, typically intermittent neutropenia, but other blood cell fractions may also be affected. Affected patients are short in stature and most commonly suffer from one or more symptoms, which include diarrhea due to malabsorption, failure to thrive, and recurrent infections [68]. In contrast to cystic fibrosis, sweat chloride concentration is normal. Imaging features with replacement of pancreatic tissue by fat (Fig. 3.5) or diffuse fatty infiltration are rather characteristic [69]. Although a majority of the pancreatic tissue is replaced by fat, resulting in a variable degree of steatorrhea, which can even somewhat improve when the children get older, the islet cells of Langerhans and the ductal architecture remain largely intact [70,71]. Hence neither diabetes nor pancreatitis is a consistent feature of SDS. Virtually all patients with SDS have consistent evidence of exocrine pancreatic insufficiency, although clinical signs and symptoms of maldigestion may be absent.

The pathogenesis of the exocrine pancreatic defect in SDS has been partly elucidated. In SDS cells, ribosome biogenesis and protein synthesis are altered and the most likely underlying mechanism is a Complex IV impairment with resulting defects in oxidative phosphorylation, ATP depletion, increased glycolysis, and endoplasmic reticulum stress, the last associated with high intracellular

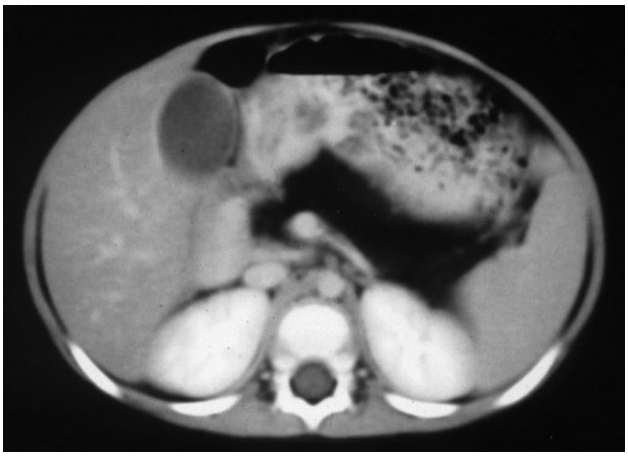

**Figure 3.5** Fatty replacement of the entire pancreas (black central box on the abdominal CT) in Shwachman–Diamond syndrome. *Source:* Wilschanski M et al. J Pediatr Gastroenterol Nutr 1994;19:111–113, Fig. 1. Reproduced with permission of Wolters Kluwer Health.

**Table 3.1** Isolated deficiency of pancreatic enzymes.

| Enzyme | Gene | Locus | Defect genetically confirmed in affected patients |
|---|---|---|---|
| Trypsinogen | *PRSS1* | 7q35 | No |
| Lipase | *PNLIP* | 10q26 | Yes (two families) |
| Colipase | *CLPS* | 6pter–p21.1 | No |
| Pancreatic amylase | *AMY2A* *AMY2B* | 1p21 | No |
| Enterokinase[a] | *PRSS7* | 21q21 | Yes (one family) |

[a] Duodenal brush border enzyme; deficiency presents like trypsinogen deficiency.

calcium concentrations [72]. Unlike in cystic fibrosis, where pancreatic disease is caused by ductal obstruction, in SDS the pancreatic acini fail to develop properly or undergo a very early degeneration. Histologically, the SDS pancreas shows normal ductal architecture and islets, absent or sparse acinar cells, and extensive fatty replacement [73].

Inheritance of SDS is autosomal recessive. The disease is caused by mutations in the *SBDS* gene (denoting the full name Shwachman–Bodian–Diamond syndrome) on chromosome 7q11 [74]. *SBDS* encodes a predicted protein of 250 amino acids. A pseudogene copy (*SBDSP*) with 97% nucleotide sequence identity resides in a locally duplicated genomic segment of 305 kb. Interestingly, recurrent mutations often (89%) result from gene conversion with at least one of two pseudogene-like sequence changes that result in protein truncations. The protein SDBS is a member of a highly conserved protein family involved in ribosome formation function with putative orthologs in diverse species, including archaea and eukaryotes. The protein is thus involved in RNA metabolism.

Diagnosis of SDS is based on the characteristic clinical findings, but it may be delayed in atypical or mild cases. Treatment is symptomatic. Most recently, biallelic mutations in DNAJC21 have apparently been found in association with SDS [75].

A distinct autosomal recessive syndrome with pancreatic, hematopoietic, and skeletal features has been termed "exocrine pancreatic insufficiency, dyserythropoietic anemia, and calvarial hyperostosis" (OMIM 612714) and related to mutations in the *COX4I2* gene [76].

### Pearson Marrow Pancreas Syndrome

Pearson syndrome (OMIM 557000) is characterized by refractory sideroblastic anemia with vacuolization of marrow precursors and exocrine pancreatic dysfunction. Severe, transfusion-dependent, macrocytic anemia usually starts in infancy. In contrast to SDS, the pancreas rather shows fibrosis in Pearson syndrome and the disorders also differ in bone marrow morphology. Pearson syndrome was found to be a mitochondrial disorder resulting from deletions of mitochondrial DNA (mtDNA) [77]. The disorder may be progressive and a phenotypic shift from a predominantly hematopoietic disorder (Pearson syndrome) to a disease with overt muscle dysfunction (mitochondrial myopathy) was repeatedly observed, with eventual evolution to a fully developed Kearns–Sayre syndrome, depending on the distribution of deleted mtDNA [78].

### Johanson–Blizzard Syndrome

Johanson–Blizzard syndrome (JBS) (OMIM 243800) is characterized by congenital pancreatic exocrine insufficiency and a peculiar malformation of the nose with hypoplasia or aplasia of the nasal wings (Fig. 3.6). Additional features that are present in a large proportion of patients include short stature, scalp defects, oligodontia, deafness, hypothyroidism, imperforate anus, and intellectual disability [79]. The condition is inherited as an autosomal recessive trait and has an estimated incidence of one in 250,000 [80].

It was shown that JBS is caused by mutations in the gene *UBR1*, leading to severe deficiency of the homonymous ubiquitin ligase of the N-end rule pathway [80]. As this pathway is responsible for the degradation of intracellular proteins, it is likely that the excess or increased half-life of hitherto unknown proteins is involved in the pathogenesis of the pancreatic and other defects of JBS.

Pancreatic disease is an obligate feature of JBS [81]. Histologically, the pancreas of infants who died from complications of the syndrome was shown to lack almost completely acinar cells, which are replaced by fat and connective tissue, whereas the ductal architecture and islets are fairly well preserved [82,83]. Corresponding to these findings, it was demonstrated that JBS patients had preserved ductular output of fluid and electrolytes with decreased secretion of zymogens [84]. It has been shown that the acinar cell loss is likely caused by an intrauterine destruction of these cells resembling a pancreatitis of prenatal onset [85]. Mice deficient in *UBR1* were shown to have milder abnormalities of pancreatic function,

**Figure 3.6** Prominent aplasia of the nasal wings as a characteristic feature of Johanson–Blizzard syndrome.

including decreased zymogen secretion and increased susceptibility to experimental pancreatitis.

Diagnosis of JBS is established on the basis of the characteristic clinical picture and treatment is symptomatic.

## Isolated Congenital Disorders of Pancreatic Endocrine Function

### Congenital Hyperinsulinism

Hyperinsulinemic hypoglycemia of neonatal onset is a clinically and etiologically heterogeneous disease [86,87]. Congenital hyperinsulinism (CHI) was formerly called "nesidioblastosis," assuming abnormal proliferation of β cells from ductal epithelium as the underlying cause [88], but it was later demonstrated that this histologic pattern may normally be found in early infancy and that "nesidioblastosis" does not correspond to an abnormal β-cell proliferation [89,90]. In fact, two major histopathologic types of CHI can be differentiated: The diffuse form (60–70%) is characterized by the presence of islet cells with enlarged nuclei, abundant cytoplasm, and histologic evidence of increased metabolic activity throughout the pancreas. In the focal form (30–40%), hyperplasia of apparently normal islets involves a limited region of the pancreas, whereas β cells outside the focal lesion have small nuclei and sparse cytoplasm corresponding to suppression of insulin secretion [91]. A third, mosaic type has more recently been proposed [92]. In contrast, insulin-producing adenomas, the most common cause of hyperinsulinism in older children and adults, are merely seen in infants. Islet cell hyperplasia may be a consequence of chronic fetal exposure to hyperglycemia due to maternal diabetes. In this case, hyperinsulinism is transient and rarely lasts for more than a few days or weeks. Transient hyperinsulinism due to islet cell hyperplasia is also a feature of Beckwith–Wiedemann syndrome (see later). It may also occur in other syndromic conditions such as Costello syndrome (OMIM 218040), Kabuki syndrome (OMIM 147920), Sotos syndrome (OMIM 117550), congenital disorders of glycosylation (OMIM 212065), and other rare diseases [86,87]. Many cases, particularly of transient CHI, are sporadic without an obvious underlying cause.

Persistent hyperinsulinemic hypoglycemia of infancy is considered to have a strong genetic contribution and most cases have an identifiable monogenic cause (synonym: familial hyperinsulinism; OMIM 256450). Inheritance may be autosomal recessive or dominant and several genes in which mutations cause familial hyperinsulinism are known [86,87]. Some genetic entities have specific features associated with hyperinsulinemic hypoglycemia that make them recognizable clinically, such as hyperammonemia in hyperinsulinism–hyperammonemia syndrome caused by *GLUD1* mutations, abnormal levels of 3-hydroxyglutaric acid in urine in 3-hydroxyacyl-CoA dehydrogenase deficiency (*HADH* gene), and exercise-induced hypoglycemia caused by mutations of the *SLC16A1* gene [86,87].

The most common cause of familial hyperinsulinism is genetic defects affecting the subunits of the pancreatic β-cell ATP-dependent potassium channel ($K_{ATP}$), SUR1 and Kir6.2, encoded by *ABCC8* and *KCNJ11*, respectively [87]. Recessive and a few dominant $K_{ATP}$ mutations are associated with the *diffuse* type of CHI. The *focal* type instead requires a paternally inherited $K_{ATP}$ channel mutation and a second somatic event leading to a loss of the maternal allele within the focal lesion. The imbalance in the expression of various imprinted genes in the chromosomal region 11p15.5 where *ABCC8* and *KCNJ11* are located has been shown to promote β-cell hyperplasia [87]. Other monogenic forms of CHI are caused by mutations in the genes *GCK*, *HNF4A*, *HNF1A*, and *UCP2* [86,87]. Treatment of CHI includes glucose infusions, dietary measures, and medical options (diazoxide, octreotide). Surgery is the treatment of choice in cases with severe focal CHI, where it leads to complete remission, but may also be an option in refractory cases with diffuse CHI [93,94].

Congenital hyperplasia of other endocrine cells or deregulation of their hormone output is extremely rare.

### Isolated Congenital Endocrine Insufficiency

Blum et al. described a newborn with congenital absence of the insulin-producing β cells from otherwise normal-appearing pancreatic islets, causing insulin-dependent neonatal diabetes mellitus [95]. An isodisomy of chromosome 6 was found in this child, suggesting that the gene responsible for this disorder is located there [96]. The imbalance in the expression of imprinted genes of the region 6q24 is now established as the most common cause of *transient* neonatal diabetes mellitus (TNDM; OMIM 601410) [97]. Affected newborns are usually small for gestational age. Hyperglycemia usually requires insulin and resolves by the age of 18 months, but recurrence of diabetes mellitus in adolescence or adulthood is common. 6q24-related TNDM can be caused by paternal uniparental disomy (41%), duplications of the paternal allele (29%), and hypomethylation of the maternal differentially methylated region (30%). The last may represent an isolated epimutation or may be caused by homozygous or compound heterozygous *ZFP57* mutations. Accordingly, while the majority of patients with TNDM are sporadic cases, familial occurrence is also possible. In a study of

97 patients with TNDM, 72% had an abnormality at the 6q24 locus, whereas of the remaining 28 TNDM patients without 6q24 abnormalities, 26% were found to have a mutation in the *ABCC8* or *KCNJ11* genes, which usually cause *permanent* neonatal diabetes mellitus (PNDM; OMIM 606176) [98].

In contrast to the *ABCC8* and *KCNJ11* changes in congenital hyperinsulinism, the PNDM-related mutations in these genes cause a gain of function of $K_{ATP}$ and are inherited in a dominant manner. PNDM may also be caused by mutations in the genes encoding pancreatic glucokinase (*GCK*) and insulin (*INS*). Inheritance for GCK-related PNDM is autosomal recessive [99]. Abnormal morphologic findings of the pancreatic islets have not been described in patients with TNDM or PNDM. Aside from these functional islet cell defects, neonatal diabetes may also result from any type of agenesis or severe hypoplasia of the pancreas, as already mentioned.

Congenital absence of the islets of Langerhans may be part of the X-linked immunodysregulation, polyendocrinopathy, and enteropathy syndrome (IPEX; OMIM 304790) [100]. It has been shown to be caused by mutations in the *FOXP3* gene, and overwhelming systemic autoimmunity starting in early life is supposed to be the pathogenetic basis of the islet cell defect [101]. Infantile-onset (often within the neonatal period) diabetes mellitus is also a typical sign of Wolcott–Rallison syndrome (OMIM 226980), which is caused by recessive mutations in *EIF2AK3*. This gene is highly expressed in pancreatic islet cells and presumed to act as a regulator of protein synthesis [102]. A syndrome of neonatal diabetes mellitus with congenital hypothyroidism (OMIM 610199) has been associated with mutations of *GLIS3* encoding a pancreatic transcription factor involved in the transcriptional regulation of neurogenin-3 and insulin [103]. A number of other extremely rare syndromes may also present with neonatal diabetes.

Inherited disorders of insulin secretion leading to adult noninsulin-dependent diabetes mellitus or maturity-onset diabetes of the young (MODY) are not discussed here, with the sole exception of carboxyl ester lipase (CEL), a bile salt-dependent lipolytic enzyme produced by acinar cells, mutations in which had initially been identified in Norwegian patients with MODY diabetes. An extended search recently identified a hybrid allele *(CEL-HYB*) originating from a crossover between *CEL* and its neighboring pseudogene, *CELP*. In a cohort with familial chronic pancreatitis, the *CEL-HYB* was found with an odds ratio (OR) of 15.5 and in three replication cohorts of nonalcoholic chronic pancreatitis patients with an OR of 5.2, making this variant the most recent addition to the growing list of pancreatitis-causing genes [104].

## Other Hereditary Disorders with Variable Pancreatic Involvement and Metabolic Diseases Affecting the Pancreas

Pancreatic abnormalities have been described in a number of congenital or inherited multisystem disorders where they are rarely one of the leading symptoms or may even remain clinically inapparent. In addition, several metabolic disorders may be associated with pancreatic manifestations, mainly pancreatitis.

### Polycystic Kidney Disease

Multiple cysts of the pancreas can be present as part of polycystic systemic disorders, including autosomal recessive (ARPKD, OMIM 263200) and autosomal dominant polycystic (ADPKD; OMIM 173900) disease. ARPKD is caused by mutations in the *PKHD1* (polycystic kidney and hepatic disease 1) gene on chromosome 6p12 [105]. The disease presentation of ARPKD is highly variable. In newborns, the disease results in significantly enlarged polycystic kidneys, and may be associated with pulmonary hypoplasia resulting from oligohydramnios as a major cause of morbidity and mortality. Liver involvement is detectable in approximately half of infants and comprises cysts and periportal fibrosis. Pancreatic cysts and pancreatic fibrosis have been reported repeatedly as an imaging finding or at autopsy in children with ARPKD, but clinical symptoms of pancreatic involvement are exceptional. The same is true for ADPKD, where the development of sonographically visible pancreatic cysts is a much more common feature. ADPKD is a common condition affecting one in 800 live births from all ethnic groups. It results in progressive loss of renal function, with more than half of affected individuals requiring renal replacement therapy by the age of 60 years or older. Pancreatic cysts are present in about 10% of the patients, but rarely in infancy, and pancreatic involvement is typically less severe than renal and hepatic involvement. Occasionally, pancreatic cysts may lead to pancreatitis [106]. Genetic heterogeneity exists but mutations in one gene (*PKD1* on chromosome 16p) are responsible for most cases (approximately 85%) [107]. A second gene termed *PKD2* located on chromosome 4 has also been recognized as underlying the disease [108], and most recently *GANAB*, encoding the glucosidase II-α subunit, was reported to cause autosomal-dominant polycystic kidney and liver disease [109].

### Von Hippel–Lindau Syndrome

One of the inherited disorders that are associated with single or multiple cysts in different parenchymal organs including the pancreas is von Hippel–Lindau syndrome (VHL; OMIM 193300). VHL is an autosomal dominant familial cancer syndrome predisposing to a variety of benign and malignant neoplasms. It is caused by mutations in the VHL tumor suppressor gene on chromosome 3p25 [110], but genetic changes in the cyclin D1 gene on chromosome 11q13 may further modify the phenotype [111]. The incidence is estimated at one in 36,000 and affected patients are at risk for developing cerebellar, spinal, and retinal hemangioblastoma, renal cell carcinoma, pheochromocytoma, pancreatic neuroendocrine tumors, pancreatic and renal cysts, and epididymal cystadenoma [112]. VHL has previously been classified as type 1 (without pheochromocytoma) and type 2 (with pheochromocytoma). Other authors have subdivided VHL further into type 2 and type 2A (with pheochromocytoma) and type 2B (with pheochromocytoma and renal cell carcinoma). Pancreatic lesions in VHL include multiple cysts, serous cystadenoma, and neuroendocrine tumors. Pancreatic carcinoma and adenocarcinoma of the ampulla of Vater have also been reported. Pancreatic cysts are relatively common in VHL, and involvement can range from a single cyst to multiple cysts, virtually replacing the pancreas. Cysts are reported in up to 30% of patients in imaging studies [49], but can be found in up to 72% in patients with VHL at autopsy. Peripheral calcifications may also be present. These cysts may be the first indication of disease during routine screening and may precede any other manifestation of VHL by several years.

### Beckwith–Wiedemann Syndrome

The cardinal features of Beckwith–Wiedemann syndrome (BWS; OMIM 130650) are exomphalos, macroglossia, and gigantism in the neonate. Hypertrophy of the pancreas is an imaging feature and severe hypoglycemia of affected neonates caused by transient hyperinsulinism is the most threatening early clinical complication of BWS. No other clinical symptoms related to the pancreas are common features of BWS. During childhood, BWS patients are at increased risk for developing specific tumors, including adrenal carcinoma, nephroblastoma, hepatoblastoma, and rhabdomyosarcoma. Pancreatoblastoma has been described in a few instances and may also be congenital [113]. BWS is genetically heterogeneous. Epigenetic and genomic alterations of the imprinted region on chromosome 11p15.5 are the underlying cause, including paternal methylation patterns on the maternal chromosome, paternal uniparental disomy for chromosome 11p15, and mutations of the *CDKN1C* gene [114]. Most cases are sporadic.

### Jeune Syndrome and Other Ciliopathies

Jeune syndrome (OMIM 208500) is an autosomal recessive ciliopathy characterized by skeletal abnormalities of the thorax and extremities and nephronophthisis. It may be associated with pancreatic cysts and pancreatic fibrosis, leading to exocrine pancreatic insufficiency [115,116]. The leading symptom is, however, nephronophthisis, a childhood kidney disease with progressive symmetrical destruction of the kidneys involving both the tubules and glomeruli. It characteristically results in anemia, polyuria, polydipsia, isosthenuria (decreased ability to concentrate the urine), and progressive and terminal renal failure, which in itself is a risk factor for disturbed exocrine pancreatic function. Mutations in more than 15 genes have been identified to be responsible for the phenotype of Jeune syndrome. *DYNC2H1* mutations account for about half of the cases [117].

Fibrotic and cystic changes of the pancreas are a common feature in renal–hepatic–pancreatic dysplasia (OMIM 208540), another entity within the clinically overlapping and genetically extremely heterogeneous spectrum of ciliopathies. The two known genes for renal–hepatic–pancreatic dysplasia, *NPHP3* and *NEK8*, are also involved in Meckel syndrome and nephronophthisis, respectively [118]. Similar involvement of the pancreas may also be found in other ciliopathies. A recent study using a mouse model suggested that chronic pancreatitis with perturbed acinar homeostasis and differentiation plays a role in the pathogenesis of ciliopathy-related pancreatic defects [119].

## Inherited Metabolic Disorders Affecting the Pancreas

Acute and chronic recurrent pancreatitis has been reported in patients with a variety of rare inborn errors of metabolism (Table 3.2). In most of these, pancreatitis is not very common, with the exception of some disorders of lipid metabolism as briefly discussed in the following [120].

Hyperlipidemia is one of the most common metabolic causes of recurrent pancreatitis [121]. A number of familial disorders, including lipoprotein lipase deficiency, apolipoprotein C-II deficiency, and common hypertriglyceridemia, can result in massive plasma accumulations of chylomicrons or triglycerides. Triglyceride levels above 2000 mg/dL (22.6 mmol/L) are generally considered to put patients at a significant risk for developing pancreatitis.

Hereditary lipoprotein lipase (LPL) deficiency (OMIM 246650) is an autosomal recessive condition with an estimated incidence of one in $10^6$. The first symptoms often

**Table 3.2** Inherited metabolic diseases with increased risk of pancreatitis

| Disorder | OMIM | Gene | Locus | Nature of pancreatitis |

[a] Related to gallstones.

arise in early childhood and the most common clinical presentation includes abdominal pain caused by recurrent attacks of pancreatitis, eruptive cutaneous xanthomatosis, and hepatosplenomegaly. Almost 30% of patients with LPL deficiency develop pancreatitis [120,122]. The pancreatitis associated with LPL deficiency is most often recurrent, sometimes severe and necrotizing, and only rarely leads to diabetes, pancreatic calcifications, or exocrine pancreatic deficiency. The diagnosis of LPL deficiency should be suspected in hyperlipidemic patients when chylomicrons are detectable in refrigerated fasting plasma and no significant very low-density lipoprotein (VLDL) elevation is found. The diagnosis of LPL deficiency can be made by measuring the enzyme activity in post-heparin plasma (heparin releases the enzyme into the bloodstream) with a commercially available enzyme-linked immunosorbent assay (ELISA). The treatment of pancreatitis in these patients is not different from that with other causes of the disease, but an aggressive lipid-lowering therapy by dietary restriction of fat intake is paramount to prevent recurrence. Medium-chain triglycerides can serve as a substitute because they are not incorporated into chylomicrons after absorption. Hereditary LPL deficiency has, as of 2012, become the first and only disorder for which a gene therapy has been approved in the European Union. The agent alipogene tiparvovec (Glybera) addresses the enzyme deficiency by introducing an LPL gain-of-function allele delivered by an adeno-associated virus-type vector via intramuscular injection. The effect (and the reason for approval by the regulatory authorities) is a lowering of the rate of pancreatitis episodes in affected patients [123].

Apolipoprotein C-II deficiency is caused by mutations in the *APOC2* gene, and is inherited as an autosomal recessive disorder with a worldwide distribution. The

defect results in an impaired clearance of chylomicrons from the blood. Apolipoprotein C-II deficiency is less common than LPL deficiency. As apolipoprotein C-II functions as an activator for LPL, its deficiency clinically resembles LPL deficiency, but it generally has a milder course and later onset of symptoms (between 13 and 60 years). However, pancreatitis represents a more frequent and sometimes severe complication of apolipoprotein C-II deficiency, and up to 60% of patients are affected by episodes of pancreatitis [124]. The diagnosis is made by measuring LPL activity in post-heparin plasma as already described or on gel electrophoresis of VLDL apolipoproteins. A distinction from LPL deficiency can be readily made because the addition of apolipoprotein C-II to the assay completely restores lipolytic activity but does not affect the plasma of patients with LPL deficiency. Also, for apolipoprotein C-II deficiency, treatment modalities based on gene therapy concepts are under investigation.

Several other disorders of lipid metabolism have been reported that can lead to either chylomicronemia or hypertriglyceridemia and are not associated with defects in the LPL system. The incidence of patients with lipid disorders that result in such elevated triglyceride levels is estimated to be between 10 and 20 per 100,000 and is therefore much higher than that of disorders caused by inborn errors of the LPL system. Often, the high triglyceride levels are not caused by the disorder alone, but are precipitated by additional factors such as diabetes mellitus, alcohol, β-adrenergic blockers, glucocorticoids, estrogens, diuretics, and other drug therapies. All of these factors can greatly increase the extent of hypertriglyceridemia and raise it above the threshold level for developing pancreatitis. The most common familial disorders associated with chylomicronemia are the type I and type V hyperlipoproteinemias (according to Levy and Fredrickson [125]). They comprise a diverse group of primary and secondary disorders with moderate to severe hypertriglyceridemia. Individuals with monogenic familial hypertriglyceridemia are rare and often have only mild hypertriglyceridemia, and the above-mentioned additional factors are often required before the risk of developing pancreatitis becomes significant. Pancreatitis associated with metabolic diseases is further discussed elsewhere in this book.

In addition to the hyperlipidemias, various disorders of branched-chain amino acid degradation, homocystinuria, hemolytic disorders, acute intermittent porphyria mitochondrial disorders, and several amino acid transporter defects may also be associated with pancreatitis (Table 3.2). The clinical, biochemical, and genetic characteristics of those inborn errors of metabolism differ from those of other pancreatic disorders and they need to be distinguished from other hereditary causes of pancreatic diseases.

### Hereditary Pancreatitis

Pancreatic changes associated with cationic trypsinogen mutations (hereditary pancreatitis; OMIM 167800) and *CFTR* and *SPINK1* mutations (idiopathic pancreatitis) are discussed in dedicated chapters of this book.

## Section 2

## Physiology and Pathophysiology of Pancreatic Functions

# 4

# Physiology of Acinar Cell Secretion

*Ole H. Petersen*

*Cardiff School of Biosciences, Cardiff University, Cardiff, UK*

## Introduction

The acinar cell is the dominant cell type in the pancreas. In terms of percentage volume, the pancreas consists of 82% acinar cells, 4% duct cells, 4% blood vessels, 2% endocrine cells, and 8% extracellular matrix [1]. However, the acinar cell itself is not the functional unit in the exocrine pancreatic tissue because acinar cells are organized into acini consisting of up to several hundred acinar cells linked by numerous gap-junctional channels that allow both direct chemical and electrical intercellular communication [2,3]. There is an additional cell type that has not previously featured much in descriptions of acinar cell function, namely the pancreatic stellate cells (PSC). These very thin periacinar cells come very close to the acinar cells, but are nevertheless functionally isolated from the acinar cells [4–6]. The PSC play an important role under pathophysiologic conditions where they exert effects on the acinar cells [4–7], but it is unknown whether they have any physiologic role in the control of acinar cell secretion. The principal function of the acinar cells is to secrete a potent mixture of digestive enzymes in response to food intake. This secretory response is mediated by vagal nerve stimulation, releasing acetylcholine (ACh) from nerve endings close to the acinar cells, and the circulating hormone cholecystokinin (CCK). The digestive (pro)enzymes are packaged into secretory vesicles called zymogen granules (ZG) and the secretion process itself occurs by exocytosis, that is, fusion of the granule membrane with the apical (luminal) cell membrane and subsequent opening of a pathway (pore) allowing direct movement of the zymogens from the granule interior to the acinar lumen. In order to move the zymogens into the duct system and thereafter into the gut, there is also a need for fluid secretion. The acinar cells secrete a neutral $Cl^-$-rich fluid, produced in response to stimulation with ACh and CCK. Additionally the small ducts secrete a $HCO_3^-$-rich fluid when stimulated by the hormone secretin. The aim of this chapter is to explain the cellular mechanisms underlying the very acute and finely controlled normal physiologic regulation of acinar fluid and enzyme secretion.

## Composition of Pancreatic Acinar Juice

ACh or CCK activates acinar cells to secrete an isotonic NaCl-rich fluid (Fig. 4.1a) containing a multitude of enzymes and precursor enzymes. The protease precursors are trypsinogen, chymotrypsinogen, and procarboxypeptidases. These precursors are activated in the small intestine, initiated by conversion of trypsinogen to trypsin by the intestinal enzyme enteropeptidase. Trypsin then activates trypsinogen autocatalytically and also activates the other precursors. The acinar fluid also contains active α-amylase, lipases, and colipase as well as various other enzymes (e.g., collagenase, elastase, phospholipase A, and ribonuclease) [11]. The neutral NaCl-rich fluid containing these enzymes and enzyme precursors is delivered to the small ducts, where it is mixed with the $HCO_3^-$-rich fluid produced by the duct cells in response to stimulation with secretin (Fig. 4.1b,c).

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

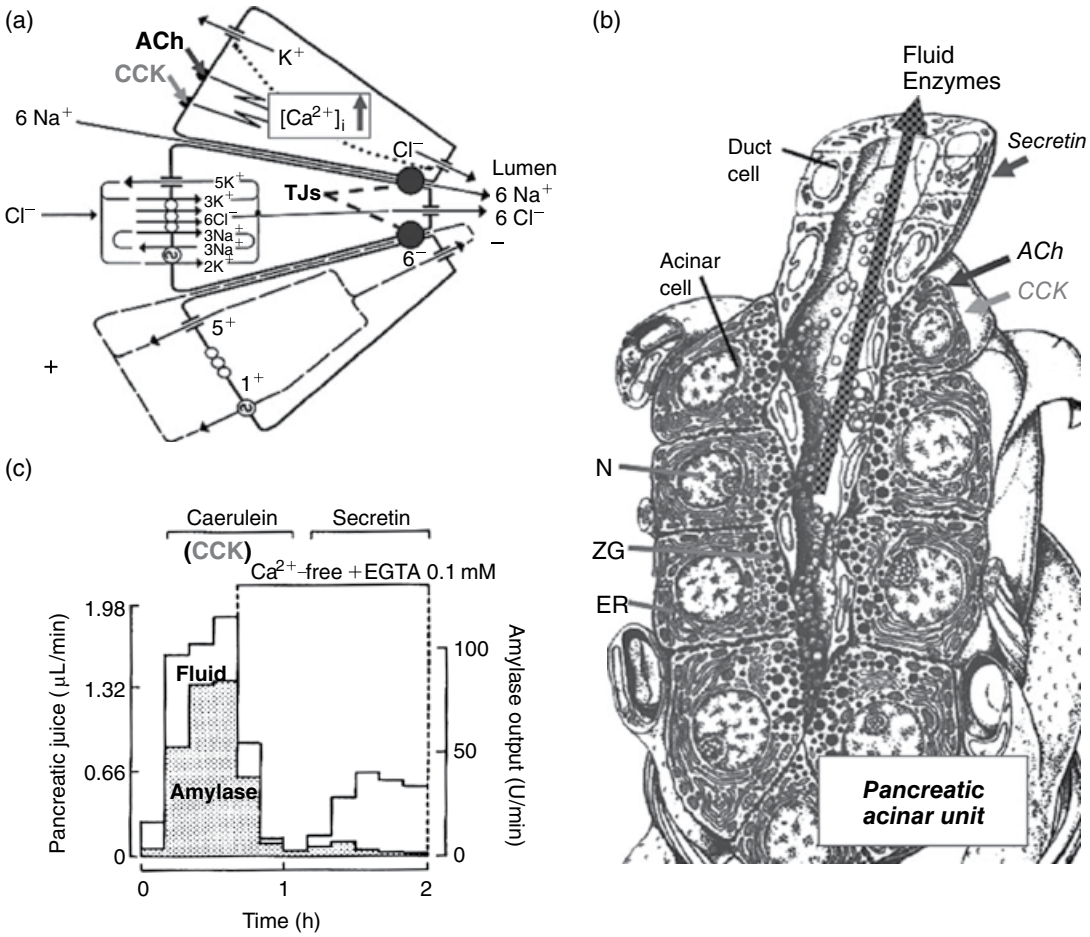

**Figure 4.1** Fluid and enzyme secretion from acinar cells. (a) Acinar transport model illustrating the individual ion transport events that work together to produce an isotonic NaCl-rich fluid. For graphical convenience, different aspects of the processes are shown in separate cells. In the top cell it is shown that ACh or CCK stimulation of their respective specific receptors on the basolateral membrane elicits a rise in the cytosolic $Ca^{2+}$ concentration ($[Ca^{2+}]_i$), which in turn activates $Cl^+$ channels in the apical (luminal) membrane and $K^+$ channels in the basolateral membrane (for graphical convenience all events in the basolateral membrane are shown only in the basal membrane). The middle cell illustrates transcellular $Cl^-$ transport. The $Na^+/K^+/2Cl^-$ cotransporter, the $K^+$ channel, and the $Na^+/K^+$ pump are shown in the basal membrane and it is indicated that the net transport event is uptake of $Cl^-$, whereas at the apical membrane $Cl^-$ exit into the lumen simply occurs through a $Cl^-$ channel. The lower cell illustrates the overall electrical circuit and explains the transepithelial electrical potential difference. The $Na^+/K^+/2Cl^-$ cotransporter is electrically neutral, so the only electrogenic event at the basolateral membrane is the transport of cations ($K^+$ and $Na^+$) through the $K^+$ channel and $Na^+/K^+$ pump ($3Na^+$ pumped out for $2K^+$ taken in). This net outward (cation exit) current has to be matched by an inward (anion exit) current across the apical membrane and the completion of the circuit depends on the high conductance of the so-called tight junctions (TJs). *Source:* Adapted from [8] with permission. (b) Model drawing of acinar unit with small duct segment attached. The polarity of acinar cells is shown with the nucleus (N) surrounded by endoplasmic reticulum (ER) in the basal part and zymogen granules (ZG) in the apical part. *Source:* Adapted from [9] with permission. (c) Fluid and amylase secretion from isolated perfused rat pancreas stimulated by the frog skin peptide cerulein (analog of CCK) and secretin. *Source:* Adapted from [10] with permission.

## Acinar Fluid and Enzyme Secretion

There is separate control of acinar and duct secretion, as shown in experiments on the isolated perfused pancreas (Fig. 4.1c). Sustained fluid and enzyme secretion, due to stimulation with either ACh or CCK, is acutely dependent on the presence of $Ca^{2+}$ in the extracellular solution, whereas the $HCO_3^-$-rich fluid secretion evoked by secretin in the ducts occurs normally in the complete absence of external $Ca^{2+}$ (Fig. 4.1c).

It is well established that exocytosis in general is activated by a rise in cytosolic $Ca^{2+}$ concentration ($[Ca^{2+}]_i$) [11]. In nerve and endocrine cells, exocytosis is normally activated by $Ca^{2+}$ entering the cell interior via special voltage-activated $Ca^{2+}$ channels in the plasma membrane, which open on membrane depolarization caused by action

potentials [11]. However, the pancreatic acinar cell is electrically nonexcitable and cannot fire action potentials [12]. $Ca^{2+}$ needed for stimulus–secretion coupling is therefore delivered to the cytosol from intracellular stores [12]. It was established many years ago that the initial secretory response to stimulation with either ACh or CCK is independent of extracellular $Ca^{2+}$ [13], whereas sustained secretion is acutely dependent on external $Ca^{2+}$ (Fig. 4.1c). This is explained by the limited capacity of the intracellular $Ca^{2+}$ stores and the fact that release of $Ca^{2+}$ from stores into the cytosol inevitably activates $Ca^{2+}$ pumps in the plasma membrane extruding $Ca^{2+}$, so that after a shorter or longer period of stimulation (depending on the intensity of stimulation) the contents of the intracellular $Ca^{2+}$ stores have been exported to the extracellular solution [14]. A reduction of $[Ca^{2+}]$ in the intracellular stores activates a process known as store-operated $Ca^{2+}$ entry. A signal is transmitted from the stores to the plasma membrane activating special $Ca^{2+}$ channels (store-operated channels) that allow $Ca^{2+}$ entry [15]. It is this $Ca^{2+}$ entry process that sustains the secretory response during prolonged stimulation, after the stores have been emptied.

## $Ca^{2+}$ Signaling

It is well established that stimulation of acinar cells with either ACh or CCK elicits a rise in $[Ca^{2+}]_i$ (Fig. 4.2). At low, physiologically relevant, concentrations of neurotransmitter or hormone, the typical $Ca^{2+}$ signal pattern consists of repetitive $[Ca^{2+}]_i$ spikes confined to the apical (granular) pole. Increasing the stimulating agonist concentration causes $Ca^{2+}$ signal globalization, a process whereby a local $Ca^{2+}$ signal initiated in the apical pole spreads as a wave from the apex to the base of the cell (Fig. 4.2).

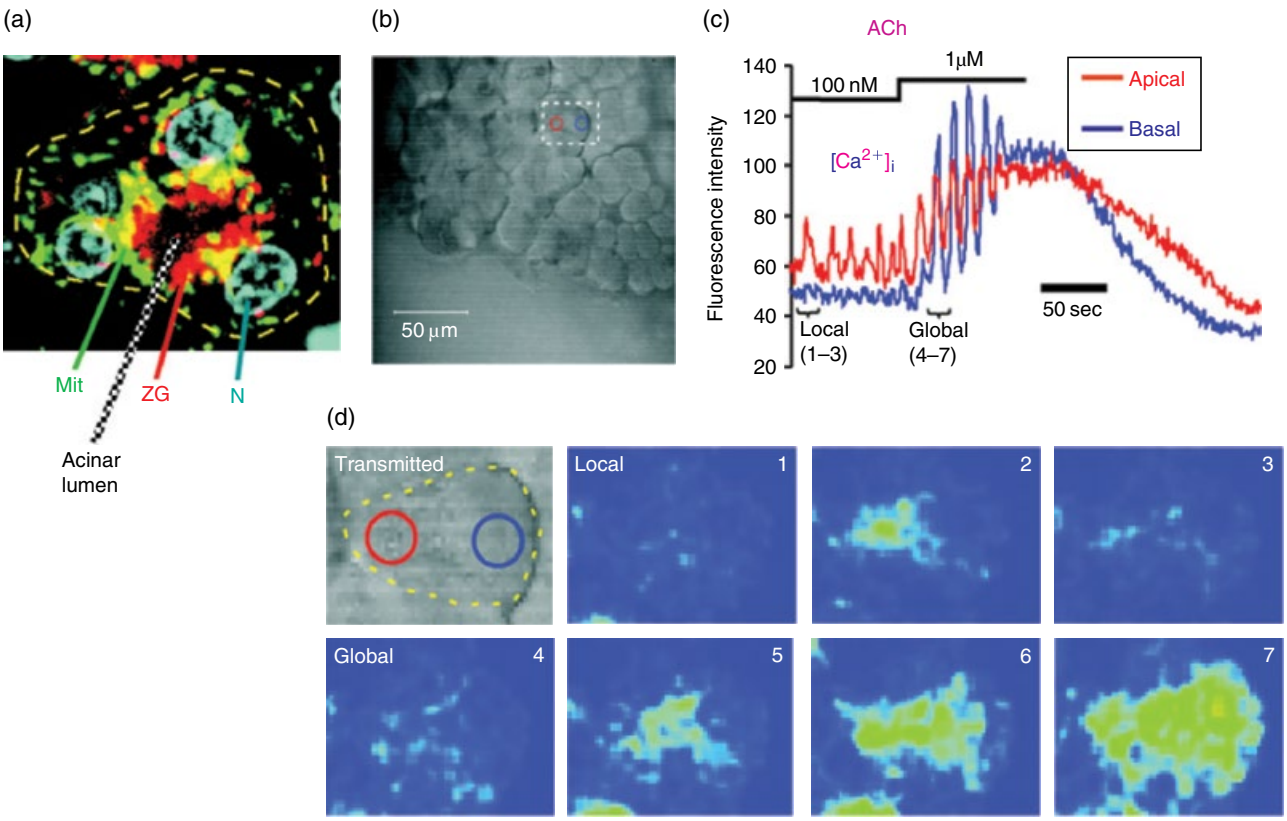

**Figure 4.2** $Ca^{2+}$ signaling and organelle distribution in the intact mouse pancreas. (a) Merged confocal images showing distribution of specific fluorescent markers for zymogen granules (ZG – red), nuclei (N – blue), and mitochondria (Mit – green). The optical slice goes through three cells (nuclei). The ZG are seen distributed around the lumen and are surrounded by mitochondria. Mitochondria are also located around the nuclei and close to the plasma membrane. (b) Confocal image of larger part of the pancreas showing many acinar units. One cell is highlighted by white dashed lines and in this cell apical (red) and basal (blue) regions of interest are signposted. The traces shown in (c) are from these two regions. (c) ACh-elicited cytosolic $Ca^{2+}$ signals. At the low ACh concentration of 100 nM, repetitive $Ca^{2+}$ spikes are seen exclusively in the apical pole. When the ACh concentration is increased to 1 µM, there is a rise in $[Ca^{2+}]_i$ in both the apical and basal regions. (d) Fluorescent images showing (upper row) a single local apical $Ca^{2+}$ spike (numbers refer to time points in (c)) and (lower row) the initial $Ca^{2+}$ wave generation following the increase in ACh concentration (numbers again refer to time points signposted in C). *Source:* Adapted from Ashby et al. 2003 [16].

## Organelles Important for $Ca^{2+}$ Homeostasis

The earliest work on $Ca^{2+}$ transport in exocrine glands indicated that ACh evokes $Ca^{2+}$ signals in acinar cells by causing release of $Ca^{2+}$ from the endoplasmic reticulum (ER) [17]. In 1972, the link between ACh occupation of muscarinic receptors on the cell surface and the outflow of $Ca^{2+}$ from the ER was obscure. About 10 years later, Irene Schulz and coworkers discovered that the intracellular water-soluble messenger inositol 1,4,5-trisphosphate ($IP_3$), generated inside the cell by receptor-activated phospholipase C action on a membrane phospholipid, phosphatidylinositol 4,5-bisphosphate ($PIP_2$), releases $Ca^{2+}$ from the ER in permeabilized pancreatic acinar cells [18]. All subsequent work on many different cell types confirmed the generality of the concept that hormone- or neurotransmitter-elicited intracellular $Ca^{2+}$ release is mediated principally via $IP_3$-evoked $Ca^{2+}$ release from the ER [19]. Although the original discovery of $IP_3$-evoked $Ca^{2+}$ release was made on pancreatic acinar cells [18], there are difficulties in applying this concept to these particular cells. The problem is that the physiologically relevant $Ca^{2+}$ signals occur specifically in the apical granular pole (see Fig. 4.2), which contains mostly ZG and little ER. This difficulty was finally overcome by the results of the so-called $Ca^{2+}$ tunnel experiments, in which it could be shown that $Ca^{2+}$ taken up at the base of the cell into the ER could diffuse easily in the ER lumen and reach the apex via thin ER extensions penetrating deeply into the granular area between the ZGs (see Fig. 4.3). Upon stimulation, $Ca^{2+}$ is released primarily from the ER elements in the apical pole due to the high concentration of ER $Ca^{2+}$ release channels specifically in this part of the cell (Fig. 4.3) [20,22].

It was initially a surprise that cytosolic $Ca^{2+}$ signals initiated in the apical pole could remain local in such a relatively small cell (~20 µm diameter). This could not be easily understood before it was discovered that the mitochondria in the acinar cell are distributed in a very specific manner [23]. The mitochondria are primarily localized in a belt surrounding the ZG, separating the

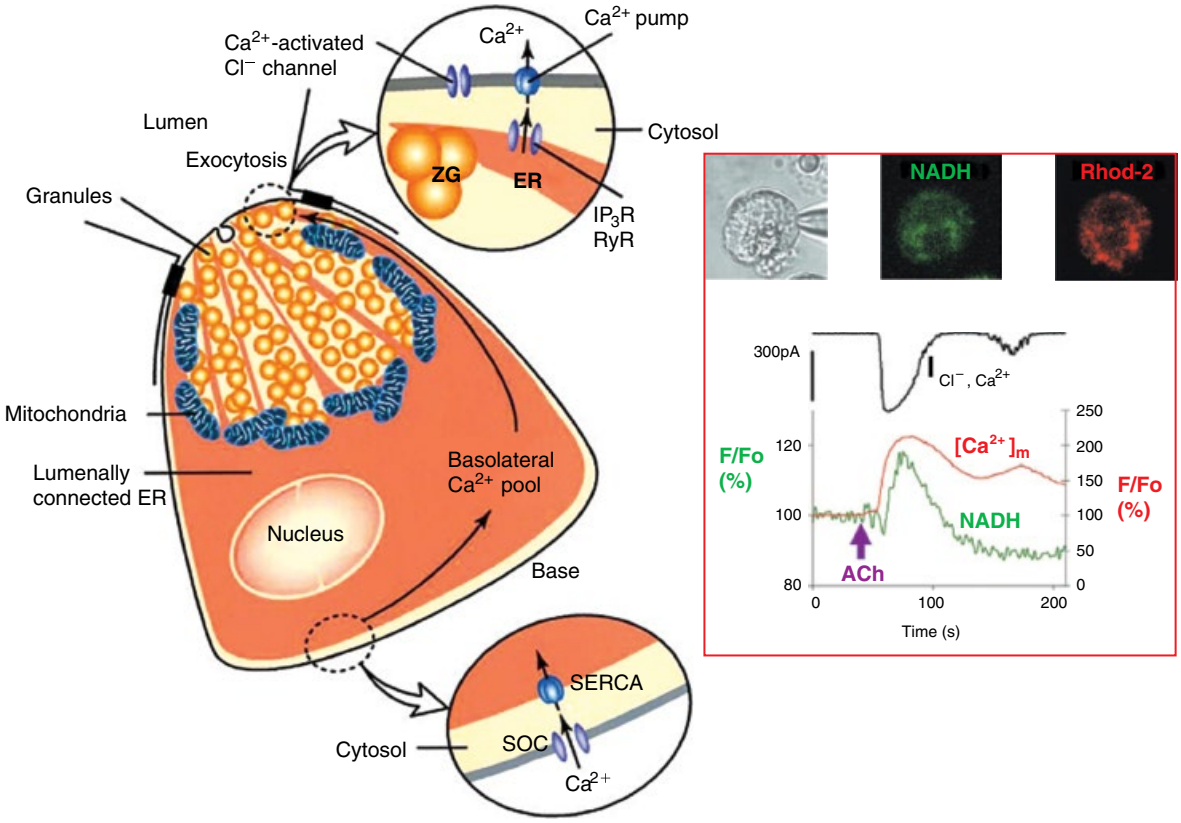

**Figure 4.3** Organelle distribution and $Ca^{2+}$ transport events in acinar cell. The main part of the figure shows a model cell with the distribution of organelles and $Ca^{2+}$ transport pathways signposted. Insert (in red frame) shows triple measurements of $Ca^{2+}$-activated $Cl^-$ current ($I_{Cl-,Ca^{2+}}$), mitochondrial $Ca^{2+}$ concentration ($[Ca^{2+}]_m$—measured by Rhod-2 fluorescence—and concentration of NADH (autofluorescence). It is seen that ACh evokes a rapid rise in $I_{Cl-,Ca^{2+}}$, which is followed immediately by a rise in $[Ca^{2+}]_m$ and after a small delay by an increase in the NADH concentration signifying activation of mitochondrial metabolism and therefore ATP production. *Source:* Adapted from Petersen et al. 2001 [20] and Voronina et al. 2002 [21].

apical granular pole from the rest of the cell (see Figs 4.2 and 4.3). Due to their ability to take up $Ca^{2+}$, the mitochondria function as a $Ca^{2+}$ diffusion barrier, effectively acting as a firewall preventing the spread of cytosolic $Ca^{2+}$ signals from the apical pole into the basal part of the cell containing the nucleus (Fig. 4.3). The nucleus is well protected against $Ca^{2+}$ signal invasion from the apical pole, since there is an additional mitochondrial belt surrounding the nucleus (Fig. 4.2). Finally, there is a concentration of mitochondria just beneath the plasma membrane (Fig. 4.2). The general concept that has emerged from studies of $Ca^{2+}$ transport in the cytosol, ER, and mitochondria is that $Ca^{2+}$ moves easily in the ER lumen, but with much more difficulty in the cytosol, due to the barriers created by the mitochondria [24].

The fact that the physiologically most important $Ca^{2+}$ signals occur in the apical granular area has also prompted interest in the possibility that $Ca^{2+}$ could be released from ZG and possibly other acid pools in the apical pole. In studies on isolated ZG, it was shown that both $IP_3$ and another $Ca^{2+}$-releasing messenger, cyclic ADP-ribose (cADPR, derived from NAD) can liberate $Ca^{2+}$ stored in this organelle (see Fig. 4.4). This has been

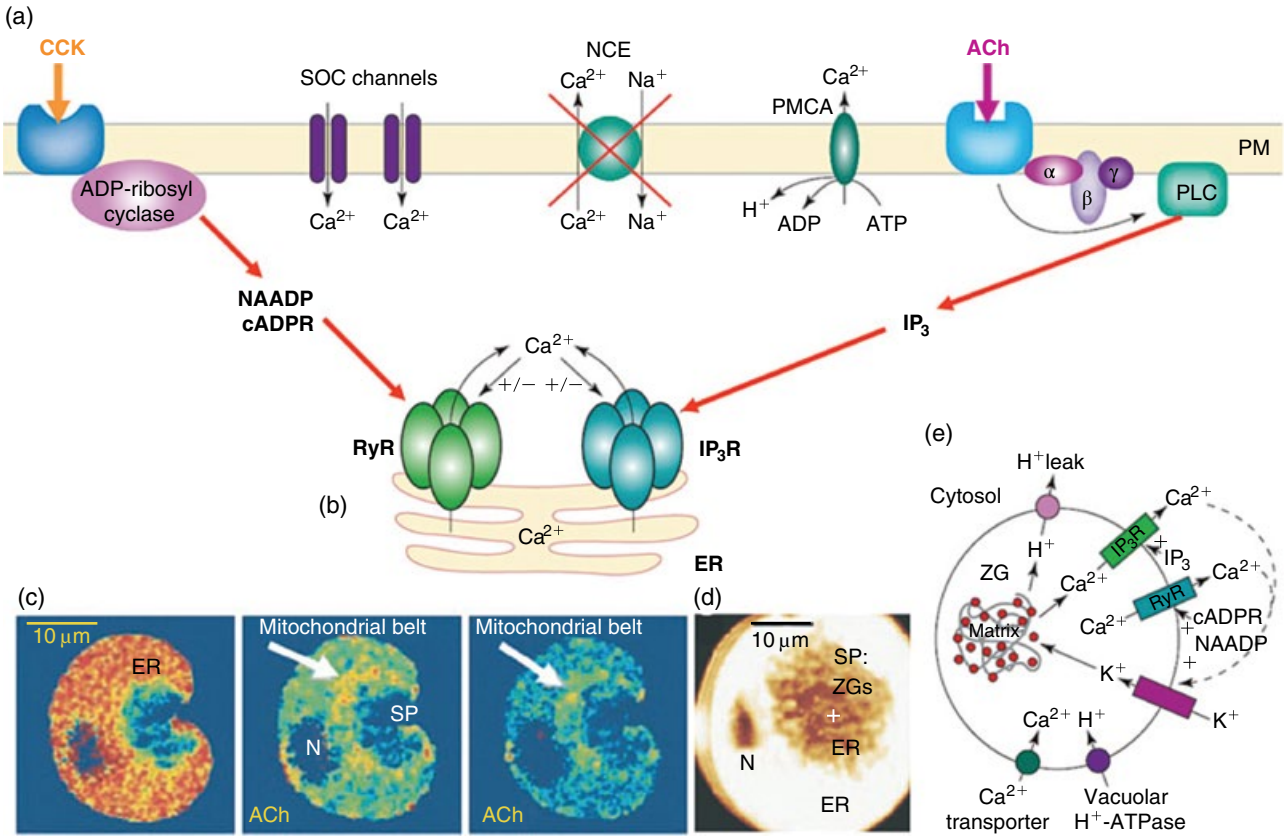

**Figure 4.4** $Ca^{2+}$ transport and signaling events in acinar cell. (a) Events at the plasma membrane. Two receptor pathways are shown. CCK interaction with CCK1 receptors results in activation—via an unknown mechanism—of the cytosolic enzyme ADP-ribosyl cyclase, which generates two separate messengers, namely cADPR and NAADP. ACh binding to muscarinic M3 receptors activates, via interaction with a classical trimeric G-protein, phospholipase C (PLC) generating the messenger $IP_3$ (as well as diacyl glycerol—not shown in diagram). The absence of the $Na^+/Ca^{2+}$ exchanger is highlighted. $Ca^{2+}$ extrusion by the plasma membrane $Ca^{2+}$-activated ATPase is shown. $Ca^{2+}$ entry occurs through store-operated $Ca^{2+}$ channels (SOC). (b) Schematic illustration of $Ca^{2+}$ release from the ER through the $IP_3R$ elicited by $IP_3$ and through the RyR by NAADP or cADPR. Positive and negative $Ca^{2+}$ interactions between the two $Ca^{2+}$ release channels are also shown. (c) Confocal fluorescent images illustrating changes in organellar $[Ca^{2+}]$ following ACh stimulation. The left image shows the high resting $[Ca^{2+}]$ in the ER (mostly in the basal (left) part of the cell). After maximal ACh stimulation, $[Ca^{2+}]$ in the ER has been reduced markedly (shift from warm (red) to cold (green) color) and the perigranular mitochondrial belt is now clearly seen (yellow). This indicates that $Ca^{2+}$ lost from the ER has been taken up in part by the mitochondria. The third image shows the almost complete loss of $Ca^{2+}$ from the ER and the still elevated $[Ca^{2+}]$ in the perigranular mitochondria. (d) Confocal image showing the distribution of fluorescent thapsigargin (white), a very specific marker for the ER $Ca^{2+}$ pump. The optical slice goes through two cells (but only through one nucleus – N). It is seen that by far the highest ER $Ca^{2+}$ pump density is in the basolateral parts of the cell, but it is important to note that there are some light elements in the darker granular (secretory pole – SP) areas signifying ER elements with $Ca^{2+}$ pumps also in this part of the cell. (e) Schematic drawing of $Ca^{2+}$, $H^+$, and $K^+$ transports across the ZG membrane. *Source:* Adapted from Petersen and Sutton 2006 [25].

confirmed in a study of permeabilized pancreatic acinar cells, in which it was shown that $IP_3$, cADPR, and yet another $Ca^{2+}$-releasing messenger, nicotinic acid adenine dinucleotide phosphate (NAADP, derived from NADP), can all release $Ca^{2+}$ from the ER as well as from acid pools in the apical granular area, which is dominated by the ZG [26]. The $Ca^{2+}$ release from the acid pools in the apical pole has been dissected further in a recent study on internally perfused acinar cells, in which it was shown that $Ca^{2+}$ release occurs not only from ZG but also from lysosomes and endosomes [27]. Although all messengers can release $Ca^{2+}$ from all the pools, the balance of the contributions from these various sources depends critically on the specific messenger employed. This allows generation of specific $Ca^{2+}$ signal patterns by differential coupling between various stores and messengers [27]. This may explain the somewhat different $Ca^{2+}$ signal patterns that can be generated by CCK and ACh [28].

## Mechanisms of $Ca^{2+}$ Signal Generation

Fig. 4.4 illustrates some of the most important steps. There are two major signal transduction pathways, one initiated by hormonal (CCK) stimulation and the other by nervous (ACh) stimulation. CCK acts on high-affinity CCK1 receptors in the basolateral plasma membrane [29,30], whereas ACh acts on muscarinic M3 receptors which are also localized predominantly in the basolateral membrane [16]. With state-of-the-art imaging technology, it is now possible to visualize some of the most important signal transduction steps.

Fig. 4.5 demonstrates the ACh-elicited breakdown of $PIP_2$ in the basolateral membrane and the appearance of the water-soluble $Ca^{2+}$-releasing messenger $IP_3$ in the cytosol. The enzyme responsible for $PIP_2$ breakdown, phospholipase C, can in some cases be $Ca^{2+}$ activated. However, the experimental result shown in Fig. 4.5

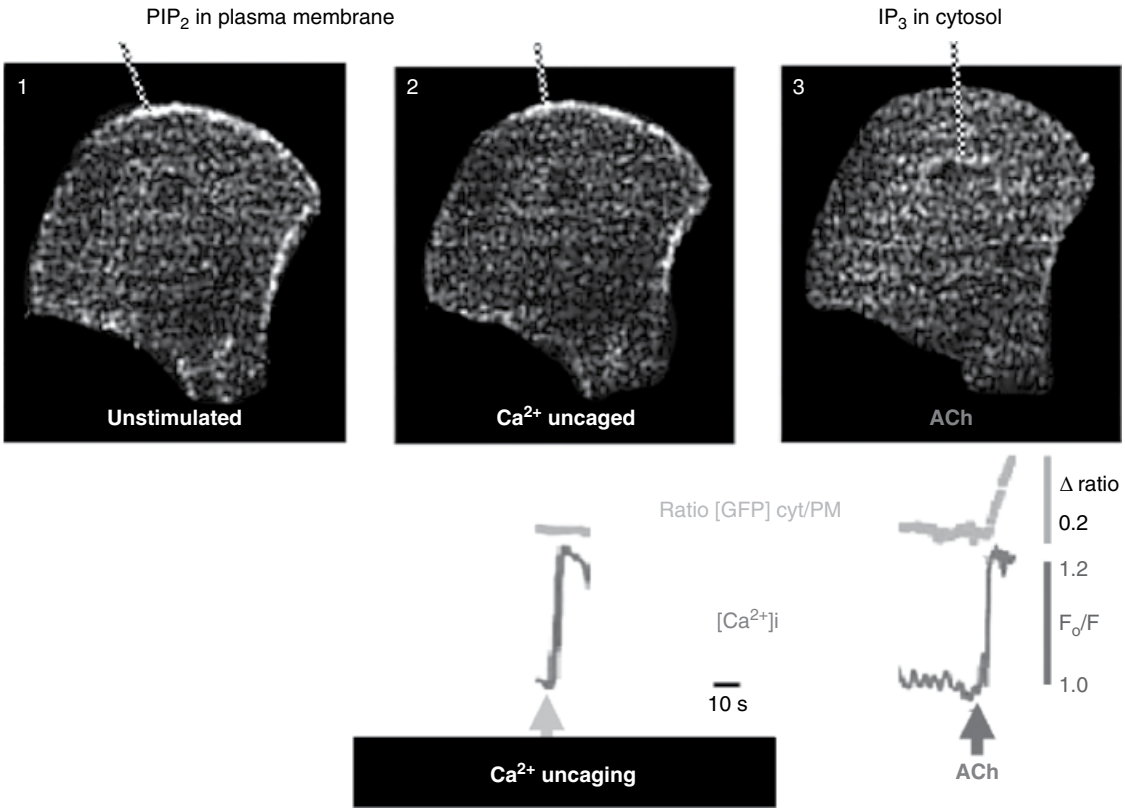

**Figure 4.5** Acetylcholine (ACh)-induced breakdown of phosphatidylinositol 4,5-bisphosphate ($PIP_2$) in the plasma membrane (PM) and generation of inositol 1,4,5-trisphosphate ($IP_3$) in the cytosol (cyt). The green fluorescent protein (GFP)-linked PH domain of $PLC_\delta 1$ binds with high affinity to both $PIP_2$ and $IP_3$. (1) Before stimulation, the main GFP fluorescence is seen in the basolateral membrane, indicating the presence of $PIP_2$ at this site. (2) Generation of a substantial rise in $[Ca^{2+}]_i$ by photolytic release of $Ca^{2+}$ into the cytosol from caged $Ca^{2+}$ does not cause any reduction in the $PIP_2$ concentration in the membrane. (3) ACh (1 μmol/L) causes a rise in $[Ca^{2+}]_i$ of similar magnitude to that seen after $Ca^{2+}$ uncaging, but in this case there is loss of GFP fluorescence from the basolateral membrane, signifying loss of $PIP_2$, and appearance of fluorescence in the cytosol indicating appearance of $IP_3$. *Source:* Adapted from [31] with permission.

demonstrates that, at least in the pancreatic acinar cell, the disappearance of $PIP_2$ from the plasma membrane and the appearance of $IP_3$ in the cytosol are not secondary to $Ca^{2+}$ signal generation, since a directly generated $Ca^{2+}$ signal (via uncaging of $Ca^{2+}$ in the cytosol) does not induce these effects, whereas ACh does.

Direct infusion of $IP_3$ into isolated cells elicits repetitive cytosolic $Ca^{2+}$ spikes confined to the apical granular pole (see Fig. 4.6), in this way mimicking the effect of externally applied ACh (see Fig. 4.2). The importance of functional $IP_3$ receptors ($IP_3R$) for ACh-elicited $Ca^{2+}$ signal generation and secretion in pancreatic acinar cells has been demonstrated very clearly by knockout experiments, in which it was shown that knockout of either type 2 or type 3 $IP_3R$ had very little effect, whereas double knockout of both these receptors abolished ACh-elicited $Ca^{2+}$ signal generation as well as secretion [34]. This directly confirms earlier data in which it was shown that intracellular infusion of the $IP_3R$ antagonist heparin abolished both $IP_3$- and ACh-elicited $Ca^{2+}$ spiking [35].

There is no doubt about the crucial importance of $IP_3R$ in controlling $Ca^{2+}$ signals and thereby secretion, but $IP_3$ is not the only important internal messenger. More than 10 years ago, it was already known that cADPR can evoke $Ca^{2+}$ signals that are very similar to those elicited by $IP_3$. Pharmacologic data indicate that cADPR primarily activates the ryanodine receptor (RyR), a different class of intracellular $Ca^{2+}$ channel from the $IP_3R$ (see Fig. 4.4) [36]. The physiologic importance of this finding only became clear several years later, when it was shown that $Ca^{2+}$ signals generated by physiologic CCK concentrations (low picomolar) could be blocked by a cADPR antagonist, whereas this was not the case for ACh-elicited $Ca^{2+}$ signaling [37].

More recently, it has become clear that the novel $Ca^{2+}$-releasing messenger NAADP has a very specific role in $Ca^{2+}$ signal generation. NAADP is a real intracellular messenger for CCK-induced activation of pancreatic acinar cells. Work from Galione's group in Oxford shows that physiologic CCK concentrations (1–10 pmol/L)

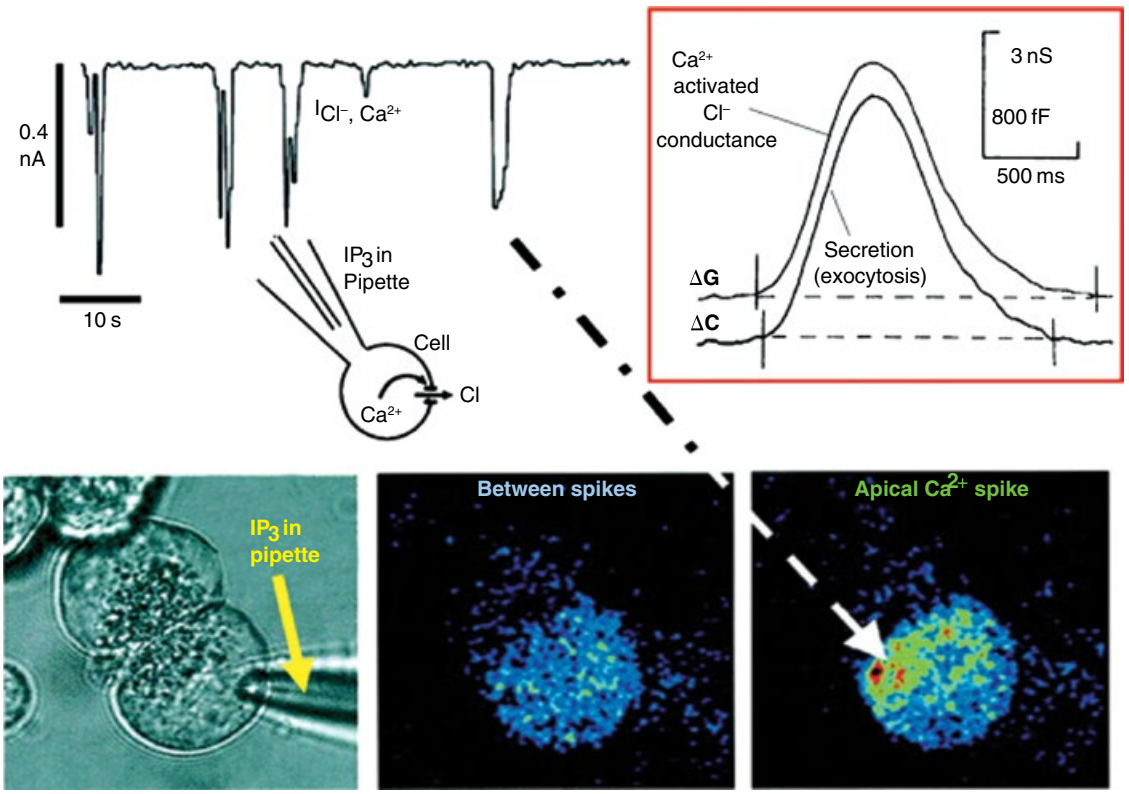

**Figure 4.6** $IP_3$-elicited local apical $Ca^{2+}$ spikes and exocytotic secretion. The main part of the figure shows the result from a patch clamp experiment with internal acinar cell perfusion. The trace shows the repetitive spikes of $Ca^{2+}$-dependent $Cl^-$ current elicited by intracellular $IP_3$ infusion (10 µM). The images below illustrate the configuration and the distribution of the elevated $[Ca^{2+}]_i$ during the height of a spike. It is clearly seen that the $Ca^{2+}$ signal occurs in the apical granular pole. *Source:* Adapted from Cancela et al. 2002 [32]. The insert (in red frame) shows correlation between a single apical $Ca^{2+}$ spike (during $IP_3$ infusion), recorded here as an increase in $Cl^-$ conductance (ΔG), and the exocytotic response recorded as an increase in membrane capacitance (ΔC). It is seen that the increase in $Cl^-$ conductance (a sensitive indicator of $[Ca^{2+}]_i$) slightly precedes the rise in capacitance and that the secretory response is completed just before $[Ca^{2+}]_i$ returns to the inter-spike level. *Source:* Adapted from Maruyama and Petersen 1994 [33].

evoke clear and dose-dependent increases in the cellular NAADP concentration. This effect is specific for CCK, since ACh has no effect on the NAADP level [38].

Intracellular infusion of NAADP, even at concentrations much lower (nanomolar) than those needed to obtain effects of $IP_3$ or cADPR, elicits repetitive cytosolic $Ca^{2+}$ spikes in the apical pole that look very similar to those generated by $IP_3$ and cADPR [32]. The NAADP receptor has the interesting property that it can be inactivated by relatively high (micromolar) intracellular NAADP concentrations. Using such selective inhibition of the NAADP receptor, it has been shown that $Ca^{2+}$ spiking evoked by physiologic CCK concentrations (<10 pmol/L) is blocked by a high intracellular NAADP concentration. This blocking effect is specific for the CCK response, since ACh-elicited $Ca^{2+}$ spiking is unaffected [39]. Studies on isolated nuclei (basically a pure ER preparation) have shown that the primary $Ca^{2+}$-releasing effect of both cADPR and NAADP is mediated by RyR, whereas $IP_3$ primarily activates $IP_3R$ [40].

$Ca^{2+}$ signaling events in intact acinar cells are complex, since it has been demonstrated that repetitive $Ca^{2+}$ spiking requires cooperation between functionally active $IP_3$ and RyR [24]. These conclusions are summarized in Fig. 4.4, highlighting $IP_3$-mediated $Ca^{2+}$ release from $IP_3R$ in the ER and cADPR- and NAADP-elicited $Ca^{2+}$ release from RyR. The important $Ca^{2+}$-mediated positive and negative interactions between $IP_3R$ and RyR are also shown (Fig. 4.4). These positive and negative interactions are functionally important. For example, a $Ca^{2+}$ signal initiated by an increase in the intracellular $IP_3$ concentration will subsequently activate RyR, inducing further $Ca^{2+}$ release. This positive feed-forward effect explains the rising phase of the cytosolic $Ca^{2+}$ spike. However, at a higher level of $[Ca^{2+}]_i$, a further $[Ca^{2+}]_i$ rise inhibits opening of both $IP_3R$ and RyR. This explains the falling phase of the spike [41]. Fig. 4.4 also shows that very similar processes occur in the ZG. They also contain both $IP_3R$ and RyR. Furthermore, there is now also evidence in pancreatic acinar cells (not illustrated in Fig. 4.4) demonstrating $Ca^{2+}$ release from other acid stores, such as lysosomes and endosomes [27]. It has recently become clear that there is another class of channel involved in intracellular $Ca^{2+}$ release, namely the so-called two-pore channel (TPC). In the pancreatic acinar cells, these channels are important specifically for the $Ca^{2+}$ release evoked by CCK, which is mediated by NAADP. The sequence of events with regard to CCK-elicited $Ca^{2+}$ signal generation is likely to be an initial release of a very small (trigger) amount of $Ca^{2+}$ from endosomes/lysosomes, which is then amplified by a much more substantial liberation of $Ca^{2+}$ from the ER and the zymogen granules occurring via RyR [42].

## $Ca^{2+}$ Entry and Exit

Although the primary event responsible for activation of secretion by ACh or CCK is intracellular $Ca^{2+}$ release, it is also very important for both physiology and pathology to consider the overall cellular $Ca^{2+}$ homeostasis, that is, $Ca^{2+}$ entry and exit. All cells have to be protected against cellular $Ca^{2+}$ overload, since it is well established that this causes cell death [43]. The plasma membrane must therefore be relatively impermeable to $Ca^{2+}$ and there must be mechanisms for cellular $Ca^{2+}$ extrusion. As shown in Fig. 4.4, $Ca^{2+}$ entry and exit across the plasma membrane of pancreatic acinar cells is controlled by specific transport mechanisms. Unlike many electrically excitable cells (e.g., cardiac cells), the acinar cells do not possess functional $Na^+/Ca^{2+}$ exchangers, so that the only mechanism for extruding $Ca^{2+}$ across the plasma membrane is via the plasma membrane $Ca^{2+}$-activated ATPase (PMCA) (Fig. 4.4). This pump is activated by increases in $[Ca^{2+}]_i$ above the basal level of 0.1 µmol/L, but has limited capacity. Interestingly, this pump is not uniformly distributed over the plasma membrane, but is specifically concentrated in the apical plasma membrane and therefore extrudes $Ca^{2+}$ principally into the acinar lumen (see Fig. 4.7). The concentration of the pump in the apical membrane is functionally important, since the principal intracellular $Ca^{2+}$ release sites are located in the apical pole (Figs 4.2 and 4.6), but carries the risk that $Ca^{2+}$ overload, due to inappropriate $Ca^{2+}$ entry across the basal membrane in pathologic conditions, cannot be dealt with adequately [25].

Physiologic stimulation of acinar cells does not primarily increase the permeability of the plasma membrane for $Ca^{2+}$, but after depletion of the ER $Ca^{2+}$ store there is specific opening of the so-called store-operated $Ca^{2+}$ channels in the basolateral membrane. This can most easily be visualized by measuring the uptake of $Ca^{2+}$ entering the base of the cell into the peripheral mitochondria situated immediately beneath the plasma membrane, as shown in Fig. 4.7. In these types of experiments, the ER $Ca^{2+}$ store is depleted by poisoning the $Ca^{2+}$ pump in the ER very specifically with thapsigargin in the absence of external $Ca^{2+}$. Thereafter, $Ca^{2+}$ is readmitted to the external solution and an increase in the $Ca^{2+}$ concentration of those mitochondria situated very close to the plasma membrane can be visualized directly (Fig. 4.7). The nature of the store-operated $Ca^{2+}$ channels in the pancreatic acinar cells has been clarified by patch clamp studies, in which it has been possible to record directly the tiny $Ca^{2+}$ currents flowing across the baso-lateral membrane upon depletion of the ER $Ca^{2+}$ store. The biophysical properties of this current shows that the

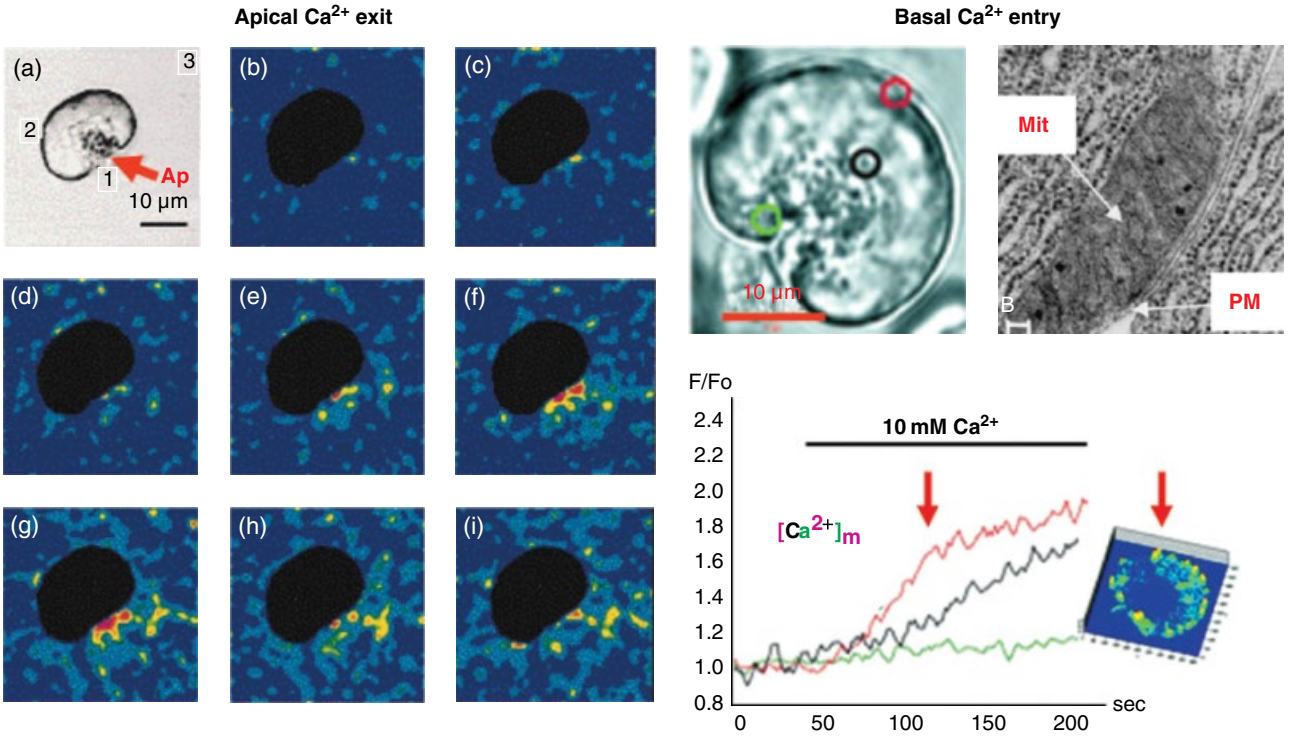

**Figure 4.7** Overall $Ca^{2+}$ homeostasis: $Ca^{2+}$ entry and exit. The left part illustrates an experiment in which $[Ca^{2+}]$ is measured outside an isolated acinar cell by using a $Ca^{2+}$-sensitive fluorescent indicator linked to high molecular weight dextran, thereby limiting the indicator mobility. The morphology of the cell, with clear identification of the granular apical (Ap) pole is shown in (a). (b) to (i) are fluorescent images (taken at 3-s intervals) showing the distribution of the extracellular $[Ca^{2+}]$ rise immediately following stimulation with ACh (10 µM). It is clear that the $Ca^{2+}$ extrusion from the cell occurs predominantly across the apical membrane. The right part of the figure illustrates the rise in $[Ca^{2+}]$ of mitochondria close to the basal plasma membrane during store-operated $Ca^{2+}$ entry. Mitochondrial $[Ca^{2+}]$ ($[Ca^{2+}]_m$) was measured with a fluorescent probe and traces from three regions of interest (red, black, and green) are shown. The cell was initially poisoned with thapsigargin in the absence of external $Ca^{2+}$ to deplete the ER of $Ca^{2+}$. During the time period indicated by the bar labelled 10 mM $Ca^{2+}$, $Ca^{2+}$ was readmitted to the external solution and it is seen that there was a marked rise in $[Ca^{2+}]_m$ particularly in the red region of interest, very close to the basal plasma membrane. The image marked with a red arrow shows the distribution of the elevated $[Ca^{2+}]$ at the time indicated by a similar red arrow above the fluorescence traces. Clearly the elevation of $[Ca^{2+}]_m$ has essentially occurred in a region very close to the plasma membrane. The EM picture shows a mitochondrion (Mit) situated very close to the plasma membrane (PM). *Source:* Adapted from Belan et al. 1996 [44] and Park et al. 2001 [45].

channels belong to the very $Ca^{2+}$-selective CRAC ($Ca^{2+}$ release activated $Ca^{2+}$) channel type, which is also present in various immune cells [46]. These channels, including those in the acinar cells, can be blocked by very specific CRAC channel inhibitors [46,47].

During sustained stimulation with either ACh or CCK, one can usually observe a plateau of elevated $[Ca^{2+}]_i$, which represents a delicate balance of $Ca^{2+}$ entry through store-operated $Ca^{2+}$ channels in the basal membrane and $Ca^{2+}$ exit mainly through $Ca^{2+}$ pumps located in the apical plasma membrane. $Ca^{2+}$ extrusion is energy-dependent. Therefore, if intracellular ATP levels fall during pathologic conditions, for example when cells are exposed to nonoxidative alcohol metabolites [48], $Ca^{2+}$ extrusion stops and dangerous $Ca^{2+}$ overload occurs, resulting in necrosis [48,49].

## $Ca^{2+}$-Mediated Control of Enzyme Secretion

It has been known for many years that intracellular $Ca^{2+}$ is the main acute regulator of exocytosis [50]. In experiments on the isolated perfused pancreas, it has been demonstrated that during sustained stimulation with high concentrations of ACh or CCK, both fluid and enzyme secretion are acutely dependent on the presence of external $Ca^{2+}$ (see Fig. 4.1). During this phase of the secretory response, the ER will have been partly depleted of $Ca^{2+}$ and $Ca^{2+}$ therefore has to be supplied by entry from the external solution through store-operated $Ca^{2+}$ channels as described earlier. However, during physiologic stimulation, with low concentrations of CCK or

ACh, there is not a sustained elevated $[Ca^{2+}]_i$ but rather a series of short-lasting $Ca^{2+}$ spikes localized specifically in the critical apical region (Figs 4.2 and 4.6). These spikes are essentially independent of external $Ca^{2+}$ and are due to repetitive release of small amounts of $Ca^{2+}$ from the ER [51] and acid stores in the apical pole [27].

Can the short-lasting local $Ca^{2+}$ spikes, evoked by low agonist concentrations or direct intracellular messenger infusion, control secretion? The most sensitive method for evaluating exocytotic secretion is measurement of membrane capacitance. When granules fuse with the plasma membrane, the surface area of the plasma membrane increases, but only transiently since the additional membrane inserted is subsequently removed by the process of endocytosis. As shown in Fig. 4.6 (inset), there is indeed a transient increase in the pancreatic acinar membrane capacitance during an individual short-lasting $Ca^{2+}$ spike, which can most easily be recorded by electrophysiologic methods. It appears that the $Ca^{2+}$ sensitivity of exocytosis is slightly lower than that of $Cl^-$ channel activation in the apical membrane, since the membrane conductance increase precedes the capacitance increase and the membrane capacitance returns to normal before the $Cl^-$ conductance has returned to the prespike resting level (Fig. 4.6). Results, such as those recorded in Fig. 4.6, demonstrate clearly the very fine control exerted by the local apical $[Ca^{2+}]_i$ on exocytotic secretion.

## $Ca^{2+}$-Mediated Control of Fluid Secretion

How is acinar fluid secretion regulated? The generally accepted model for isotonic fluid secretion by exocrine glands is illustrated in Fig. 4.1a. The principal step for activation of fluid secretion is $Ca^{2+}$-activated opening of $Cl^-$ channels, which are specifically located in the apical plasma membrane [52]. This will cause $Cl^-$ exit into the acinar lumen. The increased lumen negativity will attract cations and the principal extracellular cation, $Na^+$, will move through the very leaky junctions between the acinar cells, which are named (inappropriately!) tight junctions. These junctions sit very close to the apical membrane and separate the luminal fluid compartment from the basal and interstitial compartments, and also separate the very different properties of the apical and basolateral membranes (Fig. 4.1a). NaCl in the acinar lumen will osmotically attract water, which can pass through both the cell membranes (via aquaporins) and the tight junctions.

The principal activating step of acinar fluid secretion, namely the exit of $Cl^-$ from the cell interior to the lumen through $Ca^{2+}$-activated $Cl^-$ channels, only occurs if there is an electrochemical gradient favoring transport in this direction. The intracellular $Cl^-$ concentration must be held above thermodynamic equilibrium and a $Cl^-$-accumulating mechanism is therefore needed. As shown in Fig. 4.1a, an $Na^+/K^+/2Cl^-$ cotransporter is situated in the basolateral membrane (for graphical convenience shown in Fig. 4.1a only in the basal membrane). Energy for this process comes from the transmembrane $Na^+$ gradient established by the $Na^+/K^+$ pump, which is also situated in the basolateral membrane. Increased $Cl^-$ secretion requires stimulation of the $Na^+$ pump, which occurs via the increased intracellular $Na^+$ concentration mediated by enhanced turnover of the $Na^+/K^+/2Cl^-$ cotransporter. This in turn requires additional $K^+$ cycling across the plasma membrane, which is mediated by $Ca^{2+}$ activation of specific $K^+$ channels situated in the basolateral membrane (Fig. 4.1a).

As seen in Fig. 4.1a, it is the concerted $Ca^{2+}$ activation of $Cl^-$ and $K^+$ channels that controls the fluid secretion process. It is important to understand that the whole of the basolateral membrane is uniform with regard to distribution of surface membrane ion channels. Thus, the $Ca^{2+}$-activated $K^+$ channels are found not only in the basal membrane as illustrated in Fig. 4.1a, but also in the lateral membranes, up to the tight junctions. Therefore, local apical $Ca^{2+}$ signals will be able to activate both $Cl^-$ channels in the apical membrane and $K^+$ channels in the part of the lateral membrane close to the tight junctions. A limited amount of fluid secretion can proceed without special activation of $K^+$ channels, since rodent pancreatic acinar cells lack $Ca^{2+}$-activated $K^+$ channels [12]. If the resting $K^+$ permeability is sufficiently high, recirculation of $K^+$ can still occur. However, human pancreatic acinar cells, like all salivary and lacrimal glands in all species so far studied, do possess very sensitive $Ca^{2+}$-activated $K^+$ channels, which undoubtedly contribute to the fine regulation of human acinar fluid secretion [53]. In the human acinar cells, these $Cl^-$ and $K^+$ channels will be activated by the short-lasting repetitive local $Ca^{2+}$ signals in the secretory granule region, which have been directly demonstrated in response to stimulation with either ACh or physiologic concentrations (low pM) of CCK [54].

## Dangers of $Ca^{2+}$ Signaling

As described in this chapter, local $Ca^{2+}$ signaling elicited by physiologically relevant agonist concentrations is a remarkably precise mechanism for fine regulation of pancreatic acinar secretion (Fig. 4.6). These $Ca^{2+}$ signals also control the production of ATP (Fig. 4.3), which is required to fuel both fluid and enzyme secretion. However, $Ca^{2+}$ signaling carries a risk of cellular

$Ca^{2+}$ overload, which has the capacity to kill cells [43]. This occurs when acinar cells are hyperstimulated with, for example, CCK. In this situation $Ca^{2+}$ spiking is replaced by a sustained elevated $[Ca^{2+}]_i$ which, by a still poorly understood mechanism, activates the digestive proteases inside the cells [25]. The sustained elevated $[Ca^{2+}]_i$ is due to open CRAC channels and can be severely reduced by CRAC channel inhibitors [46,47]. A sustained elevated $[Ca^{2+}]_i$, unlike repetitive short-lasting $Ca^{2+}$ spikes, does not stimulate mitochondrial ATP production, but inhibits it [55]. The combination of a global and sustained high $[Ca^{2+}]_i$ with a low cytosolic ATP level is lethal [56]. Intracellular digestive enzyme activation is a hallmark of pancreatitis, which is mostly related to biliary disease or excessive alcohol intake. Both bile-related and alcohol-related acute pancreatitis are due to cytosolic $Ca^{2+}$ overload and the associated reduced cytosolic ATP level, which have been brought about by excessive opening of CRAC channels in the plasma membrane triggered by excessive release of $Ca^{2+}$ from intracellular stores. Both bile acids and the combination of ethanol and fatty acids (generating fatty acid ethyl esters) have the capacity to elicit excessive release of $Ca^{2+}$ from intracellular stores [48,57]. The cytosolic $Ca^{2+}$ overload leads to mitochondrial $Ca^{2+}$ overload which causes opening of the so-called mitochondrial permeability transition pore (MPTP) and this depolarizes the inner mitochondrial membrane resulting in loss of ATP production [58,59]. The dangerous effects of bile acids or fatty acid ethyl esters can be markedly inhibited by reducing the intracellular $Ca^{2+}$ release via caffeine inhibition of $IP_3$ receptors [35,58], by reducing $Ca^{2+}$ inflow via CRAC channels using specific CRAC channel inhibitors [46,60] or by inhibiting the MPTP [59]. The pancreatic acinar cell therefore lives dangerously. It very effectively employs $Ca^{2+}$ signaling as a finely coordinated mechanism for regulation of both fluid and enzyme secretion, but excessive intracellular $Ca^{2+}$ release or $Ca^{2+}$ entry has the capacity to cause necrosis.

## Introduction

The cardinal function of the pancreatic duct is fluid and $HCO_3^-$ secretion. Pancreatic ductal secretion is a fundamental function of the pancreas that determines the volume and the electrolyte composition of the pancreatic juice and guards the acinar cells from damage by various stressors. Ductal fluid and electrolyte transport is compromised in diseases that stress the pancreas, such as cystic fibrosis and pancreatitis. Ductal secretion is coupled to acinar cell secretion that provides the initial isotonic, plasma-like fluid. The duct then secretes the bulk of the fluid in the pancreatic juice by making economical and recirculating use of the electrolytes provided by acinar cells. Therefore, to understand ductal secretion and physiology, we have to understand the mechanism of acinar secretion and its regulation. The generation and secretion of fluid of defined composition by acinar and duct cells are mediated by selective transporters at the basolateral and luminal membranes that mediate vectorial transport of osmotically active ions. Ductal and acinar cell secretion is highly regulated at both the resting and secreting states by multiple inputs that transmit their signals through the two main second messengers $Ca^{2+}$ and cAMP. The $Ca^{2+}$ and cAMP inputs are integrated into a synergized high-fidelity final response. Other important regulators of the entire secretory process are the transported ions. This is highlighted in the regulation of ductal transporters and secretion by intracellular $Cl^-$. This chapter discusses the principles of ductal fluid and $HCO_3^-$ secretion and its regulation and how it can be corrected in pancreatic disease states.

## Sequential Secretion by Acinar and Duct Cells

### Fluid and Electrolyte Secretion by Acinar Cells

Pancreatic fluid and electrolyte secretion is a two-step, sequential process. The acinar cells secrete a small amount of isotonic, NaCl-rich fluid and the duct secretes most of the fluid and determines the final ion composition of the pancreatic juice [1]. Understanding ductal secretion requires an understanding of acinar cell secretion. The key transporters and the mechanism of fluid secretion by acinar cells are modeled in Fig. 5.1. Vectorial ion transport depends on the $Na^+$ and $K^+$ gradients and the membrane potential that are set by the basolateral $Na^+$,$K^+$-ATPase pump [2]. The $Ca^{2+}$-activated $K^+$ channel at the basolateral membrane Kcnma1 sets the membrane potential near the $K^+$ diffusion potential of about −60 mV [3]. About 60–70% of acinar cells' salt uptake is mediated by the ubiquitous basolateral $Na^+/K^+/2Cl^-$ cotransporter NKCC1 [1]. The remaining salt uptake is mediated by the basolateral $Na^+/H^+$ exchanger NHE1 and by a $Cl^-/HCO_3^-$ exchange activity. It is generally assumed that the ubiquitous AE2 mediates the $Cl^-/HCO_3^-$ exchange that supports fluid flux. However, recent work on salivary glands revealed that another $Cl^-/HCO_3^-$ exchange called AE4 mediates the exchange that drives fluid secretion [4]. NHE1 and AE2 also control the cytoplasmic pH ($pH_{in}$) to prevent large fluctuations of $pH_{in}$ during the secretion [5,6]. Under resting conditions, NKCC1, AE2, and AE4 maintain intracellular $Cl^-$ ($Cl^-_{in}$) at 40–60 mM [7]. The importance of $Cl^-_{in}$ is

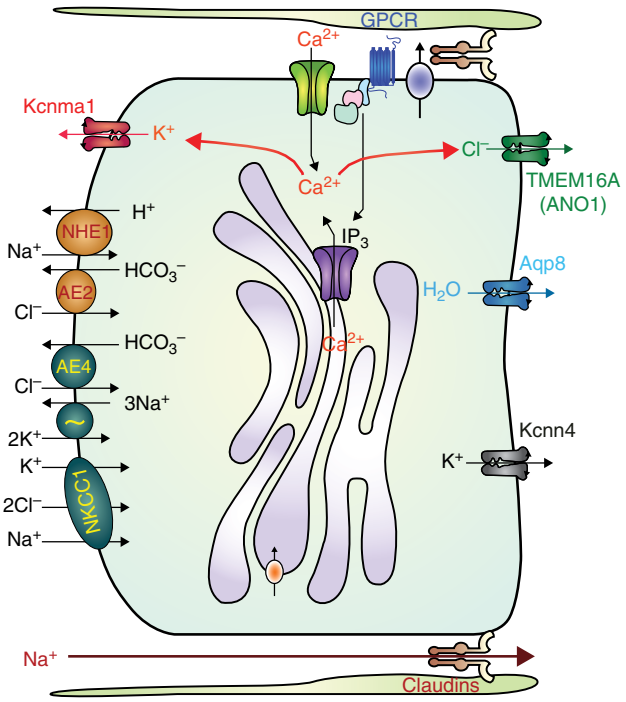

**Figure 5.1** Mechanism of fluid and electrolyte secretion by acinar cells. The model shows the key transporters and the relationships between them that mediate the bulk of fluid and electrolyte secretion by acinar cells.

discussed later in relation to regulation of the secretory process. $Cl^-$ exits across the luminal membrane through the $Ca^{2+}$-activated $Cl^-$ channel TMEM16A/Ano1 [8] and water flows through the water channel AQP8 [9]. The acinar cells' tight junction is the main route of transcellular $Na^+$ flux, which may be mediated by one of the acinar claudins [10].

Acinar cell fluid and electrolyte secretion is regulated by Gq-coupled receptors that increase free cytoplasmic $Ca^{2+}$ ($[Ca^{2+}]_i$) and is enhanced by the cAMP/PKA pathway. Physiological stimulation involves activation of only 1–5% of the G proteins that evoke $Ca^{2+}$ oscillations to prevent $Ca^{2+}$ toxicity by a much stronger stimulation. The $Ca^{2+}$ oscillations initiate at the apical pole and often propagate to the basal pole [11,12]. Acinar cell secretion starts by an increase in apical $[Ca^{2+}]_i$ to activate Ano1 [8], propagation of $[Ca^{2+}]_i$ to the basal pole to activate the $K^+$ channels [13], $Cl^-$ efflux into the luminal space, and $K^+$ efflux to the interstitial space. $Na^+$ transport through the tight junctions results in the net secretion of NaCl and generation of an osmotic gradient that drives water flow through Aqp8. The resulting cell shrinkage reduces $[Ca^{2+}]$ and activates the volume-sensitive NKCC1 [14], NHE1 [15], and AE2 [16] to recover cytoplasmic electrolytes and cell volume. The cycle is repeated with each $Ca^{2+}$ spike making acinar cells function as a $Ca^{2+}$-driven ion and water pump.

## Fluid and Electrolyte Secretion by Duct Cells

The main transporters mediating ductal fluid and $HCO_3^-$ secretion are shown in Fig. 5.2. Transport is fueled by the $Na^+$ gradient and the membrane potential set the $Na^+$,$K^+$-ATPase pump [17], the $K^+$ channels $K(Ca^{2+})1.1$ [18], and an unknown basolateral $K^+$ channel. $HCO_3^-$ enters the ducts by basolateral $1Na^+$–$2HCO_3^-$ cotransport [19,20] mediated by the electrogenic NBCe1-B isoform [21] that accumulates cytoplasmic $HCO_3^-$ and osmolytes. The basolateral $Na^+/H^+$ exchanger NHE1 [20] and $Cl^-/HCO_3^-$ exchange, likely AE2, control $pH_{in}$ and $Cl^-_{in}$, which is required for stimulated secretion [22].

The bulk of $HCO_3^-$ exit across the luminal membrane is mediated by the interrelated activity of the cAMP-activated $Cl^-$ channel cystic fibrosis transmembrane conductance regulator (CFTR) and the exchanger slc26a6 [1]. Slc26a6, is an electrogenic $1Cl^-/2HCO_3^-$ exchanger [23,24] that mediates net solute transport and therefore, in addition to $HCO_3^-$ secretion, slc26a6 is essential for ductal fluid secretion. CFTR has finite $HCO_3^-$ permeability [25] and CFTR-mediated $HCO_3^-$ flux becomes important at the distal portion of the ducts when luminal and cytoplasmic $Cl^-$ are low. Other luminal membrane ductal transporters of note are the $Na^+/H^+$ exchanger NHE3 [26] and $H^+$,$K^+$-ATPase pump ATP12A [27]. Recent work showed that expression of ATP12A in the luminal membrane and pharmacological inhibition of ATP12A reduced ductal secretion suggested to be due to inhibition of $H^+$ absorption [27]. However, molecular studies showed expression of ATP12A in the airway epithelium that secretes $H^+$ in exchange for $K^+$ and contributes to the pathology in cystic fibrosis [28], a disease that prominently affects the pancreas. It is clear that ATP12A plays an important role in the duct, but the underlying mechanism remains to be established. We have suggested that $H^+$-secreting transporters such as NHE3 and perhaps ATP12A function to salvage $HCO_3^-$ in the ductal resting state [26] (Fig 5.2a).

Ductal secretion is stimulated by the Gs-coupled secretin receptor that transmits its signal by increasing cAMP to activate protein kinase A (PKA) [1]. PKA phosphorylates the R domain of CFTR to activate the channel. CFTR then activates the slc26a6 by interaction of CFTR R domain with the slc26a6 STAS domain [29]. In turn, this interaction further activates CFTR. At the same time, CFTR inhibits NHE3 to prevent $H^+$ secretion into the lumen [30]. The $Cl^-$ absorbed by slc26a6 is recycled by CFTR to maintain $HCO_3^-$ secretion by slc26a6. Net osmolyte secretion by slc26a6 in the form of $HCO_3^-$ together with paracellular $Na^+$ flow drives osmotic water secretion to generate the final volume of the pancreatic juice.

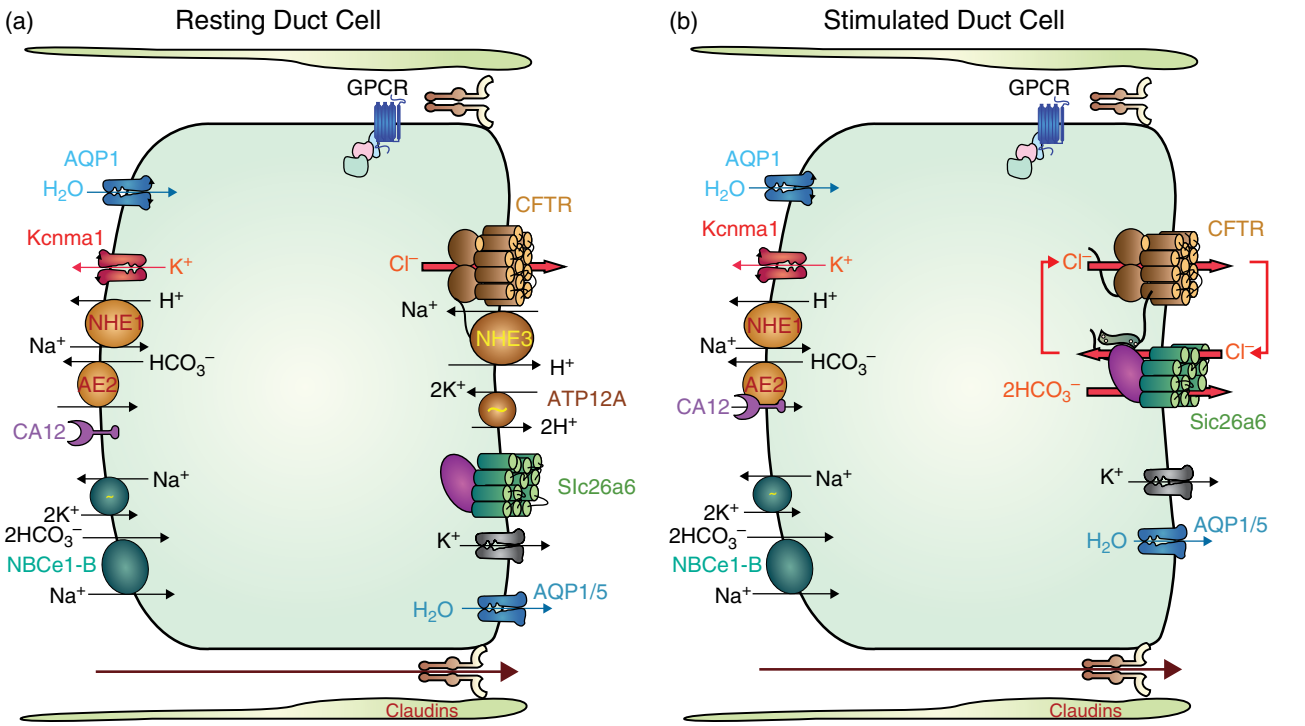

**Figure 5.2** Mechanism of fluid and electrolyte secretion by duct cells. The models show the key transporters and the relationships between them in the resting (a) and stimulated ducts (b). The resting duct can secrete $H^+$ by NHE3 and perhaps ATP12A to salvage $HCO_3^-$, while slc26a6 is away from CFTR and not active. In the stimulated state the $H^+$-secreting transporters are inhibited and slc26a6 and CFTR are mutually activated to cause fluid and electrolyte secretion.

## Regulation of Ductal Secretion

Ductal secretion is dynamically regulated in both the resting and stimulated states by kinase and phosphatase pathways and scaffolding proteins. In addition, $Cl^-_{in}$ regulates the transporters that mediate ductal secretion by affecting their activity and selectivity. The resting state is set by the WNKs and SPAK/OSR1 kinases. Mammals have four WNK [31], with WNK1, WNK3, and WNK4 expressed in the pancreas [1]. The WNKs regulate $Na^+$, $K^+$, $Cl^-$, $HCO_3^-$, and $Ca^{2+}$ transporters in epithelia by determining their surface expression and/or activity [31]. SPAK and OSR1 are homologous stress-activated kinases that act downstream of the WNKs, with the WNKs serving as scaffolds to the SPAK/OSR1. The SPAK/OSR1 can affect surface expression and inhibit or activate the ion transporters [32]. Another level of regulation of the WNK kinases is through interaction with kelch-like 3 (KLHL3) and cullin 3 (CUL3) that regulate WNK levels by ubiquitination and degradation [33].

In the pancreatic duct, the WNKs and the SPAK/OSR1 kinases function in the same pathway, with the WNKs acting as scaffolds for the SPAK/OSR1 kinases. The WNK/SPAK pathway regulates ductal NBCe1-B [34], Slc26a6 [25], and CFTR [34,35] by inhibiting surface expression and the activity of the transporters. Notably, knockdown of the WNKs and of SPAK enhanced stimulated ductal fluid secretion, indicating that the kinases exert tonic inhibition of the secretion [34] to set the basal nonsecretory state (see the model in Fig 5.3a).

The multifunctional protein IRBIT ($IP_3$-binding protein released with $IP_3$) regulates the pancreatic duct-stimulated secretory state. IRBIT was discovered as a protein that binds to the $IP_3$ receptors ($IP_3R$) [36] and as an activator of the NBCe1-B [37]. The IRBIT has an N-terminal protein phosphatase 1 (PP1) binding motif, a PEST domain, a coiled-coil domain, and a PDZ ligand at the end of the C-terminus [38]. The PEST domain has multiple phosphorylation sites that are required for all IRBIT function [38,39]. The coiled-coil domain participates in activation of target proteins by IRBIT [40] and the PDZ ligand locates IRBIT close to the $HCO_3^-$ transporters [34]. IRBIT activates transporters by two mechanisms, by increasing their surface expression and their transport activity. This is best understood with NBCe1-B. The first 85 residues of NBCe1-B form an autoinhibitory domain (AID) [41]. IRBIT interacts with the AID to prevent the NBCe1-B self-inhibition [37]. In addition, IRBIT reverses the inhibition of NBCe1-B by WNK/SPAK by recruiting PP1 to the transporter that dephosphorylates the SPAK phosphorylated Ser65 [42].

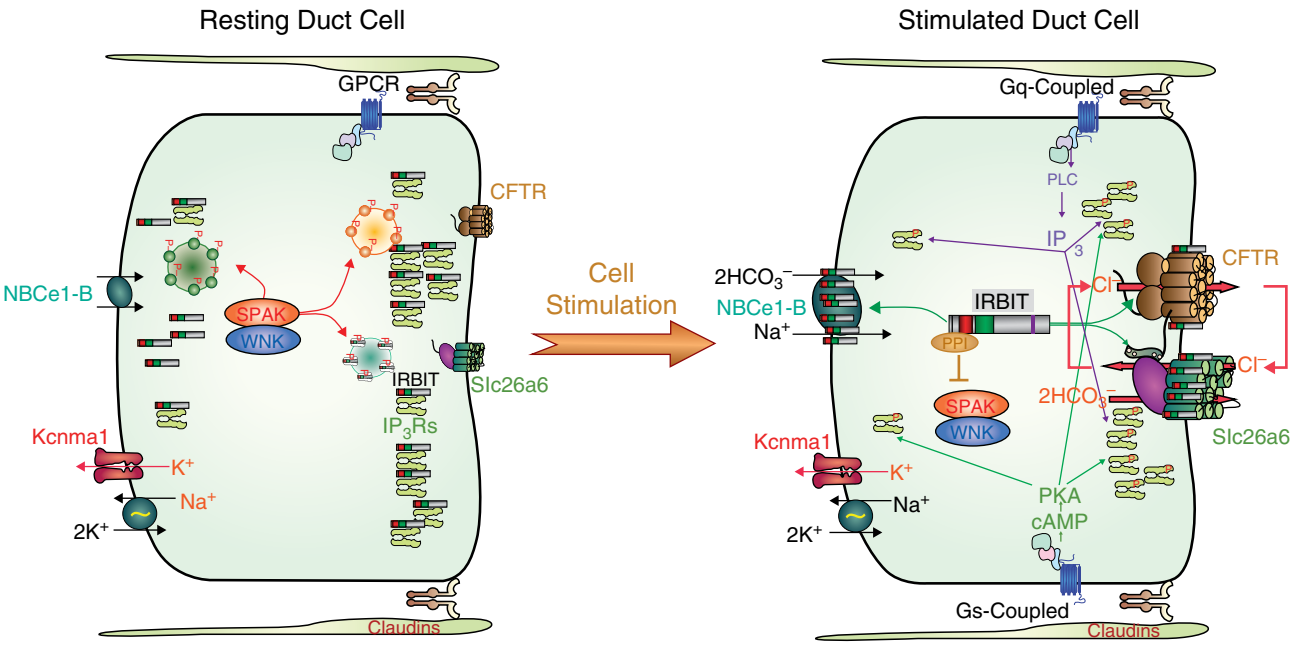

**Figure 5.3** IRBIT mediates synergistic activation of the cAMP and $Ca^{2+}$ signaling pathways. In the resting state, the WNK/SPAK kinases associate with the transporters and SPAK phosphorylates NBCe1-B AID, Slc26a6, and CFTR to sequester most of them in intracellular organelles and IRBIT is sequestered by the $IP_3Rs$. When the cells are stimulated with physiologic concentrations of $IP_3$ and cAMP generating agonists, PKA phosphorylates the $IP_3R$ to facilitate release of IRBIT from the $IP_3R$ by $IP_3$ binding. IRBIT recruits PP1 to the transporters to dephosphorylate them at the SPAK phosphorylation sites and target them to the plasma membrane. IRBIT remains bound to the transporters AIDs further activate the transporters and ductal secretion.

IRBIT also interacts with and potently activates CFTR [34,40] and slc26a6 [42] by interacting with a sequence similar to the NBCe1-B AID that is present in the CFTR R domain and slc26a6 STAS domain [42]. IRBIT similarly recruits the PP1 to NBCe1-B, CFTR, and slc26a6 [34,42]. The key role of IRBIT in ductal secretion was established by showing that knockout of IRBIT in mice markedly inhibits ductal fluid secretion. The reduced secretion due to IRBIT knockdown was partially recovered by knockdown of SPAK [34], showing the interplay between the IRBIT/PP1 and the WNK/SPAK pathways in modulating ductal secretion, as illustrated in Fig 5.3b.

$HCO_3^-$ secretion depends on strict regulation of both intracellular and surface membrane $HCO_3^-$ concentrations, which are determined by carbonic anhydrases (CA). CA are either cytoplasmic or membrane anchored with their active site at the extracellular cell surface [43]. The surface CA control the supply or removal of $HCO_3^-$ at the surface of the plasma membrane and the cytoplasmic CA buffer cytoplasmic $HCO_3^-$. The plasma membrane-localized CA interact with many $H^+$ and $HCO_3^-$ transporters [44]. We know very little about the role and molecular identity of the CA that are important in ductal secretion. Some information became available from human disease in which mutations in CA12 causes salt wasting [45,46]. CA12 is a critical activator of AE2 and ductal secretion. Deletion or mutation in CA12 inhibits ductal secretion by about 50% and overexpression of CA12 markedly increases ductal secretion [22]. Hence activation of CA12 is a potential treatment of ductal hypofunction.

Another prominent regulator of ductal function is $Cl^-_{in}$. $Cl^-_{in}$ has a key role in ductal function by driving $HCO_3^-$ secretion through slc26a6, controlling the luminal membrane potential through CFTR and of $pH_{in}$ through AE2 (Fig 5.2). Sensing $Cl^-_{in}$ is therefore essential for tuning the secretory process. $Cl^-_{in}$ regulates the function of at least two $HCO_3^-$ transporters, NBCe1-B and CFTR. $Cl^-_{in}$ regulates CFTR $HCO_3^-$ permeability [25]. At $Cl^-_{in}$ below 8 mM CFTR became the $HCO_3^-$ channel to increase pancreatic juice $HCO_3^-$ concentration from 120 to 140 mM [47]. A more dramatic regulation by $Cl^-_{in}$ is seen with NBCe1-B. IRBIT-activated NBCe1-B is regulated between 5 and 20 mM $Cl^-_{in}$ [48]. Ductal secretion starts when resting $Cl^-_{in}$ is about 35 mM and decreases to 4 mM toward the latter phase of $Cl^-$ absorption and $HCO_3^-$ secretion [1,49]. At $Cl^-_{in}$ above 20 mM, the activity of NBCe1-B is inhibited by 70%, which is sufficient to support $HCO_3^-$ secretion at the proximal duct. As the demand for cytoplasmic $HCO_3^-$ increases in the face of accumulation of luminal $HCO_3^-$, $Cl^-_{in}$ is reduced toward 4 mM to increase the activity of NBCe1-B threefold [48], which ensures continued $HCO_3^-$ supply.

## The $Ca^{2+}$ and cAMP Pathways Synergize to Activate Ductal Secretion

Synergism between signaling pathways is a fundamental concept in biology that serves to prevent cell toxicity by overstimulation. Signaling pathways function at 1–3% of capacity and synergize to generate the maximal physiological response. The $Ca^{2+}$ and cAMP signaling pathways synergize in a mechanism mediated by IRBIT [42]. At the resting state, IRBIT is bound to $IP_3$ receptors. Physiologic secretin stimulation increases ductal cAMP to phosphorylate the $IP_3$Rs to increase their affinity for $IP_3$ and reduce their affinity for IRBIT [42]. A small increase in $IP_3$ by physiologic stimulation with $Ca^{2+}$-mobilizing receptors releases IRBIT from the $IP_3$R that then binds to CFTR, slc26a6, and NBCe1-B and activates them and ductal secretion [42]. This important physiologic mode of synergism is illustrated in Fig. 5.3.

## Ductal Secretion-Associated Pancreatic Diseases

Ductal fluid and $HCO_3^-$ secretion not only washes digestive enzymes to the intestine, but also protects the parenchyma from damage due to stresses to the pancreas. In addition, as a chaotropic ion, $HCO_3^-$ is essential for solubilization of macromolecules such as digestive enzymes and mucins and divalent ions in biological fluids [1,50]. The duct is the first line of defense of the pancreas that must be breached before damage to acinar cells take place. Damage to ductal secretion occurs in several diseases of the pancreas, including cystic fibrosis (CF) and pancreatitis. CF leads to the destruction of the pancreas and pancreatic insufficiency [51], due to inhibition of ductal fluid and $HCO_3^-$ secretion [1]. Moreover, several studies have identified mutations in CFTR that are associated with chronic pancreatitis [52] and specifically inhibit CFTR-dependent $HCO_3^-$ transport [53] and CFTR $HCO_3^-$ permeability [54], independent of $Cl^-$ channel activity. The importance of the duct in protection of the pancreas and of CFTR in ductal function [55] led to the examination of the state of CFTR in chronic autoimmune [56] and alcoholic pancreatitis [56,57], which revealed mislocalization of CFTR in these forms of pancreatitis. Notably, treatment of autoimmune pancreatitis with corticosteroids ameliorated the disease primarily by increasing ductal $HCO_3^-$ secretion [56]. In animal models, induction of acute pancreatitis by cerulein stimulation, bile infusion, and alcohol treatment impaired ductal function [58].

The intimate involvement of the duct in the health of the pancreas and pancreatic diseases suggests that the duct should be a prime target for therapy. There are several potential targets. One can be activators of IRBIT together with inhibitors of the WNK/SPAK/OSR1 kinases. Because of their involvement in renal salt homeostasis and hypertension [33], such drugs may became available in the future. Another potential target is CA12, which affects ductal function [22] and is modified in several cancers [59]. Drugs affecting CA12 activity are being developed in the cancer field and may become useful for the treatment of pancreatitis. A very promising option is the use of CFTR potentiators and correctors that are approved for the treatment of CF [60]. These drugs should repair CFTR localization and increase ductal secretion to slow progress of the disease and may even improve the function of acinar cells.

## Introduction

Acute pancreatitis is an inflammatory disorder of the pancreas that results in significant morbidity, mortality, and hospitalizations [1,2]. In the United States alone, over 300,000 patients are admitted each year with pancreatitis, with more than $2 billion spent on their care [3]. Currently, there is no specific therapy for acute pancreatitis and treatment of patients revolves around supportive measures. The development of specific therapy for acute pancreatitis will require precise modeling of this disease in animal models and detailed elucidation of its pathogenesis. Over the last few decades, studies in animal and *in vitro* models of acute pancreatitis have led to the emergence of valuable information on both early and late events in the pathogenesis of acute pancreatitis. In this chapter, the major events in the pathogenesis of acute pancreatitis, as observed in experimental models, are described. It appears that although inflammation during acute pancreatitis is initiated in acinar cells, over the course of the disease the inflammation spills into systemic circulation. Uncontrolled systemic inflammation can lead to multiorgan failure, which is the primary cause of morbidity and mortality in acute pancreatitis.

## Models of Acute Pancreatitis

The pathogenesis of pancreatitis has been studied *in vitro* using pancreatic acini isolated from animals and *in vivo* using various animal model systems. Stimulation of acinar cells isolated from the pancreas of mice or rats with secretagogues such as caerulein (cholecystokinin analogue) or carbachol (cholinomimetic agent) leads to secretion of digestive enzymes. Higher doses of these secretagogues leads to inhibition of secretion, a phenomenon that is believed to be critical for acinar cell injury. This *in vitro* acinar cell injury induced by supramaximal stimulation has been used as a tool to model acinar cell injury during acute pancreatitis. Experiments in this relatively simple *in vitro* caerulein hyperstimulation acinar cell model has helped researchers to understand many important early events of pancreatitis, including cytosolic calcium changes, colocalization, intra-acinar zymogen activation, nuclear factor kappa B (NFκB) activation, and inhibition of secretion.

With respect to the animal models, the caerulein hyperstimulation model, in which a supramaximal concentration of the cholecystokinin (CCK) analogue caerulein is used to induce acute pancreatitis in rodents, is most widely used because of its ease of induction, noninvasiveness, and reproducibility. The arginine-induced pancreatitis model, in which administration of L-arginine leads to induction of severe acute pancreatitis, is another commonly used model. The duct obstruction model of acute pancreatitis mimics gallstone obstruction-induced acute pancreatitis in the clinical setting and does not require a sophisticated surgical technique. However, duct ligation in rodents produces only mild pancreatitis without extensive necrosis or infectious complications, and therefore is unsuitable for evaluating these clinically important features. In the duct perfusion model, pancreatitis is induced by infusion of various noxious stimuli, such as bile salts, into the pancreatic duct. Importantly, the severity of pancreatitis in this model can be modulated by controlling the type, concentration, and volume of infusate and the duration and pressure of infusion. The pancreatitis in this model tends to be patchy and limited to the head of the pancreas. The choline-deficient ethionine-supplemented (CDE) diet-induced acute pancreatitis model is another less commonly used model.

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

Although these unique but complementary models have been very useful for the elucidation of the early events in pancreatitis, their relevance to human disease has been questioned. For example, administration of supramaximal doses of cholecystokinin analogues to rodents leads to induction of acute pancreatitis but the presence of cholecystokinin receptors on human acinar cells has not been confirmed. Similarly, with the exception of case reports, excessive levels of L-arginine is not a common cause of pancreatitis in humans. The duct obstruction model and the duct perfusion models are the only animal models that come close to modeling gallstone pancreatitis, the most common cause of acute pancreatitis in humans. Furthermore, no good model for alcohol-induced acute pancreatitis, the second most common cause of human pancreatitis, is available. Ethanol feeding alone in animals causes a mild and variable pathologic response in the pancreas, making investigations into the cellular and molecular mechanisms of ethanol's effect exceedingly difficult. The lack of valid models of acute pancreatitis may partially explain why many investigational therapies (antiplatelet activating factor, antiprotease) that had shown promise in animal models have not lived up to expectations in clinical trials. Although these models are not perfect, they accurately mimic the histopathology and pathophysiology of acute pancreatitis, including some of the clinical aspects. Although better models are needed, a wealth of information on the pathophysiology of acute pancreatitis has been generated using these models and this information should eventually lead to the development of novel and effective therapies. The important early events in acute pancreatitis learned from the experimental models are described in the following.

## Phases of Acute Pancreatitis

Acute pancreatitis is initiated in acinar cells. Injurious stimuli lead to multiple intra-acinar events that culminate in local acinar cell injury and activation of inflammatory pathways and secretion of various cytokines and chemokines. These cytokines and chemokines interact with and activate resident immune cells and also attract inflammatory cells from circulation into the pancreas. The activated neutrophils and immune cells and inflammatory cytokines are responsible for the systemic injury that is the major cause of morbidity and mortality in acute pancreatitis. Furthermore, as discussed later, the systemic inflammation can actually aggravate the local injury by various mechanisms.

When patients with acute pancreatitis present for medical attention, most of the intra-acinar events have already transpired and the inflammation has progressed to the systemic level. Unfortunately, most of the older acute pancreatitis experimental studies evaluated various therapeutic strategies in prophylactic fashion, that is, with the agent of interest administered before induction of acute pancreatitis, which is clinically irrelevant except in cases of endoscopic retrograde cholangiopancreatography (ERCP)-induced acute pancreatitis. This may be another reason why various therapies that have been shown to be effective in animal models have failed to induce clinical improvement. Hence it is important to evaluate novel therapies in experimental models not only prophylactically but also therapeutically.

## Early Intra-Acinar Events in Acute Pancreatitis

### Intrapancreatic Enzyme Activation

The pancreas is an enzyme factory that synthesizes and secretes large amounts of digestive enzymes. These enzymes are stored intracellularly as inactive zymogens to prevent autodigestion of the pancreas. Furthermore, there are many intracellular mechanisms that protect the acinar cells against low levels of intracellular zymogen activation occurring under physiologic conditions. The presence of trypsin inhibitors, nonoptimal pH, and the presence of proteases that degrade the activated enzymes help to protect the acinar cells against damage caused by intra-acinar cell activation of proteases. In healthy organisms, pancreatic proteases remain inactive during their synthesis, secretion from acinar cells, and transport through the pancreatic duct. Once the enzymes have reached the intestinal lumen, enterokinase cleaves the pancreatic zymogen trypsinogen to form trypsin. Trypsin then activates all other pancreatic zymogens (e.g., proelastase, procarboxypeptidase) and thus helps in the digestion of food. In acute pancreatitis, the enzymes are believed to be activated inside the acinar cells. That pancreatitis is autodigestion of the pancreas was first proposed by Chiari in 1896 [4]. This "autodigestion" hypothesis triggered research looking into premature activation of digestive enzymes as a possible mechanism. Since then, a number of studies have demonstrated the findings of premature activation of digestive enzymes, both in experimental models (Fig. 6.1) and in clinical studies. During experimental acute pancreatitis, activation of trypsinogen and other pancreatic zymogens is observed [5–7] as early as 15 min after caerulein-induced acute pancreatitis. That trypsin activation is important for the pathogenesis of acute pancreatitis is supported by the fact that all of the other markers of pancreatitis, such as hyperamylasemia, pancreatic edema, and acinar cell vacuolization, are observed only after the intra-acinar

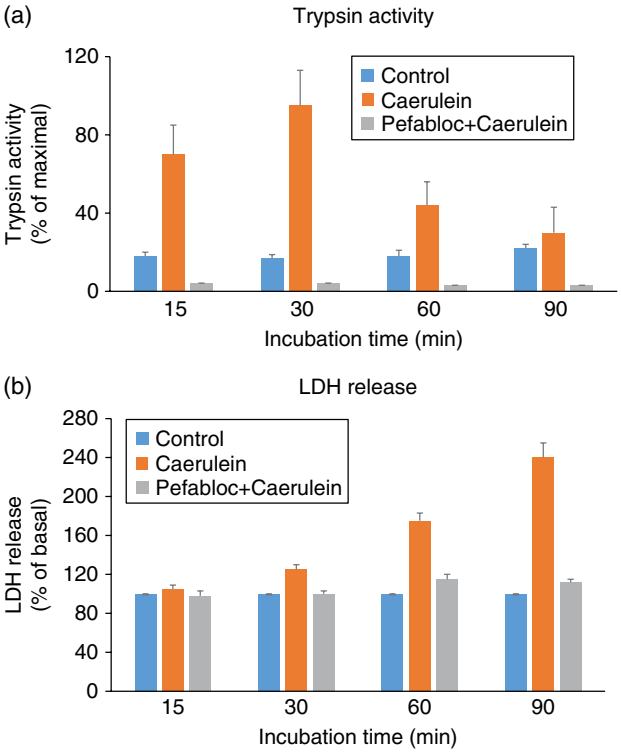

**Figure 6.1** Trypsin activation is observed early on in acute pancreatitis and it contributes to acinar cell injury. (a) Effect of stimulation with a high concentration of caerulein (0.1 μM) on trypsin activation in rat pancreatic acini. Acini were stimulated with either caerulein alone (0.1 μM) or in the presence of Pefabloc (2 mM, added 15 min before addition of caerulein) or incubated in buffer alone for specified times. (b) Increase in trypsin activity in response to a high dose caerulein stimulation resulted in increased release of lactate dehdrogenase (LDH) in the incubation medium, indicating acinar cell injury. This effect was blocked in the presence of the trypsin inhibitor Pefabloc. *Source:* Modified from Hofbauer et al. 1988 [44]. Reproduced with permission.

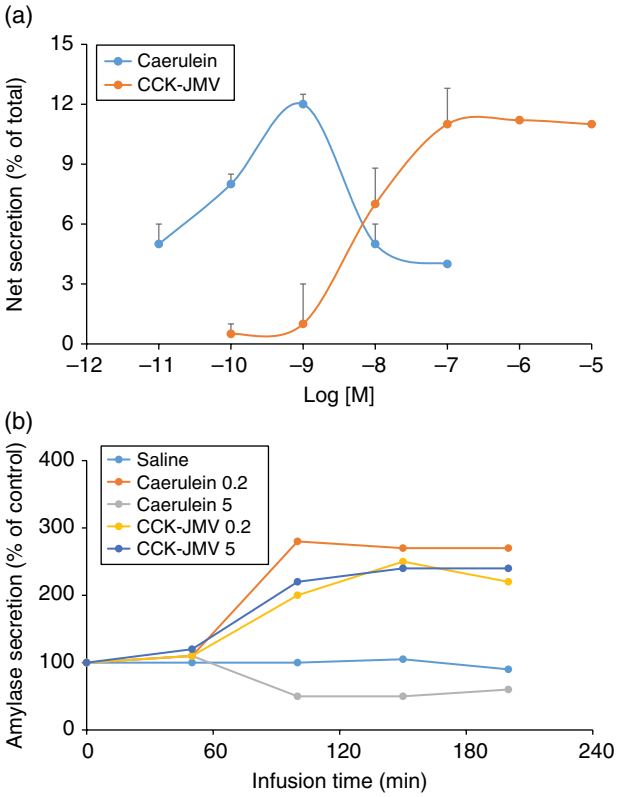

**Figure 6.2** Caerulein but not CCK-JMV-180 leads to inhibition of secretion at supramaximal doses. (a) Effect of caerulein or CCK-JMV-180 on secretion from rat pancreatic acini *in vitro*. (b) Effect of caerulein and CCK-JMV-180 on *in vivo* amylase secretion. Rats were infused with heparinized saline alone or saline containing caerulein (0.2 μg/kg/h, maximal dose), caerulein (5 μg/kg/h, supramaximal dose), CCK-JMV-180 (0.2 mg/kg/h, maximal dose), CCK-JMV-180 (5 mg/kg/h, supramaximal dose), or caerulein (5 μg/kg/h) plus CCK-JMV-180 (5 mg/kg/h). All animals were infused with saline alone for the first 30 min. *Source:* Modified from Saluja et al. 1989 [45]. Reproduced with permission.

zymogen activation has occurred. Furthermore, studies that demonstrated that pretreatment with protease inhibitors (presumptively inhibiting trypsin) reduces the severity of acute pancreatitis in animal models also supported the trypsin central hypothesis of acute pancreatitis. Pretreatment of acinar cells with cell-permeable protease inhibitors (such as Pefabloc) (Fig. 6.1b) prior to supramaximal stimulation by caerulein prevents both zymogen activation and acinar cell injury [8,9]. Hence intrapancreatic enzyme activation is believed to be key for acinar cell injury during acute pancreatitis.

### Inhibition of Secretion

Interestingly, the experimental models of acute pancreatitis suggest that during acute pancreatitis, not only are the zymogens prematurely activated but actually they are also retained inside the acinar cells. As discussed, supramaximal caerulein stimulation is commonly used as an *in vitro* and animal model of acute pancreatitis. It has been observed that at low doses caerulein, being an analogue of secretagogue CCK, stimulates secretion. However, with increasing doses the secretion is actually inhibited (Fig. 6.2a), and it is at the higher secretion-inhibiting doses that changes to acute pancreatitis are observed in both *in vitro* and animal models (Fig. 6.2b), suggesting a role of inhibition of secretion in the pathogenesis of acute pancreatitis. A similar pattern is observed on evaluating other secretagogues. Carbachol at higher doses inhibits acinar cell secretion and induce changes consistent with acute pancreatitis. On the other hand, CCK-JMV-180, an analogue of CCK, stimulates pancreatic secretion and does not inhibit secretion at high doses (Fig. 6.2a). Consistent with the role of inhibition of secretion in the pathogenesis of acute pancreatitis, this secretagogue does not induce acinar cell injury or other changes of acute pancreatitis.

Studies also suggest that reversal of the inhibition of secretion could actually decrease the severity of acute pancreatitis. Proteinase-activated receptor-2 (PAR-2) is expressed on pancreatic acinar cells and is actually activated during acute pancreatitis. The possible ligand for these receptors during acute pancreatitis is trypsin. Interestingly, genetic deletion of PAR-2 increases the severity of acute pancreatitis. Furthermore, stimulation of PAR-2 with the agonist SIGRIL [10] leads to reduced severity of acute pancreatitis and also reversal of the inhibition of secretion observed during acute pancreatitis [11] (Fig. 6.2b).

### Colocalization

Despite all the inbuilt protective systems, there is premature activation of zymogens during acute pancreatitis. Studies have evaluated the mechanism of this premature activation and it appears that early on in acute pancreatitis, the zymogens and lysosomes come together, a phenomenon called colocalization, which has been confirmed by both subcellular fractionation (Fig. 6.3a) and immunolocalization studies (Fig. 6.3b). Colocalization brings the zymogen enzymes and lysosomal enzymes in contact and, in these colocalized organelles, cathepsin B, a lysosomal enzyme, activates the trypsinogen to trypsin. Activated trypsin then has the capability to activate other enzymes. Colocalization has been observed as early as 15 min after initiation of the injury and all other features of acute pancreatitis such as pancreatic edema, hyperamylasemia, and acinar cell injury occur subsequently.

The role of colocalization and cathepsin B in trypsin activation has been confirmed by multiple methods. Pharmacologic inhibition of cathepsin B prevents activation of trypsinogen and results in a reduction of pancreatic injury in models of acute pancreatitis [12]. Similarly, the importance of the cathepsin B in activation of trypsin and induction of injury during acute pancreatitis has been evaluated using cathepsin B knockout mice in which the cathepsin B gene had been deleted by targeted disruption. After induction of experimental secretagogue-induced pancreatitis, the trypsin activity in the pancreas of cathepsin B knockout mice was more than 80% lower than in the wild-type animals [13]. Also, pancreatic damage, as indicated by various parameters, including the extent of acinar tissue necrosis, was substantially lower in the knockout animals [13]. Furthermore, studies suggest that phosphatidylinositol 3-kinase (PI3K) activation and increased cytosolic calcium are required for colocalization. Inhibition of colocalization by inhibiting PI3K [14] and also attenuation of cytosolic calcium by calcium chelator prevents trypsin activation and acinar cell injury during acute pancreatitis, again suggesting that colocalization is the cause rather than the effect of intra-acinar enzyme activation and acute pancreatitis.

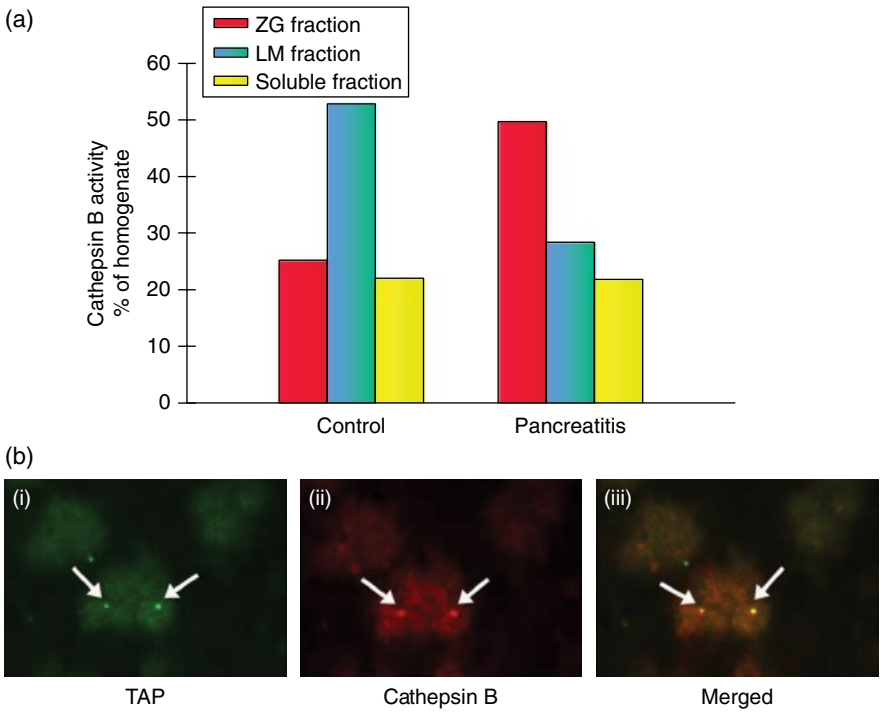

**Figure 6.3** During acute pancreatitis there is colocalization of zymogen enzymes and lysosomes. (a) Subcellular fractionation of acinar cells stimulated with supramaximal caerulein demonstrates increased cathepsin B activity in the zymogen fraction and a decrease in the lysosomal fraction. *Source:* Modified from Saluja et al. 1987 [46]. Reproduced with permission. (b) Supramaximal caerulein stimulation of the acinar cells leads to activation of trypsin as observed by generation of trypsinogen activation peptide (TAP). TAP activity colocalizes with cathepsin B, suggesting that trypsin is activated in the same compartment as cathepsin B.

### Calcium Signaling During Acute Pancreatitis

Intracellular and extracellular calcium homeostasis is important for the survival of a cell. Calcium signaling is closely linked to both the physiology and pathology of pancreatic acinar cells. However, the nature of the calcium signal observed during acute pancreatitis seems to be different with respect to the amplitude and the temporal pattern from that observed during physiologic stimulus–secretion coupling. Physiologically, a secretory signal such as CCK leads to smaller, transient, sometimes oscillatory increases in intracellular calcium, which leads to secretion of the zymogens, whereas a pathologic stimulus leads to a much larger spike followed by a sustained increase in intracellular calcium. Studies suggest that calcium signaling is required but not sufficient for acinar cell injury and other events during acute pancreatitis. The attenuation of the calcium changes during acute pancreatitis by the cytosolic calcium chelator 1,2-bis(*o*-aminophenoxy)ethane-*N*,*N*,*N*′,*N*′-tetraacetic acid (BAPTA) prevents zymogen activation, suggesting that calcium is essential for zymogen activation [9,15]. Prevention of sustained calcium increases by using $Mg^{2+}$, a natural calcium antagonist, also reduces trypsinogen activation and the severity of acute pancreatitis. Interestingly, artificial elevation of intracellular calcium by using different agents, such as thapsigargin or ionomycin, does not cause activation of trypsinogen and other changes of acute pancreatitis, suggesting that although sustained increases in calcium changes are required, they are not sufficient for the induction of acute pancreatitis.

The source of the pathologic calcium changes during acute pancreatitis has also been evaluated. The abnormal increase in cytosolic calcium is due either to excess release from intracellular stores or to influx with or without inadequate clearance of the calcium. Release from endoplasmic and mitochondrial stores, increased influx, and inadequate clearance have all been shown to contribute to the pathologic calcium increase observed during acute pancreatitis.

### Activation of Inflammatory Pathways During Acute Pancreatitis

As time progresses, the local intra-acinar events eventually lead to initiation and progression of systemic inflammation. It is the uncontrolled systemic inflammation that is the major cause of mortality and morbidity during human disease. Studies in experimental models suggest that early on during acute pancreatitis there is activation of intra-acinar inflammatory pathways that induces the synthesis and release of various cytokines and chemokines. NFκB, the master regulator of inflammatory pathways, is activated as early as 15–30 min after initiation of acute pancreatitis in both *in vitro* and animal models. It seems that intra-acinar cytosolic calcium changes in addition to activation of protein kinase C is required for activation of NFκB. Intriguingly, activation of trypsin and of NFκB are independent events. This is clear from experiments in which inhibition of trypsin, by pharmacologic inhibitors, did not influence NFκB activity. That NFκB activation and also local and systemic inflammation are independent of trypsin activation has been further confirmed using mice that lack trypsinogen-7 (T7-KO) gene. It appears that mice have numerous isoforms of trypsinogen but trypsinogen-7 is the isoform responsible for intra-acinar activation of trypsin during acute pancreatitis. Interestingly, T7-KO mice that lack intra-acinar trypsinogen activation have similar degrees of local and systemic inflammation (Fig. 6.4), again suggesting the independence of inflammation and intra-acinar zymogen activation [16]. As already discussed, cathepsin B is essential for activation of trypsin during acute pancreatitis. Halangk et al. [13] showed that cathepsin B knockout (CB-KO) mice have less necrosis than wild-type mice. However, the degree of leukocyte infiltration in the pancreas or lungs during pancreatitis was not affected by the absence of cathepsin B, indicating cathepsin B- and thus trypsin-independent evolution of systemic inflammation.

Once NFκB has been activated, it leads to the synthesis and secretion of cytokines and chemokines. Blockage of NFκB activation (by *N*-acetylcysteine, for example) prevents this induction of cytokine transcription by caerulein hyperstimulation, thus indicating the involvement of NFκB in cytokine activation by caerulein [17]. These chemokines and cytokines then not only attract neutrophils and macrophages into the pancreas but also lead to their activation. It has been postulated that activation of the innate immune system and also release of cytokine and chemokines then propagate the inflammatory injury to the systemic level. There is some controversy with respect to the role of NFκB in the pathogenesis of acute pancreatitis. The inhibition of NFκB activation in the caerulein hyperstimulation model of pancreatitis and also other models of pancreatitis significantly reduces the severity of pancreatitis. When NFκB activation was prevented by use of the antioxidant *N*-acetylcysteine or other means, all parameters of rat caerulein pancreatitis were diminished [17,18]. The only study that has actually shown the beneficial effect of NFκB in acute pancreatitis is that by Steinle et al. [19], in which inhibition of NFκB by pharmacologic inhibition led to greater pancreatic damage, thus suggesting a protective role of NFκB in acute pancreatitis. In a follow up study, the same group demonstrated similar results in genetic NFκB knockout mice [20]. However, the overall consensus in the field suggests that NFκB activation during acute pancreatitis leads to activation of an inflammatory cascade that leads

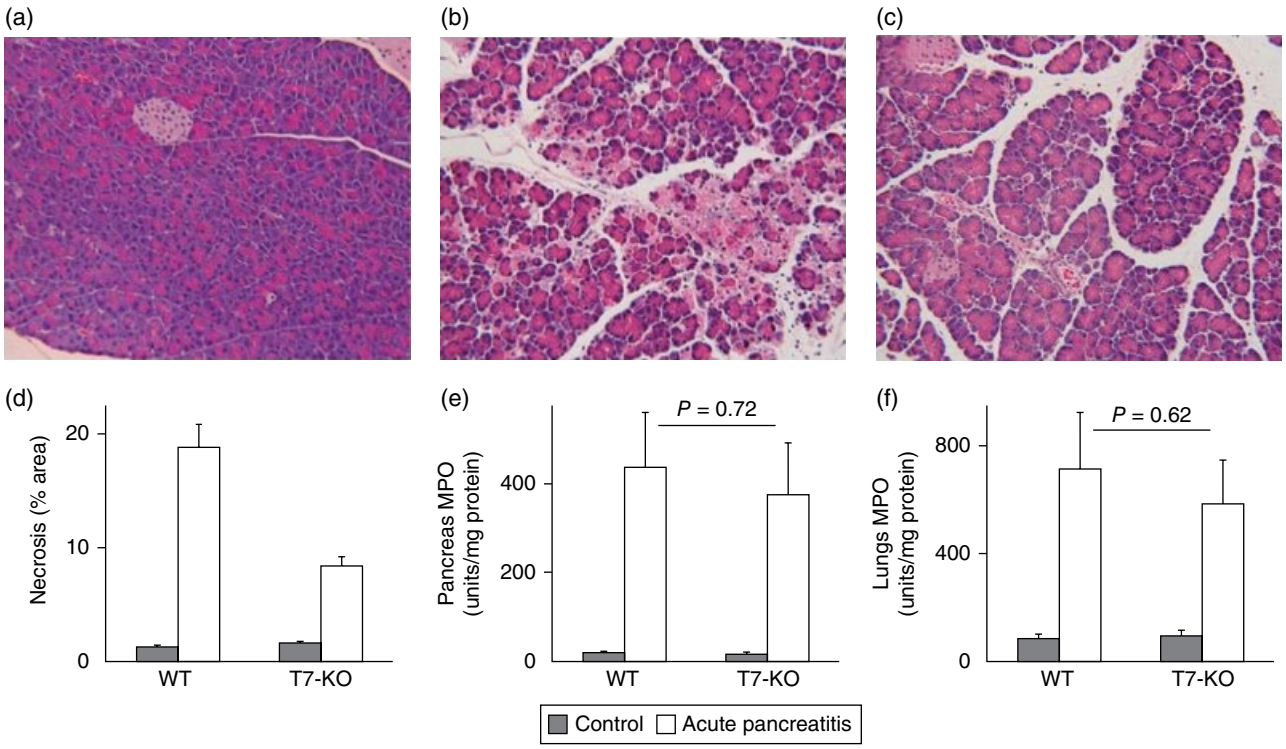

**Figure 6.4** Trypsin partially contributes to acinar cell injury during acute pancreatitis and local and systemic inflammation is independent of trypsin. Compared with (a) untreated mice, (b) supramaximal caerulein administration to wild-type mice leads to acinar cell necrosis, edema, and neutrophil infiltration. Although the acinar cell injury caused by supramaximal caerulein stimulation is reduced in (c) T7-KO mice, it is not completely prevented, suggesting that there are trypsin-independent mechanisms of acinar cell necrosis. (d) Quantification of acinar cell necrosis observed in caerulein model of acute pancreatitis in wild-type and T7-KO mice. Compared with untreated controls, wild-type and T7-KO mice had similar degrees of (e) pancreas and (f) lung inflammation as measured by myeloperoxidase levels. *Source:* Modified from Dawra et al. 2011 [16]. Reproduced with permission of Elsevier.

to cytokine and chemokine production, activation of inflammatory cells, and local and systemic injury. Future studies evaluating mechanisms to control this systemic inflammatory response syndrome should lead to the development of novel therapies for acute pancreatitis.

## Critical Analysis of the Role of Trypsin in Acute Pancreatitis

Studies suggest that inhibition of trypsin by pharmacologic inhibitors inhibits the severity of acute pancreatitis [12,21]. As already discussed, cathepsin B is important for the activation of trypsinogen to trypsin. Inhibition of trypsinogen activation by inhibiting the activity of cathepsin B or by deleting the cathepsin B gene also decreases pancreatic injury during acute pancreatitis [12,13]. Support for the trypsin-centric theory also comes from the identification of mutations in the cationic trypsinogen gene PRSS1 in patients with hereditary pancreatitis [22]. Biochemical studies of the pancreatitis-associated pR122H mutations of recombinant human cationic trypsinogen preparations show that this trypsinogen variant has an increased propensity for autoactivation and is resistant to degradation by chymotrypsin C. The role of trypsin in acute pancreatitis has been investigated in numerous experimental studies. Gaiser et al. [23] demonstrated that low constitutive expression of rat anionic trypsinogen PRSS2 in acini was sufficient to induce pancreatitis. Although the model utilized in this study lacked the transient, high-level trypsin activation observed in the experimental models of acute pancreatitis, this study again supports the role of trypsin activation in pathogenesis of pancreatitis [23]. However, this study needs to be interpreted with caution as this overexpression model is somewhat artificial and lacks the stimuli and other intra-acinar processes observed during acute pancreatitis.

Further insight into the role of trypsin in acute pancreatitis has been gained by the development and use of novel knockout mice lacking trypsinogen isoform-7 (mouse paralogue of human cationic trypsinogen [PRSS1]). In this mouse, the pathologic intra-acinar and intrapancreatic trypsin activation during acute pancreatitis is not observed. Intriguingly, in these novel T7KO mice, the acinar cell necrosis observed in experimental models of pancreatitis is reduced but not completely

obliterated (Fig. 6.4). Furthermore, NFκB activation and local and systemic inflammation are not altered by the absence of trypsin in these mice (Fig. 6.4). These studies suggest that trypsin is only partly responsible for the acinar cell necrosis observed during acute pancreatitis and local and systemic inflammation is independent of trypsin. It appears that trypsin is required only for initiation of the injury and trypsin-independent inflammatory pathways (importantly NFκB) determine disease progression and severity.

### Mechanism by which Trypsin Leads to Acinar Cell Injury

Although it is established that trypsin plays a role in acinar cell injury, the exact mechanism of this process has been elusive. This mechanism was recently investigated and it was demonstrated that trypsin leads to permeabilization of the colocalized vesicles that causes cathepsin B to escape from colocalized organelles into the cytosol, which in turn causes cell death during pancreatitis [24]. This conclusion was supported by the finding that supramaximal stimulation by caerulein causes leakage of cathepsin B in cytoplasm and this release is dependent on trypsin, as in its absence, either in T7KO mice as already described or by pharmacologic inhibition of trypsin, the release of cathepsin B into the cytosol during acute pancreatitis was prevented (Fig. 6.5). The role of trypsin in inducing apoptotic cell death in acinar cells was further proven by an experiment in which supramaximal caerulein stimulation induced apoptosis in acinar cells, and this was prevented by pretreatment with cathepsin B and trypsin inhibitors. Interestingly, when cathepsin B or trypsin was added to the permeabilized acini, to simulate the presence of cathepsin B or trypsin in the cytosol, dose-dependent activation of apoptosis was seen with the presence of cytosolic cathepsin B but not trypsin [24] (Fig. 6.5). This suggests the role of cytosolic cathepsin B but not trypsin in inducing acinar cell apoptosis. These observations have been conclusively supported by similar findings from experiments using

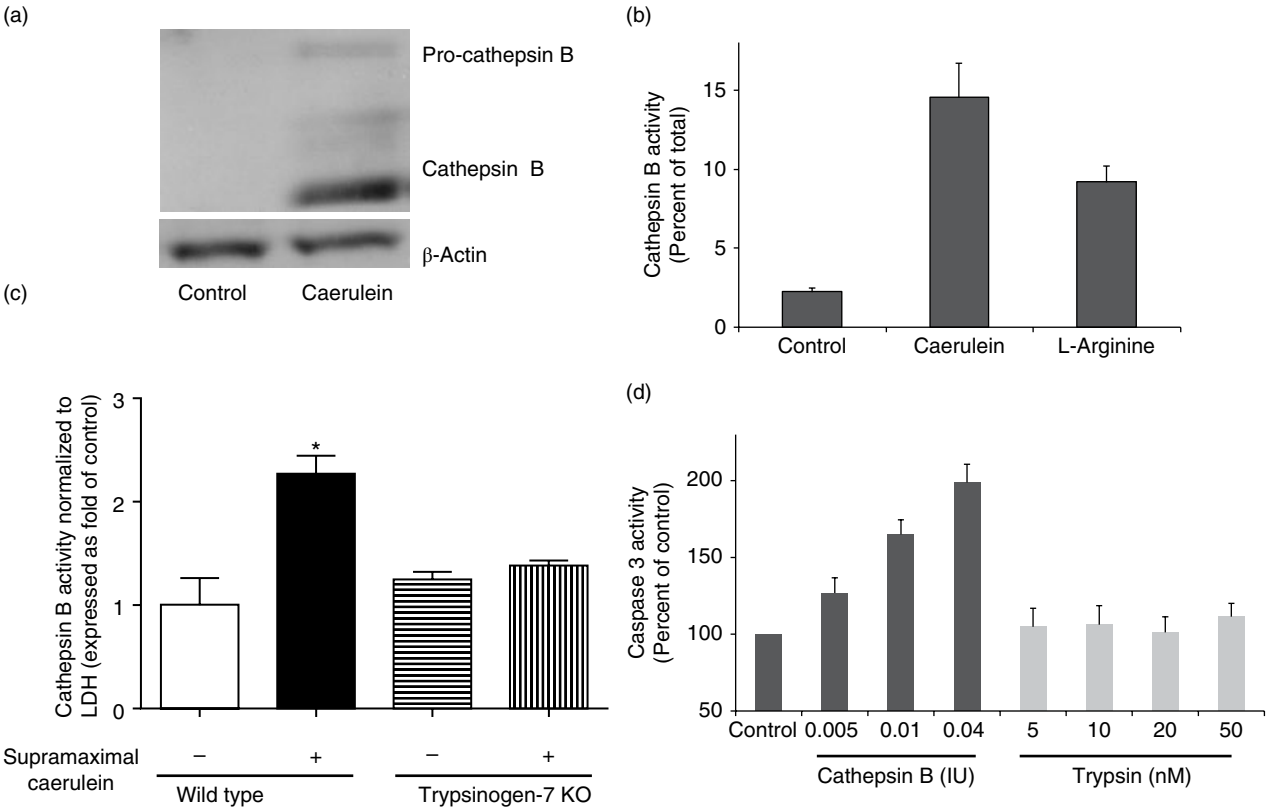

**Figure 6.5** Trypsin induces cell death in acinar cells indirectly through inducing release of cathepsin B into the cytosol. (a) Treatment of rat acinar cells *in vitro* with supramaximal caerulein leads to release of cathepsin B into the cytosol. (b) During caerulein and L-arginine pancreatitis in rats, there is release of cathepsin B into the cytosol. (c) Cathepsin B is released into the cytosol in a trypsin-dependent fashion as the T7-KO mice did not demonstrate release of cathepsin B into the cytosol in response to caerulein hyperstimulation. (d) Addition of cathepsin B, but not trypsin, to SLO-permeabilized acinar cells leads to activation of caspase-3, suggesting that during acute pancreatitis cytosolic cathepsin B, but not trypsin, activates apoptosis. *Source:* Modified from Talukdar et al. 2016 [24]. Reproduced with permission of Elsevier.

T7-KO and CBKO animals [24]. From these studies, the most logical inference is that active trypsin within the colocalized organelles is involved in making the organelles "leaky," causing leakage of cathepsin B into the cytosol, where the newly released cathepsin B activates apoptotic pathways. Inhibition of trypsin prevents the colocalized organelles from becoming fragile, thereby preventing the release of cathepsin B into the cytosol. Exogenous trypsin failed to activate caspase when incubated with streptolysin O (SLO)-permeabilized acinar cells, suggesting that trypsin does not directly cause acinar cell death.

There are two major pathways through which apoptosis occurs, namely extrinsic and intrinsic pathways. The extrinsic pathway involves death receptors and occurs in response to external signals, whereas the intrinsic pathway involves mitochondria and occurs in response to internal signals. Lysosomal disruption has been implicated in initiating the intrinsic apoptotic pathway involving cleavage of the proapoptotic Bcl-2 family member Bid. Upon apoptotic stimuli, the Bcl-2 apoptosis-promoting protein Bax undergoes a conformational change and translocates to mitochondria, where it oligomerizes and forms pores that allow the release of cytochrome *c* into cytoplasm. It has also been shown that in the early stages of experimental acute pancreatitis, there is a release of cytochrome *c* into the cytosol, which in turn activates caspase-9, subsequently leading to caspase-3 activation. Caspase-3 then executes the intracellular changes of apoptosis via different downstream mediators. A recent study suggests that during acinar cell death, cathepsin B is released into the cytosol and induces apoptosis predominantly via the intrinsic pathway by inducing Bid cleavage and Bax activation. Truncated Bid and activated Bax cause release of cytochrome *c* from mitochondria, which in turn leads to caspase-3 activation and acinar cell apoptosis.

#### Altered Autophagy Pathways During Acute Pancreatitis

Autophagy is a homeostatic process involving lysosomal degradation of long-lived protein and damaged organelles. During autophagy, there is the formation of double-membrane vacuoles called autophagosome containing the proteins and organelles that are to be recycled. The autophagosomes fuse with endosomes and then with lysosomes, thus generating autolysosomes. The sequestered material is degraded by lysosomal enzymes and the degradation products such as amino acids are recycled back into the cytoplasm. Given the high levels of protein synthesis and degradation in pancreatic acinar cells, these cells have a high autophagic flux. Studies have demonstrated that during pancreatitis, there is accumulation of autophagic vacuoles that are largely autophagolysosomes [25]. This is further supported by increased levels of LC3II, a marker of autophagic vacuoles. Interestingly, during acute pancreatitis, there is decreased autophagic efficiency, as suggested by increased levels of p62. Together this suggests that during acute pancreatitis, there is increased formation of autophagic vacuoles, but the steps beyond these initial steps including lysosomal enzyme-induced degradation of the contents of autolysosomes are blocked. It appears that well-functioning autophagy machinery is important for homeostasis of the pancreas and its impairment can lead to pancreatic injury in the form of atrophy, fibrosis, and chronic pancreatitis [26,27].

#### Mitochondrial Dysfunction

Mitochondria are the power plants of cells and provide most of the energy required for normal cellular processes. Mitochondrial dysfunction has been observed in acute pancreatitis. Excessive reactive oxygen species (ROS) and other stimuli during acute pancreatitis lead to direct damage to the mitochondria, leading to mitochondrial permeability, transition pore opening, and loss of mitochondrial potential. There are two major consequences of these events: (i) there is release of mitochondria content into the cytosol, and many of these contents, such as cytochrome *c*, activate the cell death pathway; and (ii) there is lack of production of ATP. Studies suggest that in the absence of ATP, the cell death pathways channel toward necrosis as apoptosis requires energy. However, how these pathways are different from mitochondria-dependent cell death pathways in other diseases is unclear.

#### ER Stress During Acute Pancreatitis

Unfolded protein response (UPR) is one of the early events in acute pancreatitis. It is now established that pathologic conditions such as hypoxia and oxidative stress lead to the accumulation of unfolded proteins in the endoplasmic reticulum (ER) lumen and ER stress. This leads to activation of the UPR, which augments protein folding and helps cell survival. However, if the UPR is overwhelmed, there is activation of cell death pathways. Given that the protein synthesis demands of pancreatic acinar cells are greater than those of any tissue in the body, acinar cells have a robust UPR system. Previous studies [28,29] showed the activation of the UPR during experimental pancreatitis. In mammalian cells, the UPR is controlled by three ER sensors, namely PERK (PKR-like ER kinase), IRE1 (inositol-requiring enzyme 1), and ATF6 (activating transcription factor 6). When ER homeostasis is perturbed, the accumulating misfolded proteins bind Grp78, thus activating the ER sensors. IRE1 initiates downstream signaling through an unconventional splicing of the transcription factor

Xbp-1, which binds to the ER stress response element leading to transcription of ER chaperones. PERK activation leads to the phosphorylation of the translational initiation factor eIF2α, which leads to inhibition of protein synthesis, thus decreasing the load of unfolded protein on ER. Activation of ATF6 also increases transcription of grp78 and CHOP. Limited studies in pancreatitis suggest that all of these pathways are activated upon induction of acute pancreatitis [29,30]. However, how ER stress integrates in the known paradigm of acute pancreatitis, that is, its relationship to zymogen activation, colocalization, and activation of inflammatory pathways, is unclear.

The role of ER stress in pancreatitis has also been evaluated in models of alcoholic pancreatitis. In an interesting study, Lugea et al. [31] demonstrated that feeding mice an ethanol diet led to activation of UPR and increased levels of XBP-1 and protein disulfide isomerase (PDI), a well-known XBP-1 target. Although ethanol feeding in animal models activates UPR, the damage to the acinar cells is minimal. However, if the UPR was perturbed, for example by XBP-1 deficiency, ethanol feeding reduced expression of ER regulators, upregulation of proapoptotic signals, and activation of authophagy, and increased acinar cell injury. How the balance shifts from ER stress being a beneficial to a harmful event during ethanol-induced acute pancreatitis is not clear.

## Systemic Injury

The intra-acinar events and activation of inflammatory pathways lead to the synthesis of chemokines and cytokines. These signaling molecules recruit inflammatory cells such as neutrophils and macrophages to the pancreas. Secretion of cytokines by resident macrophages and endothelial and epithelial cells also helps in the recruitment of these inflammatory cells. The infiltrating cells then induce further acinar cell injury and lead to the secretion of multiple proinflammatory cytokines such as tumor necrosis factor-alpha (TNF-α), interleukin (IL)-1, IL-2, IL-6, and other chemokines and anti-inflammatory factors such as IL-10 and IL-1 receptor antagonist. This leads to magnification and propagation of inflammation to the systemic level. Systemic inflammation is primarily responsible for determining the severity of pancreatitis and is responsible for the mortality and the majority of the morbidity of acute pancreatitis. Given the role of various proinflammatory cytokines in the pathogenesis of systemic injury, the therapeutic potential of downregulating levels of a few individual cytokines has been evaluated in experimental models. For example, mice with genetic deletion of some of these cytokines, such as TNF-α, have a reduced severity of acute pancreatitis [32]. Downregulation of platelet activating factor (PAF) by accelerating its degradation by recombinant PAF acetylhydrolase [33] or PAF antagonists [34] ameliorates the severity of experimental pancreatitis. Similarly, the severity of experimental pancreatitis is reduced in mice lacking substance P receptors or pretreated with substance P receptor antagonist [35]. Unfortunately, these findings were evaluated in clinical studies and did not show benefit. The discordance of experimental and clinical findings can be explained potentially by the fact that many of these therapies were evaluated in experimental models in prophylactic fashion, whereas in clinical situations, when the patients present the cytokines are already elevated and the treatments may not be as effective in reversing the damage that has already been done. Moreover, the cytokine system is very redundant and the effects of multiple cytokines are overlapping. Hence abolishing one cytokine may not provide dramatic results.

### Neutrophil-Inducing Local Injury

There is abundant experimental evidence to indicate that the sequestration of neutrophils into the pancreas, in response to initial injury from intra-acinar events, further contributes to tissue damage. The sequestration of neutrophils into the pancreas requires upregulation of endothelial adhesion molecules and their interaction with leukocytes. Elevated levels of endothelial adhesion molecules such as P- and E-selectins have been observed in acute pancreatitis and correlates with the severity of pancreatic and systemic injury. Initial experimental evidence with respect to the role of neutrophils in the pathogenesis of acute pancreatitis was based upon experiments in which neutrophils were depleted by treatment with antineutrophil serum [36] or anti-Gr-1 antibody [37,38] before induction of experimental pancreatitis. In these experiments, the severity of pancreatitis was significantly reduced, indicating a role of neutrophils in tissue injury. In subsequent studies, experimental approaches to achieve a reduction in neutrophil infiltration in pancreatic tissue either targeted P-selectin [39] or used CXCR2 antagonist [40]. In these experiments also, along with a significant decrease in neutrophils, a decrease in pancreatic injury was observed. Platelet-derived CXCL4 regulates neutrophil infiltration [41]. Administration of antiplatelet antibody prior to initiation of acute pancreatitis reduced CXCL4 levels, neutrophil infiltration, and pancreatitis-related tissue damage. Mechanisms of neutrophil-mediated pancreatic injury have been investigated. There is evidence to indicate that the presence of activated neutrophils in the pancreas activates trypsinogen [37] and active trypsin can further enhance damage to the tissue. Neutrophil infiltration is considered to be responsible for the second phase of trypsin activation observed during pancreatitis; however, initial activation of trypsinogen is independent

of neutrophils. Neutrophil-dependent activation of trypsin is considered to be mediated through NADPH oxidase [36]. Matrix metaloproteinase-9 (MMP-9) is present in neutrophils [42] and released after activation; use of its specific inhibitor (BB-94) also resulted in decreased trypsinogen activation but the mechanism of MMP-9-mediated trypsin activation is not clear. In addition to trypsinogen activation, other mechanisms such as increased ROS and neutrophil elastase-mediated injury have been considered. Recent studies point to the role of neutrophil extracellular traps (NET) in tissue injury, which again is considered to be mediated through increased trypsin activation, but how NET induce activation of trypsinogens is not clear [43]. Given the important role of neutrophils in both local and systemic injury during acute pancreatitis, a better understanding of the mechanism by which neutrophils become activated and induce injury in acute pancreatitis will lead to the development of strategies to modulate their function selectively for therapeutic gain.

## Conclusion

In summary, experimental studies have provided much needed information on the pathophysiology of acute pancreatitis. Although the currently used *in vitro* and animal models have significant shortcomings, they precisely model the histopathology and pathophysiology of acute pancreatitis. These models have elucidated multiple key pathophysiologic events such as zymogen activation, colocalization, inhibition of secretion, intracellular calcium changes, autophagy dysfunction, ER stress, NFκB activation, and mitochondrial dysfunction. Recent studies have proved that trypsin contributes only partially to acinar cell injury and the local and systemic inflammation are independent of trypsin activation. The local and systemic inflammation are the major sources of mortality and morbidity during acute pancreatitis. A better understanding of the pathophysiology and progression of inflammation during acute pancreatitis will lead to the development of strategies to modulate it and thus change the outcomes of patients with acute pancreatitis.

## Introduction

The presence of the gallbladder and biliary tract was described in some of the earliest recorded observations of humans [1], but their role in digestion was not appreciated until much later. In the sixteenth century, a membrane near the distal end of the common bile duct thought to impede reflux of duodenal contents into the bile duct was described, but it was not until 1887 that this structure was described as a sphincter and named after Rugero Oddi, who published a detailed description of its anatomy as a result of dissections undertaken while studying medicine [2]. The physiologic role of the sphincter of Oddi was further appreciated after the hormone cholecystokinin (CCK) was shown to contract the gallbladder and reduce sphincter of Oddi resistance. These and subsequent studies firmly established that an intimate relationship existed between gallbladder contraction, sphincter of Oddi function, and the flow of bile into the duodenum.

## Anatomy and Morphology

The terminal parts of the common bile duct and pancreatic duct, the common channel, and major duodenal papilla of Vater are invested with varying thicknesses of smooth muscle that together form the sphincter of Oddi segment (Fig. 7.1). The major part of the human sphincter of Oddi lies within the duodenal wall, and is anatomically and functionally independent of the duodenal muscle.

Distinct sphincters are present at the terminal end of the common bile duct (sphincter choledochus), pancreatic duct (sphincter pancreaticus), and common channel (sphincter ampullae) [3]. However, studies using a combination of radiologic, duct cast techniques, and histologic sectioning methods did not distinguish separate sphincters [4], and human autopsy studies have concluded that the common bile duct and pancreatic duct become fused in a common connective tissue sheath outside the duodenal wall and pass together through a slit in the duodenal muscle known as the "choledochal window." However, the lumina do not join at this level but are separated by a thick, muscular septum. In most subjects, fusion of the two lumina occurs in the submucosal layer of the duodenum to form a common channel that varies in length between 2 and 17 mm. Before entering the duodenum, each duct becomes completely surrounded by circular muscle, some of which forms a figure-of-eight pattern around the two ducts. The point at which the smooth muscle starts on each duct is readily identified radiologically as a notch. Distal to the notch, each lumen becomes narrow as it traverses the duodenal wall, this narrowing being associated with thickening of the duct wall due to smooth muscle, connective tissue, and mucous glands. As the ducts pass through the duodenal wall longitudinal muscle, fibers interdigitate between the circular ductular muscle fibers and the duodenal muscle. The ducts emerge from the duodenal muscle layers and pass through the duodenal submucosa for a variable distance before opening onto the papilla of Vater; throughout this submucosal course, the ducts are ensheathed by circularly oriented smooth muscle. Manometric studies in humans support Hand's description of the sphincter of Oddi in that separate sphincteric zones have not been identified [5].

The mucosa of the human sphincter of Oddi segment is lined by columnar epithelium and contains numerous mucus-secreting glands. The mucosa is thrown into

longitudinal folds likened to mucosal valvules [6]. These folds are least marked proximally and increase distally, becoming maximal in the common channel. The mucosal folds may occasionally be seen projecting through the orifice of the duodenal papilla.

## Innervation

The extrahepatic biliary tract is innervated by dense networks of extrinsic and intrinsic nerves that regulate smooth muscle tone and epithelial cell function of the extrahepatic biliary tree. The celiac ganglia contribute both motor and sensory nerves made up of sympathetic fibers that originate in the T7–T10 spinal segments. The hepatic plexus is formed by nerve fibers from both vagi and supplies parasympathetic motor nerves to the extrahepatic biliary system [7].

The wall of the biliary tract is composed of three layers: serosal, muscularis, and mucosal. Ganglionated nerve plexuses are located in the subserosal and subepithelial layers. The sphincter of Oddi has a rich ganglionic plexus. It has a predominance of cholinergic ganglia and a smaller number of adrenergic ganglia. Immunohistochemical studies in our laboratory have demonstrated the presence of a wide range of peptidergic neurons in the sphincter region, including galanin-, substance P-, and somatostatin-containing nerves. In addition, the inhibitory transmitter nitric oxide has been demonstrated in nerves to the sphincter and is thought to have an important function in modulating sphincter relaxation. It has been shown that the nerves in the sphincter region communicate with the proximal biliary tract, the gallbladder, and the duodenum [8,9].

## Physiology

Bile reaches the sphincter of Oddi via the common hepatic and common bile ducts. The sphincter of Oddi not only regulates the flow of bile and pancreatic juice into the duodenum, but is also the regulatory valve to prevent reflux of duodenal contents into the pancreatobiliary passages. The role of the common bile duct in the control of bile flow has been confused owing to anatomic differences in the species studied. Histologic studies in humans have demonstrated only thin, longitudinally oriented layers of smooth muscle within the walls of the common bile duct [10]. The major tissue component appears to be elastic fibers. However, in other species, such as sheep, the common bile duct is invested with circularly oriented smooth muscle that exhibits peristaltic activity.

The weight of evidence suggests that the human common bile duct does not have a primary propulsile function. However, the elastic fibers and the longitudinally oriented smooth muscle provide a tonic pressure that may help overcome the tonic resistance of the sphincter of Oddi. The diameter of the human common bile duct before and after cholecystectomy has been the subject of controversy. Part of the disagreement is due to the methodology used in determining duct size. It has become obvious that duct size as determined by ultrasonography and magnetic resonance cholangiography (MRC) cannot be equated with duct size determined by endoscopic retrograde cholangiopancreatography (ERCP) or intraoperative extraluminal measurements. Ultrasound and MRC record the nondistended lumen, whereas the contrast used during ERCP produces distension. Intraoperative measurements include wall thickness. In general, the normal diameter of the common bile duct as determined by ultrasound is less than 6 mm, by ERCP less than 10 mm, and by intraoperative extraluminal measurements less than 12 mm. What has become clear is that the common bile duct does not increase in diameter significantly following cholecystectomy [11,12]. The major cause of a dilated common bile duct is increased intraluminal pressure, which generally is produced by either primary or secondary obstruction at the sphincter of Oddi.

## Motility of the Sphincter of Oddi

The primary function of the sphincter of Oddi is to control the delivery of bile and pancreatic juice into the duodenum. This is possible because of low pressure within the bile duct. Approximately 800–1500 mL of bile flows through the human sphincter of Oddi. Various studies in animals and humans have tried to evaluate the mechanism by which the sphincter of Oddi controls the flow of bile and pancreatic secretions. These studies have shown that there is anatomic variability between species and that sphincter of Oddi motility differs from one species to another. Hence, although many commonalities exist, one has to be circumspect in comparing animal data directly with the motility and function of the human sphincter of Oddi.

## Sphincter of Oddi Motility Studies in Animals

*In vivo* studies in dogs, cats, rabbits, and monkeys have demonstrated that the sphincter of Oddi exhibits muscle contractions that are independent of duodenal activity. The common bile duct and pancreatic duct proximal to the sphincter do not demonstrate spontaneous motor activity. Results from the dog studies have suggested that the sphincter of Oddi has a milking effect on bile, thus propelling small volumes of fluid from the common bile duct into the duodenum [13]. Manometric and electromyographic studies of the opossum sphincter of Oddi have demonstrated that the predominant mechanism of common bile duct emptying in the opossum is the antegrade sphincter of Oddi phasic contractions that propagate the entire length from the cephalic to the caudal end [14,15]. However, the frequency of the phasic contractions varies periodically during fasting. In cats, CCK inhibits the sphincter phasic contractions and produces a fall in sphincter tone by stimulation of nonadrenergic, noncholingeric inhibitory neurons – this effect overriding a lesser, direct smooth muscle stimulatory action of the hormone [16].

Studies have shown that the sphincter may act as a pump or a resistor and that bile duct pressure influences it [17]. This intrinsic activity is controlled by interstitial nerves of Cajal and is modulated by hormones [16], ATP and adenosine [18], and nitric oxide [19].

Neurohistochemical studies have demonstrated both adrenergic and cholinergic neurons within the sphincter of Oddi, and experiments in animals have determined the pharmacologic effects of histaminergic, cholinergic, and adrenergic stimulation on the sphincter muscle [14]. However, the physiologic significance of these drug actions on the sphincter of Oddi requires further investigation.

The function of the vagus nerve in sphincter of Oddi physiology remains obscure. Sphincter of Oddi neurons likely receive vagal input and their activity is modulated by release of neuropeptides from sensory fibers, a significant source of excitatory synaptic input to these cells arising from the duodenum. This duodenum–sphincter of Oddi circuit likely plays an important role in the coordination of sphincter of Oddi tone with gallbladder motility in the process of gallbladder emptying [20]. Studies in dogs have suggested that following vagal transection, the resistance to flow across the sphincter of Oddi is decreased [21]. However, in the prairie dog, increased resistance to flow through the sphincter of Oddi occurs after truncal vagotomy. Results from vagal stimulation studies have failed to define clearly the role of the vagus in biliary dynamics.

The Australian possum sphincter of Oddi demonstrates activity similar to that of the human sphincter. In this species, inhibition of sphincter phasic contractions promotes flow of bile. It has been shown that this inhibition is mediated by neural release of nitric oxide [16]. There is evidence that nitric oxide mediates the cerulein- and CCK octapeptide-mediated relaxation of the canine sphincter of Oddi [22]. The neuropeptide galanin selectively stimulates longitudinally oriented sphincter of Oddi smooth muscle via a direct mechanism, leading to a moderate reduction in trans-sphincteric flow [23]. Table 7.1 illustrates the effects of various bioactive agents on the sphincter of Oddi.

**Table 7.1** Effects of various bioactive agents on the sphincter of Oddi.

| Effect | Agent |
|---|---|
| Stimulators | Morphine met-enkephalin |
| | Galanin |
| | Substance P |
| | Cholecystokinin |
| | Neuropeptide Y |
| | Nitric oxide |
| Inhibitors | Tramadol |
| | Glucagon |
| | Calcitonin gene-related peptide |
| | Cholecystokinin |
| | Peptide YY |
| | Somatostatin |

## Sphincter of Oddi Motility in Humans

Cineradiographic studies showed that the human sphincter of Oddi exhibits rhythmic contractions that propel contrast into the duodenum [24]. Sphincter of Oddi pressure studies conducted at the time of biliary tract surgery have demonstrated variations in pressure thought to be the manometric equivalent of the cineradiographic contractions [25]. Resistance to outflow of fluid from the common bile duct into the duodenum has also been demonstrated by intraoperative studies. This resistance was reduced after administration of CCK octapeptide or smooth muscle relaxants such as amyl nitrite [26].

Manometric recordings from within the sphincter of Oddi segment have been made via a pressure-sensitive catheter introduced into the sphincter of Oddi via a duodenoscope (Fig. 7.2) [27]. They demonstrated that the human sphincter of Oddi is characterized by prominent phasic contractions superimposed on a basal sphincter of Oddi pressure 3 mmHg above the pressure in the common bile duct and pancreatic duct (Fig. 7.3). The amplitude of the phasic contractions is approximately 130 mmHg and the mean frequency is 4/min. Analysis of the direction of propagation of the phasic contractions during a continuous 3 min period demonstrated that the majority of contractions (60%) are oriented in an antegrade direction from the common bile duct toward the duodenum. A smaller number of contractions occurred either simultaneously (24%) or had a retrograde orientation (15%). Intravenous bolus injection of CCK octapeptide (20 ng/kg) normally produces inhibition of the phasic contractions and a fall in the basal sphincter of Oddi pressure.

Table 7.2 shows the pressures recorded from the sphincter of Oddi of normal subjects. Studies in patients with T-tubes inserted in the common bile duct following bile duct exploration [28] have shown that the frequency of sphincter of Oddi phasic contractions during fasting exhibits a periodicity in relation to duodenal migrating

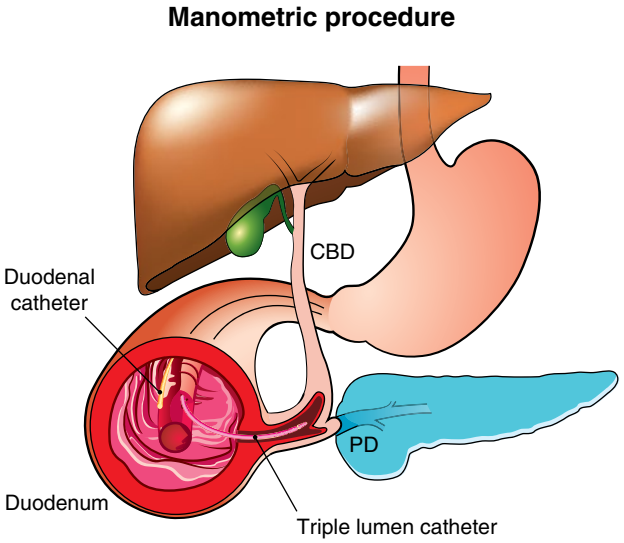

**Figure 7.2** Manometric recording from the human sphincter of Oddi. A triple-lumen pressure-sensitive catheter is positioned in the sphincter via the biopsy channel of the duodenoscope. A separate catheter records duodenal pressure. CBD, common bile duct; PD, pancreatic duct.

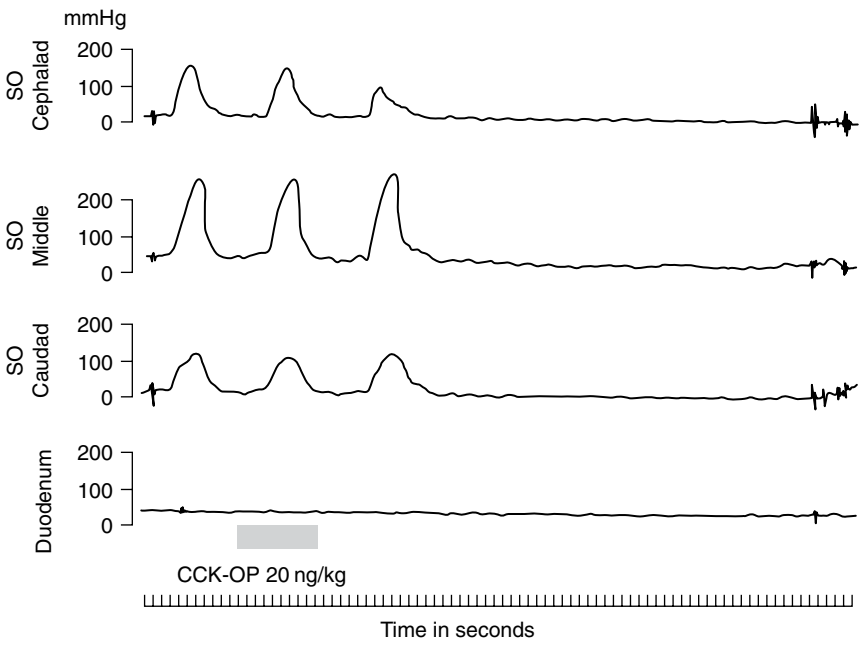

**Figure 7.3** Manometric recording from the human sphincter of Oddi (SO) showing prominent phasic contractions, which are inhibited after injection of cholecystokinin octapeptide (CCK-OP).

motor complexes, similar to that demonstrated in the opossum (Fig. 7.4).

Following the ingestion of a meal, bile flow across the sphincter of Oddi is promoted by inhibition or reduction in the amplitude of the phasic contractions and a fall in the sphincter of Oddi basal pressure. This effect on the human sphincter of Oddi is similar to that following intravenous injection of CCK octapeptide. In humans, bile flow occurs mainly between sphincter of Oddi phasic contractions during the period of diastole. The phasic contractions propel small volumes of bile into the duodenum, but this is not the major means by which bile flow occurs. The phasic contractions in humans may function to prevent reflux of duodenal contents into either the bile or the pancreatic ducts, and to maintain the ducts free of small debris. In order to promote flow across the human sphincter of Oddi, inhibition or reduction of the phasic contractions and a fall in basal pressure are necessary.

**Table 7.2** Pressures recorded from the sphincter of Oddi of normal subjects.

| | Normal | | |
|---|---|---|---|
| | **Median** | **Range** | **Abnormal** |
| Basal pressure (mmHg) | 15 | 3–35 | >40 |
| Amplitude (mmHg) | 135 | 95–195 | >300 |
| Frequency (/min) | 4 | 2–6 | >7 |
| Sequences | | | |
| Antegrade (%) | 80 | 12–100 | |
| Simultaneous (%) | 13 | 0–50 | |
| Retrograde (%) | 9 | 0–50 | |

## Pathophysiology of the Sphincter of Oddi Dysfunction (SOD)

According to the Rome III expert consensus [29], the term SOD implies motility abnormalities of the sphincter of Oddi associated with pain, elevations of liver or pancreatic enzymes, common bile duct dilatation, or episodes of pancreatitis. The most common presentations of this symptom complex include persistent or recurrent "biliary" symptoms postcholecystectomy (10–20%) [30] or features consistent with idiopathic recurrent acute pancreatitis (abnormal sphincter of Oddi manometry has been recorded in 30.5% [31]).

The diagnostic criteria for sphincter of Oddi disorders laid down by the Rome III expert consensus [29] include the presence of episodes of pain located in the epigastrium and/or right upper quadrant along with all of the criteria listed in Table 7.3. The consensus statement also listed supportive criteria, the presence of one or more of which in association with the pain may help in arriving at the diagnosis. These included nausea and vomiting, radiation to the back and/or right infrascapular region, or pain that awakens the patient from sleep in the middle of the night.

The most clinically relevant classification system for SOD is the modified Milwaukee Classification described for both biliary [32] and pancreatic [33] disorders

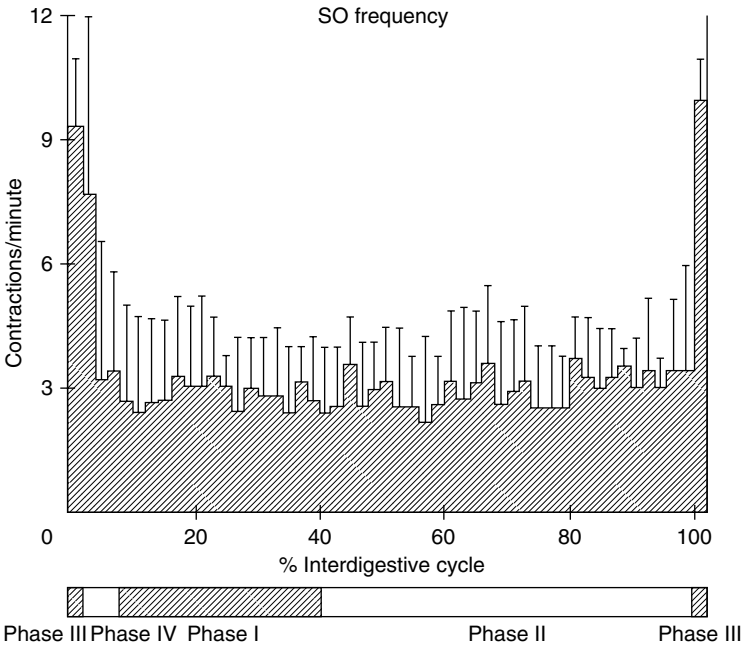

**Figure 7.4** Manometric recordings of the human sphincter of Oddi showing changes in frequency of contraction in relation to the duodenal interdigestive motility pattern.

(Table 7.4). These have been modified from the original Milwaukee Classification proposed by Hogan and Geenen [34].

Based on manometric recordings, we have previously subdivided SOD into two groups [35], namely those exhibiting a stenotic pattern (abnormally raised basal sphincter pressure >40 mmHg) and those displaying a dyskinetic pattern including paradoxical response to CCK injection, rapid contraction frequency, high percentage of retrograde contractions, or short periods of raised basal pressure [36]. These patients display an abnormal response to morphine or a fatty meal stimulus. It has been hypothesized that the latter may contribute to the development of adult choledochal cysts [37,38].

The stenotic subtype of SOD is characterized by pathomorphologic changes evident on histologic examination of sphincter complexes resected at the time of transduodenal sphincteroplasty for patients with severe postcholecystectomy pain. The changes contributing to the high basal pressure include inflammation of the papilla and its transampullary septum or fibrosis with or without inflammation, papillary cholesterolosis [39], muscle hypertrophy, or mucosal edema [40]. These findings have been reported in 58% of patients undergoing transduodenal sphincteroplasty and transampullary septectomy for postcholecystectomy pain [39] and have been hypothesized to be due to the chronic passage of small gallstones [39]. This subtype corresponds to the Modified Milwaukee type 1 and responds best to sphincterotomy (surgical or endoscopic). We have previously demonstrated that surgical sphincteroplasty and septectomy when performed for manometrically confirmed sphincter of Oddi stenosis in patients with recurrent pancreatitis resulted in a good clinical outcome in a majority of patients [41,42].

The dyskinetic subtype, on the other hand, is believed to be the result of a functional or neurohormonal disturbance in the absence of any pathologic reproducible abnormalities [35]. Infections such as *Cryptosporidium* and HIV have also been shown to lead to features of SOD [43]. This subtype corresponds to the type 2 and 3 of the Milwaukee Classification. Sphincter of Oddi manometry is essential to arrive at the diagnosis. The paradoxical response to CCK injection noted by us [40] may be the result of a defect in the enteric nervous system akin to that described for achalasia of the esophagus [44]. Whereas sphincterotomy relieves symptoms of type 1 SOD, it is less effective in alleviating symptoms of this subtype [45] and is associated with a risk of early recurrence of symptoms on follow-up [46]. However, results of sphincterotomy, in terms of pain relief, are more encouraging in those patients with type 2 and 3 SOD who had demonstrable preprocedure abnormalities in manometry [47]. The response to sphincterotomy in this subtype is not uniform. We have elucidated experimentally the various mechanisms by which galanin may be involved in the pathogenesis of acute pancreatitis [48]. Given the action of galanin on the sphincter of Oddi [23], its contribution to SOD-induced acute pancreatitis [49]

**Table 7.3** Rome III compulsory diagnostic criteria for sphincter of Oddi disorders.

1) Episodes lasting 30 minutes or longer
2) Recurrent symptoms occurring at different intervals (not daily)
3) The pain builds up to a steady level
4) The pain is moderate to severe enough to interrupt the patient's daily activities or lead to an emergency department visit
5) The pain is not relieved by bowel movements
6) The pain is not relieved by postural change
7) The pain is not relieved by antacids
8) Exclusion of other structural disease that would explain the symptoms

**Table 7.4** Modified Milwaukee Classification for biliary and pancreatic sphincter of Oddi dysfunction.

| | Diagnostic criteria | |
|---|---|---|
| **Classification** | **Biliary** | **Pancreatic** |
| Type 1 | A) Biliary-type pain<br>B) Elevated ALT, AST, ALP >1.1 times the upper limit of normal on one occasion<br>C) Bile duct diameter ≥9 mm | A) Pancreatic-type pain<br>B) Serum amylase or lipase level of 1.1 times the upper limit of normal on one occasion<br>C) Duct dilatation of >6 mm in the head and >5 mm in the body of the pancreas |
| Type 2 | A) Biliary-type pain with either B or C in the criteria mentioned in Type 1 | A) Pancreatic-type pain with either B or C in the criteria mentioned in Type 1 |
| Type 3 | A) Biliary-type pain only without other abnormalities | A) Pancreatic-type pain only without other abnormalities |

ALP, alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase.

is worthy of consideration. Use of galanin antagonists [50–53] may thus offer a potential therapy in this subgroup of patients.

The underlying causes of pain in SOD remain conjectural and include relative obstruction of flow through the sphincter of Oddi resulting in bile duct or pancreatic duct distension, "ischemic" pain arising from spastic contractions, hypersensitivity of the papilla, and severance of nerves supplying the sphincter of Oddi during cholecystectomy. Other potential explanations include duodenal-specific visceral hyperalgesia (in type 3 SOD) [54], continuous visceral pain (biliary pain) caused by local inflammatory/sensitizing processes or persistent hyperexcitability of the nociceptive neurons in the central nervous system [55], or other functional gastrointestinal disorders including intestinal dysmotility [56], irritable bowel syndrome (IBS), and nonulcer dyspepsia.

## Conclusion

The sphincter of Oddi is a small but important complex muscle that modulates flow of bile and pancreatic juice across one of the busiest anatomic junctions of the body. Its activity is controlled by an interaction of neuronal and hormonal modulators. In such a complex structure, it is not surprising that at times disorders in motility arise and these disorders lead to significant clinical syndromes.

# Neurohormonal and Hormonal Control of Pancreatic Secretion

*Chung Owyang*

*Division of Gastroenterology, Department of Internal Medicine, University of Michigan, Ann Arbor, MI, USA*

## Introduction

The pancreas, one of the most important organs in the digestive tract, has both exocrine and endocrine functions. The exocrine pancreas secretes digestive enzymes and $HCO_3^-$ to facilitate digestion and absorption of nutrients. The endocrine pancreas releases hormones that regulate metabolism and the disposition of the breakdown products of food.

The human pancreas secretes about 1 L of juice daily, containing mostly water, electrolytes, and digestive enzymes. Mediation of postprandial pancreatic secretion has been ascribed mainly to the hormones secretin and cholecystokinin (CCK) and to vagovagal reflexes that activate cholinergic postganglionic neurons in the pancreas. In addition to these classical pathways, other regulatory peptide hormones and neurotransmitters may be involved.

## Stimulation of Pancreatic Secretion

### Hormonal Mechanisms

#### Secretin

Secretin is the most potent and efficacious stimulant of pancreatic fluid and $HCO_3^-$ secretion in humans and all other species tested. It is synthesized by small intestine S-type enteroendocrine cells and is released postprandially. Duodenal pH is the major regulator of secretin release. A threshold pH of 4.5 triggers secretin release and stimulates pancreatic $HCO_3^-$ secretion [1,2]. Below this pH, pancreatic $HCO_3^-$ output is related to the total amount of titratable acid presented to the duodenum. Secretin levels in humans increase by only a few picomoles postprandially because food buffers much of the gastric acid and pancreaticobiliary secretion neutralizes the remaining acid entering the duodenum by [3]. The mechanism by which acid stimulates secretin release is unclear. In rodents it was shown that $H^+$ may release a secretin-releasing factor into the proximal intestinal lumen to stimulate secretin release [4]. Secretin-producing cells appear to have acid-sensing ion channels belonging to the transient receptor potential (TRP) channel family. Hence luminal acid likely stimulates secretin release by more than one mechanism.

Nonacid factors may influence postprandial secretin release. Nutrients such as oleic acid and other digestive products of fat can increase plasma secretin levels and pancreatic $HCO_3^-$ secretion [5,6]. Bile in the upper gut can also stimulate secretin release [7]. However, the physiologic importance of these nonacid factors in postprandial secretin release is questionable, as the postprandial plasma secretin level does not increase in achlorhydria or in health if meal-induced acid secretion is neutralized with $NaHCO_3^-$.

The pancreas appears highly sensitive to the small amounts of secretin released into the circulation postprandially [7,8]. *In vitro* animal models show that secretin stimulates $HCO_3^-$ secretion by isolated ducts or duct fragments [9,10]. $^{125}$I-labeled secretin and autoradiography revealed a secretin-binding site on pancreatic acini and duct cells [11], suggesting that secretin acts directly on the pancreas to stimulate pancreatic secretion. Conversely, *in vivo* studies have shown that the effect of secretin at physiologic doses is highly sensitive to atropine [12,13]. Receptor autoradiography, immunocytochemistry, and electrophysiology demonstrate the presence of secretin receptors in vagal afferent fibers [14–16]. Vagal nodose ganglia also contain high-affinity $CCK_1$ receptors [16]. Injection of a subthreshold dose of CCK-8 (5 pM) significantly enhances the neural response

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

to 5 pM secretin. This synergistic interaction helps to explain the robust postprandial pancreatic $HCO_3^-$ and enzyme secretion of the despite a modest postprandial increase in plasma CCK and secretin.

**Cholecystokinin**

CCK is the other gut hormone that plays an important role in pancreatic secretion. It is synthesized in specific enteroendocrine I cells in the proximal intestine and released by hydrolytic products of digestion such as amino acids and fatty acids [17]. Undigested fat is ineffective, but products of lipolysis such as fatty acids are the most potent stimulants of CCK release [18]. The CCK response to fatty acids is influenced by chain length, saturation, concentration, and total load [19].

Fasting plasma CCK levels are low, averaging about 1 pM in humans [20–22]. Postprandially, the plasma CCK concentration increases to 6–8 pM within 10–30 min, then gradually declines to basal levels during the ensuing 3 h [21,22]. Several molecular forms of CCK appear to be released into the circulation postprandially, including CCK-58, CCK-33, CCK-22, CCK-12, and CCK-8 [23], CCK-58 being predominant in dogs and humans and the only form detected in rats [24–26].

Nutrients may stimulate CCK secretion by a number of mechanisms. In species such as the rat, in which feedback inhibition of pancreatic enzyme secretion occurs, CCK release is mediated by a trypsin-sensitive CCK-releasing peptide [27]. Duodenal peptone stimulates serotonin (5-hydroxytryptamine; 5-HT) release from intestinal enterochromaffin cells, which in turn activates submucosal sensory substance P neurons. Signals are then transmitted to cholinergic interneurons and to epithelial CCK-releasing peptide-containing cells by way of cholinergic secretomotor neurons [27]. CCK release may be controlled by the level of active intraluminal proteases [28–30]. Protein, the major food stimulant of CCK secretion in rats, may bind or inhibit intraluminal endopeptidases, which would otherwise inactivate the CCK-releasing peptide [31] (Fig. 8.1).The mechanisms responsible for the actions of CCK-releasing peptide in humans are unclear, but may be similar to those in rats as feedback regulation of CCK release by proteases also occurs in humans. Study of CCK secretion from purified CCK-producing cells shows that amino acids stimulate CCK release by binding to the $Ca^{2+}$-sensing receptor [32], whereas fatty acids bind to specific G-protein-coupled fatty acid receptors [33]. Thus CCK secretion may be mediated by more than one mechanism.

CCK plays an important role in the stimulation of postprandial pancreatic enzyme secretion. The infusion of physiologic doses of CCK produces the same level of pancreatic enzyme secretion as during the postprandial state [34]. Furthermore, administration of the potent CCK antagonist lorglumide or MK-329 produces a 50–60% inhibition of meal-stimulated pancreatic secretion in dogs [35] and humans [36]. CCK can also stimulate fluid and $HCO_3^-$ secretion [37]. The effect on $HCO_3^-$ secretion is weak but physiologically relevant because CCK potentiates the action of secretin on the pancreas [38]. In intact dogs and humans, CCK-stimulated pancreatic enzyme secretion is not potentiated by secretin [34,39,40]. The mechanisms by which CCK stimulates pancreatic enzyme secretion remain controversial. *In vitro* studies using dispersed rat pancreatic acini show that CCK-stimulated amylase release is

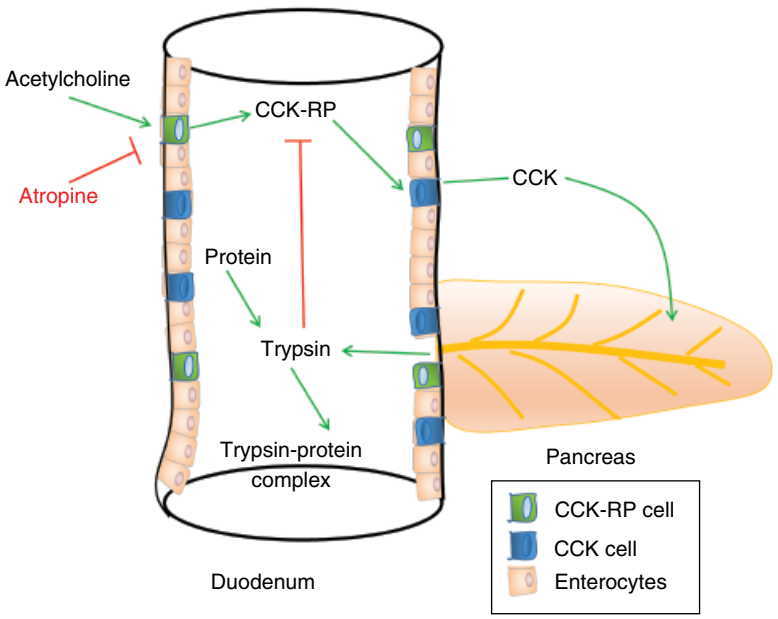

**Figure 8.1** The postulated mechanism by which cholecystokinin-releasing peptide (CCK-RP) stimulates the postprandial secretion of CCK. CCK-RP is secreted into the proximal small intestine under the influence of cholinergic pathway and inactivated by trypsin. When food enters the duodenum postprandially, protein binds to trypsin and prevents the inactivation of CCK-RP. CCK-RP stimulates CCK cells in the duodenum to release CCK into the bloodstream. CCK, in turn, stimulates pancreatic enzyme secretion.

insensitive to atropine or tetrodotoxin, indicating a direct action on pancreatic acini [41]. However, *in vivo* studies of humans and dogs have shown that atropine can block CCK-stimulated pancreatic secretion, implying involvement of cholinergic pathways [42–44]. Furthermore, enzyme output in response to low-dose CCK is reduced after vagotomy [45]. It appears that CCK can act through atropine-sensitive and atropine-insensitive pathways to stimulate pancreatic exocrine secretion. Human studies have shown that CCK-8 infusions at physiologic doses can stimulate pancreatic enzyme output predominately in an atropine-sensitive fashion [42]. Furthermore, studies in rats indicate that physiologic doses of CCK act through stimulation of vagal afferent pathways originating from the duodenal mucosa [46] (Fig. 8.2). CCK receptors have been detected in the rat vagus nerve using *in vitro* autoradiography [47]. Vagal $CCK_1$ receptors exist in high- and low-affinity states [48–50]. Under physiologic conditions, CCK appears to act through high-affinity vagal $CCK_1$ receptors to mediate pancreatic enzyme secretion [49]. In contrast, the effect of CCK on satiety is mediated by low-affinity vagal CCK receptors [51]. These findings suggest that different affinity states of the vagal CCK receptors mediate different digestive functions. Under physiologic conditions, CCK seems to stimulate postprandial pancreatic enzyme secretion through cholinergic pathways rather than through direct action on pancreatic acinar cells. M1 and M3 muscarinic receptors on pancreatic acini appear to mediate these responses [52,53] (Fig. 8.2). The molecular cloning of the CCK receptor gene and subsequent recognition that its expression is virtually absent in human pancreas [54,55] suggest that CCK acts at an extrapancreatic site. One study indicated that human acini do not respond to CCK agonists, although they respond to a muscarinic agonist [54]. In contrast, acini responded to CCK agonists after adenovirus-mediated CCK receptor gene transfer [54]. Quantitative reverse transcription polymerase chain reaction showed that $CCK_1$ receptor mRNA expression was ~30-fold lower than that for $CCK_2$ receptors, and ~10-fold lower than for $M_3$ muscarinic receptors. *In situ* hybridization did not detect $CCK_1$ receptor mRNAs in adult human pancreas, supporting the concept that CCK acts at an extrapancreatic site to stimulate enzyme secretion. By contrast, a study of isolated human pancreatic acini showed that physiologic levels of CCK induced $Ca^{2+}$ signaling, activated mitochondrial function, and stimulated enzyme secretion [56]. The physiologic relevance of these observations is unclear. $CCK_1$ receptors are expressed in human pancreatic stellate cells, which lie near acinar cells [57]. Low CCK concentrations (20 pM) stimulate acetylcholine release, which evokes enzyme secretion from pancreatic acini. Thus, it appears that CCK may regulate cholinergic stimulation of the pancreas through both neural and nonneural pathways.

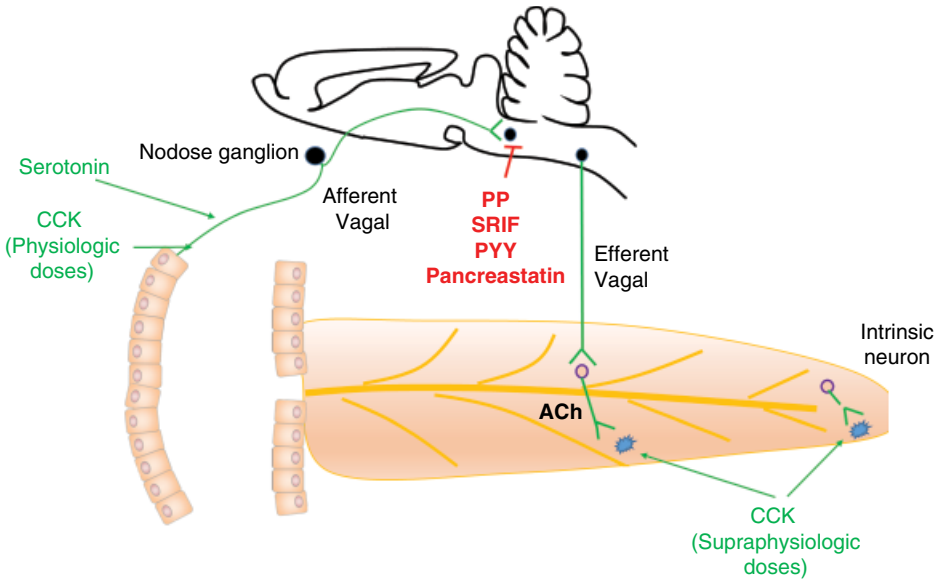

**Figure 8.2** Sites and mechanisms of action of stimulatory and inhibitory hormones to modulate pancreatic enzyme secretion. Dosages of cholecystokinin-8 (CCK-8) that produce physiologic plasma CCK levels act through stimulation of the vagal afferent pathway, which originates from the gastroduodenal mucosa. In contrast, dosages that produce supraphysiologic plasma CCK levels act on intrapancreatic neurons and, to a lesser extent, on pancreatic acini. Serotonin (5-HT), another stimulatory hormone, also acts via the vagal afferent pathway to evoke pancreatic enzyme secretion. In contrast, most of the inhibitory hormones such as PP, SRIF, PYY, and pancreastatin act at a central vagal site to inhibit pancreatic secretion. ACh, acetylcholine; PP, pancreatic polypeptide; SRIF, somatostatin; PYY, pancreatic polypeptide YY.

### Serotonin

Apart from CCK, intestinal serotonin (5-HT) appears to play an important role in mediating postprandial pancreatic enzyme secretion [58–61]. Although 5-HT is found in the myenteric plexus, the major source in the gastrointestinal tract appears to be mucosal enterochromaffin cells [62]. 5-HT is released in response to various stimuli [62], including duodenal acidification [62], instillation of hypertonic glucose, sucrose, or maltose solutions [58,63], vagal stimulation [64], and mechanical stimulation [65]. 5-HT may increase the discharge of vagal afferent fibers from the stomach and proximal intestine [66,67], which in turn can stimulate pancreatic secretion by way of a vagovagal reflex mediated by a cholinergic afferent pathway [58]. *In vivo* studies show that vagal responses to luminal osmolarity and the digestion products of carbohydrates depend on the release of endogenous 5-HT from mucosal enterochromaffin cells, which acts on $5\text{-HT}_3$ receptors on vagal afferent fibers [58] (Fig. 8.2).

5-HT and CCK are the principal mediators of postprandial enzyme secretion. A $CCK_1$ receptor antagonist inhibited 54% of postprandial protein secretion in rats. $CCK_1$ receptor and $5\text{-HT}_3$ antagonists combined almost completely abolished exocrine pancreatic secretion [58], suggesting that 5-HT-dependent pancreatic stimulants account for about 50% of postprandial pancreatic secretion. Vagal CCK and 5-HT receptors act synergistically to mediate pancreatic secretion [61], explaining how a small increase in the plasma CCK level is sufficient to produce a robust postprandial pancreatic secretion.

### Other Hormones and Stimulatory Factors

*Insulin* plays a significant role in modulating exocrine pancreatic secretion [68]. Animal studies have demonstrated that insulin potentiates the secretory response of secretin plus CCK [69], and that ouabain, an inhibitor of $Na^+,K^+$-ATPase activity, abolishes the stimulatory action of insulin. Physiologically, the actions of insulin are important because immunoneutralization experiments in conscious rats showed that pancreatic secretion of water, $HCO_3^-$, and protein stimulated by a meal or by a combined intravenous infusion of physiologic doses of secretin and CCK is markedly reduced when the circulating insulin is neutralized with a rabbit anti-insulin antibody [70]. It is well known that pancreatic enzyme secretion is often reduced in diabetes without overt pancreatic disease [71]. This may be mediated by enhanced activation of the TRESK $K^+$ channel in the nodose ganglia of diabetic rats, reducing the excitability of the nodose ganglia and contributing to decreased pancreatic secretion mediated by the vagovagal reflex [72].

*Bombesin* (a gastrin-releasing peptide in mammals), a polypeptide isolated from the skin of frogs and also found in the human digestive tract, stimulates pancreatic secretions that contain small amounts of $HCO_3^-$ and high concentrations of enzymes in humans [73,74]. Bombesin can act directly on the pancreas, or indirectly by promoting CCK release from the small intestinal mucosa [75]. In other systems, bombesin reportedly exerts its effect by way of a cholinergic pathway [76]. Hence bombesin may act through different pathways to stimulate pancreatic secretion. However, the physiologic importance of bombesin in pancreatic secretion is uncertain as bombesin receptor antagonists do not influence postprandial enzyme secretion in mammals [77].

*Neurotensin* appears to stimulate pancreatic enzyme secretion in humans and dogs [78,79]. In rats, the stimulation appears to be neurally mediated, involving cholinergic vagal afferent pathways [80]. Neurotensin is released by intestinal fatty acids, suggesting a role in mediating fat-stimulated pancreatic secretion [79]. However, exogenous infusion of neurotensin in doses that stimulate pancreatic secretion results in a plasma level much higher than after a normal meal [78,79].

*Ghrelin*, found in gastric endocrine cells and in neurons of the hypothalamic arcuate nucleus [81–83], has been shown to stimulate pancreatic enzyme secretion. It acts as an endogenous ligand for the growth hormone secretagogue receptor [81–83], which is found throughout the body, including the hypothalamus and the pancreatic islet and acinar cells. Depending on the animal species, ghrelin acts directly [84] on acinar cells or centrally through the vagal cholinergic pathways [85].

*Nitric oxide* (NO) is present in pancreatic neurons and vascular endothelium [86], and appears to play a significant role in regulating pancreatic secretion. In humans, L-NAME, an inhibitor of NO production, dose dependently reduces enzyme secretion stimulated by secretin and cerulein [87]. *In vitro*, NO synthase inhibition has no effect on amylase release or intracellular $Ca^{2+}$ concentration in rat pancreatic acinar cells stimulated by carbachol and CCK-8 [88]. L-NAME also reduces CCK-stimulated pancreatic microvascular blood flow and at the same time decreases pancreatic fluid and protein output in rats [89]. This observation may have clinical importance because inadequate blood flow has been associated with clinical pancreatitis. Interestingly, treatment with the NO donor L-arginine before and after cerulein injection increases pancreatic blood flow and reduces the severity of cerulein-induced hemorrhagic pancreatitis. These observations suggest that NO may protect the pancreas from injury, possibly because it increases pancreatic blood flow.

## Neural Mechanisms

### Parasympathetic Nervous System

The pancreas is innervated by parasympathetic and sympathetic nerve fibers. The parasympathetic fibers pass through the pancreas directly through the vagus nerve and indirectly by the celiac ganglion, the splanchnic nerves, and perhaps through the intramural plexus of the duodenum. In humans, the vagus nerve appears to play an important role in mediating pancreatic secretion. Insulin-induced hypoglycemia, which is presumed to stimulate the vagus nerve centrally, augments secretin-stimulated pancreatic protein output [90]. Vagotomy reduces the $HCO_3^-$ secretory response to exogenous hormones. Furthermore, vagotomy also reduces pancreatic enzyme responses to intestinal stimulants and food [45,91]. Cholinergic stimulation appears primarily to modulate the actions of gut peptides on pancreatic secretion but has no physiologically relevant effect on CCK or secretin release [92].

In humans, stimulation of duodenal volume receptors and osmoreceptors elicits a pancreatic enzyme response mediated by cholinergic neurons [93,94]. Increased firing in peripheral afferent vagal neurons and in central sites has been recorded after gastric distension and intestinal perfusion with amino acids and HCl [95–97].

Intrapancreatic postganglionic cholinergic neurons regulate enzyme and $HCO_3^-$ secretion. These neurons are activated by central input during the cephalic phase and by vagovagal reflexes initiated by gastric- and intestinal-phase stimulation. Acetylcholine released by pancreatic neurons may act directly on acinar cells or potentiate the action of secretin on $HCO_3^-$ secretion from duct cells *in vitro*. Acetylcholine and CCK interaction is additive. The enteropancreatic reflex may also play a role in mediating postprandial enzyme secretion [94]. This is especially important after chronic vagotomy [98].

### Sympathetic Nervous System

Adrenergic innervation of the pancreas occurs mainly through the splanchnic nerves, which are distributed to blood vessels, with a few passing to acini and ducts [38].

Activation of splanchnic nerves usually inhibits exocrine and endocrine pancreatic secretion; splanchnic nerve stimulation decreases and splanchnicectomy increases pancreatic secretion in response to pancreatic stimulants [38,99]. These responses are likely mediated by vasoconstriction caused by stimulation of α-adrenergic receptors on blood vessels. Physiologically, the major role for adrenergic activation appears to be the inhibition of fluid and $HCO_3^-$ secretion, which is mainly mediated by vasoconstriction.

### Enteropancreatic Neural Reflex

Functional and anatomic enteropancreatic neural connections have been demonstrated by anterograde and retrograde tracing. Neurons in the ganglia of the myenteric plexus of the stomach and duodenum project directly to the pancreas [100]. Stimulation of duodenal myenteric neurons can influence endocrine and exocrine pancreatic functions in the rat. These enteropancreatic neural pathways have cholinergic and serotonergic components [100,101]. The cholinergic nerves from the duodenum stimulate intrapancreatic neurons through nicotinic synapses. In contrast, stimulation of enteropancreatic serotonergic axons inhibits pancreatic secretion through presynaptic $5\text{-}HT_{1P}$ receptors on cholinergic nerves [100]. The physiologic role of the serotonergic enteropancreatic neural pathways is unclear.

## Inhibition of Pancreatic Secretion

The regulation of pancreatic secretion depends on the balance between inhibitory and stimulatory influences exerted through hormones and the autonomic nervous system. The inhibitory phase of pancreatic secretion is mediated by many hormones.

### Pancreatic Polypeptide (PP)

PP is localized in the islets of Langerhans and between the acinar cells of the exocrine pancreas [102]. PP secretion is regulated mainly by a cholinergic mechanism [103]. Postprandial PP release is mediated by a long vagovagal reflex and short local cholinergic pathways [103].

In humans and dogs, infusion of physiologic concentrations of PP inhibits basal and stimulated pancreatic secretion [103,104]. *In vivo*, PP appears to act preferentially by inhibiting vagal stimulation [105]. *In vitro*, PP inhibits pancreatic enzyme secretion by way of presynaptic modulation of acetylcholine release [106]. Because its secretion is under cholinergic control and it acts by interfering with cholinergic transmission, PP is an ideal candidate to modulate pancreatic secretion stimulated by the cholinergic enteropancreatic reflex. PP may also act centrally, as suggested by the presence of PP receptors in discrete locations in the hypothalamus, limbic system, brain stem, and other central locations [107,108]. Microinjection of PP into the dorsal motor nucleus (DMV) inhibits CCK-stimulated pancreatic secretion, suggesting that the DMV is an important site for neural feedback inhibition of pancreatic exocrine secretion [109]. Hence PP acts at multiple brain stem sites to modulate vagal cholinergic efferent output to the pancreas [110].

### Glucagon

Glucagon also inhibits pancreatic exocrine secretion stimulated by secretin and CCK or by ingestion of a test meal in dogs, cats, rats, and humans [111–113]. The inhibitory characteristics are reduced flow volume and decreased $HCO_3^-$ and enzyme secretion. Currently, the sites of action are unclear.

### Somatostatin

Somatostatin, present in the pancreas and also the upper gastrointestinal tract and central nervous system, may also play a role in the inhibition of pancreatic secretion. Research indicates that somatostatin does not act on peripheral vagal afferent or efferent pathways or directly on pancreatic acinar; it exerts its inhibitory action at a central vagal site [114]. Somatostatin injected into the DMV significantly inhibits pancreatic exocrine secretion evoked by intravenous administration of CCK-8 or 2-deoxy-D-glucose, suggesting that somatostatin acts through a central cholinergic mechanism [115,116].

### Enteroglucagon

Enteroglucagon is an intestinal hormone believed to mediate the inhibitory action of hypertonic glucose infusion into the jejunum. In animal studies, infusion of oxyntomodulin, a 37-amino acid glucagon-containing peptide isolated from porcine lower intestine, inhibits basal and cerulein-stimulated pancreatic secretion of $HCO_3^-$ and enzymes [117]. The inhibitory action of enteroglucagon is 10-fold more potent than that of pancreatic glucagon.

### Peptide YY (PYY)

PYY is a 36-amino acid peptide found in the distal intestine and colon of humans and experimental animals [118]. It is released by fat and, to a lesser extent, protein in the ileum or colon. PYY infusion in dogs significantly inhibits basal and meal-stimulated pancreatic $HCO_3^-$ and enzyme secretion [119]. Physiologic experiments demonstrate that intraileal, but not colonic, carbohydrate increases plasma PYY levels and decreases amylase secretion in dogs [120]. In humans, ileal carbohydrate perfusion inhibits exocrine pancreatic secretion. Therefore, PYY may represent a late postprandial event, serving as a physiologic signal to reduce exocrine pancreatic secretion after completion of digestion and nutrient absorption.

### Glucagon-Like Peptide 1 (GLP-1)

GLP-1 is another ileal hormone that is elevated in the circulation during ileal carbohydrate infusion. GLP-1 does not appear to act directly on the pancreas to inhibit exocrine secretion. In anesthetized pigs with cut splenic nerves, intravenous GLP-1 infusion inhibits hypoglycemia-induced pancreatic $HCO_3^-$ and protein secretion, effects absent in vagally stimulated, isolated, and perfused porcine pancreas [121], suggesting that GLP-1 acts through a central mechanism. Studies in rats indicate that GLP-1 inhibitory action depends on intact vagal nerves [122].

### Other Peptides

Although the list of peptides known to inhibit exocrine pancreatic secretion continues to expand, little is known about the mechanisms through which these and other hormones or neurotransmitters inhibit pancreatic enzyme secretion. Most of these peptides lack direct inhibition of pancreatic acinar cells and most suppress pancreatic enzyme secretion *in vivo* but do not act directly on acinar cells to reduce pancreatic enzyme release. Animal studies suggest that peptides such as PP, somatostatin, calcitonin gene-related peptide (CGRP), enkephalin, and pancreastatin inhibit pancreatic enzyme secretion by modulating cholinergic transmission, and most, if not all, act through a central vagal site [123–129].

## Feedback Regulation of Pancreatic Secretion

A series of observations in rats suggest that intraluminal actions of pancreatic proteases play an important role in regulating pancreatic enzyme secretion [28,130]. It was demonstrated that diversion of pancreatic juice in the duodenum stimulates CCK release and pancreatic enzyme secretion [29]. Conversely, intraduodenal administration of trypsin or chymotrypsin inhibits CCK release and pancreatic enzyme secretion [29]. This phenomenon is specific for activated proteases, and not with inactivated trypsin, amylase, lipase, or $HCO_3^-$.

Feedback regulation of pancreatic secretion by proteases appears to be mediated by a trypsin-sensitive substance secreted by the proximal small intestine, originally designated CCK-releasing factor (CCK-RF) [29,31]. When trypsin is present, this peptide is cleaved and inactivated. CCK-RF may mediate pancreatic enzyme secretion in response to dietary protein intake in rats. Dietary protein in the intestine competes for the trypsin that would otherwise inactivate CCK-RF [30]. The resulting increase in CCK-RF in the intestinal lumen stimulates CCK release and pancreatic enzyme secretion (Fig. 8.1).

Efforts to demonstrate a protease-sensitive feedback mechanism in humans remain controversial because of

technical limitations in removing or blocking intraluminal protease activity. Using a different approach, investigators reported that intraluminal administration of trypsin or chymotrypsin in humans suppresses CCK release and partially reduces the CCK response to intestinal administration of amino acids or oral ingestion of a test meal [22,131]. These observations support the existence of feedback regulation of pancreatic enzyme secretion in humans. Liener et al. demonstrated that Bowman–Birk soybean trypsin inhibitor, an inhibitor of chymotrypsin and elastase, strongly stimulates pancreatic enzyme secretion in humans [132].

The existence of a feedback regulation of pancreatic enzyme secretion in humans may have important clinical implications. In patients with chronic pancreatitis, decreased pancreatic enzyme secretion may result in elevated plasma CCK levels, reflecting a failure in the feedback modulation of CCK release. This may cause hyperstimulation of the pancreas and produce pain. Effective enzyme replacement therapy may reduce pancreatic stimulation, decrease intraductal pressure, and diminish pain. Large doses of pancreatic extract have reduced pain in some patients with chronic pancreatitis [133,134].

## Conclusion

Under physiologic conditions, in rodents and humans, cholinergic vagal afferent pathways rather than pancreatic acinar cells represent the primary targets on which CCK may act as a major mediator of postprandial pancreatic secretion. The vagal afferent pathways also transmit sensory information about the mechanical and physiologic state of the digestive tract, mediated in part by 5-HT, which in turn influences pancreatic secretion. A synergistic interaction between CCK and 5-HT at the level of the nodose ganglia may explain the robust postprandial pancreatic enzyme secretion despite a modest increase in plasma CCK after a meal. Interestingly, most hormones such as PP, somatostatin, CGRP, and pancreastatin act through a central vagal site to inhibit pancreatic enzyme secretion. This supports the Pavlovian concept that the neural system is the major regulator of pancreatic secretion.

# Regulation of Pancreatic Protein Synthesis and Growth

*Maria Dolors Sans and John A. Williams*

*Department of Molecular and Integrative Physiology, University of Michigan Medical School, Ann Arbor, MI, USA*

## Introduction

Regulation of pancreatic protein synthesis and growth allows the exocrine pancreas to provide an adequate supply of digestive enzymes for nutrient assimilation. In young animals, the pancreas grows along with general body growth and thereby provides an increasing amount of digestive enzymes. In the adult, digestive enzyme synthesis is regulated at both transcriptional and translational levels to match the need for both total and specific digestive enzymes. If the need for digestive enzymes is greater than can be met through these mechanisms, the pancreas can grow or regenerate. This can occur either as a result of increased food intake or because of decreased pancreatic mass due to disease. Some of the same systemic regulatory signals that regulate enzyme secretion, that is, the vagal nerve and gastrointestinal (GI) hormones, also participate in the regulation of pancreatic protein synthesis and growth, although the intracellular regulatory pathways involved are significantly different. An additional regulatory influence is provided by nutrients, especially amino acids and islet hormones, particularly insulin, which do not directly affect secretion. The purpose of this chapter is to provide a brief overview of the regulation of pancreatic protein synthesis and growth. Not all areas can be covered in depth owing to page limitations. Areas of recent progress are featured with review articles being cited to cover the older literature.

## Regulation of Protein Synthesis

Protein synthesis plays a central role in the maintenance of the pancreas and provision of digestive enzymes. Both the mRNA profile and autoradiographs of newly synthesized proteins are dominated by digestive enzymes. Whether the acinar cell can regulate digestive enzyme synthesis independent of the synthesis of cellular structural proteins is unclear. In general, the GI tract, including the exocrine pancreas, atrophies in the absence of food and protein synthesis that occurs in response to food intake helps to maintain normal function. Individual dietary components also regulate protein synthesis. In most cases, as reviewed in the following, this involves transcriptional regulation of digestive enzyme mRNA. By contrast, shorter term meal-stimulated protein synthesis is regulated primarily at the translational level. Finally, increased protein synthesis is necessary for pancreatic growth.

### Long-Term Regulation by Diet

Since the original work by Pavlov, the adaptation of the exocrine pancreas to dietary changes has been observed in a variety of species [1,2]. The content and secretion of the major digestive enzymes, proteases, amylase and lipases change in proportion to the dietary content of their respective substrates, protein, carbohydrate and fat, by stimulation of both, transcriptional and translational mechanisms [3–5]. Various hormones mediate many of these effects and in most cases their release is increased by the nutrients whose digestion they regulate. In some cases the genetic elements regulated in the promoter region have been identified although the full intracellular pathway leading to their regulation is not yet known [1].

#### Protein

Feeding a high-protein diet (typically 60–80% casein or other high-quality protein) increases the content of multiple proteases and the mRNA levels of trypsinogen, chymotrypsinogen, and proelastase [1,6], with activation

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

of the mTORC1 pathway and independently of cholecystokinin (CCK) [7]. There are, however, differential effects on different isoforms of enzymes such as trypsinogen and this increase is not mimicked by feeding a mixture of amino acids [8–10]. In another study, feeding mice a protein-free diet for 4 days resulted in a decrease in the relative pancreatic digestive enzyme content and secretion [11]. Other data showed that the stimulation of protease synthesis, by isolated pancreatic lobules following infusion of the CCK analogue caerulein, *in vivo*, was greatly increased compared with a small increase in translatable mRNA, suggesting a post-transcriptional locus for this regulation.

#### Carbohydrates

The level of carbohydrate in the diet has long been known to have significant effects on pancreatic amylase content and amylase mRNA [1,2]. This is seen when dietary carbohydrate replaces either dietary fat or protein, provided that dietary protein is adequate. Starch and sugars all similarly affect amylase, as does intravenous glucose. The effects of carbohydrate are believed to be primarily mediated by insulin. When animals are rendered diabetic, the amylase content and synthesis and mRNA levels fall dramatically, whereas lipase increases moderately [2,12]. Insulin restores the amylase synthesis and content and mRNA levels in diabetic rats. Similar decreases in amylase have been seen in obese rat and mouse models with insulin resistance. However, insulin administration to normal rats either decreases or does not change amylase, and other evidence suggests a more direct role for glucose in addition to effects on insulin. Amylase is also regulated by glucocorticoids [13], although this may not mediate dietary effects of carbohydrate. A dietary response sequence in the promoter of the amylase *Amy2.2* gene has been identified that mediates dietary adaptation and the effect of insulin [14].

#### Fat

In response to a high-fat diet (40–70% of calories as triglycerides), the content and synthesis of pancreatic triglyceride lipase increase [1]. This is accompanied by an increase in its mRNA [15,16]. Adaptation of other pancreatic lipases and colipase have been much less well studied. In neonate mice and rats, bile salt-stimulated lipase and pancreatic lipase-related protein 2 are the two predominant lipases [17]. Secretin has been proposed as a mediator of the effect of dietary lipid [18]. Fatty acids can stimulate secretin release and infusion of secretin in conscious rats led to an increase in the relative synthesis of lipase [1]. Gastric inhibitory peptide (GIP) has also been shown to increase pancreatic lipase and colipase content and mRNA levels [19]. Finally, ketones, metabolites of ingested fat, have also been proposed as a mediator of the increase in pancreatic lipase [1].

### Meal-to-Meal Regulation of Translation by Hormones and Nutrients

Whereas long-term dietary changes in digestive enzymes may be mediated by changes in mRNA expression, short-term meal-to-meal control needs to be immediate, reversible, and flexible. Such control of protein synthesis is mainly at the translational level. This section reviews the effects of food intake and hormones, especially CCK and insulin, on the exocrine pancreas translational machinery. Translation of mRNA into protein can be divided into three phases: initiation, elongation, and termination. For details on these three mechanisms, the reader is referred to recent reviews on translation [20–23]. Only a few studies have evaluated the immediate regulation of the pancreatic translational synthetic machinery after food intake. Early studies showed that fasting reduces total protein synthesis in the pancreas and refeeding stimulates it [24,25]. We have demonstrated that feeding a regular meal activates protein synthesis in the mouse pancreas at the translational level without an increase in the mRNA of the digestive enzymes [26]. In humans, feeding increases both the rate of secretion and synthesis of digestive enzymes, although the rate of turnover of zymogens remains fairly constant during feeding and fasting [27]. In rats and mice, feeding stimulates the protein kinase B (PKB/Akt)/mammalian target of rapamycin complex 1 (mTORC1) pathway and the phosphorylation of 4E-BP1 and ribosomal protein S6, downstream of mTORC1, in addition to the formation of the eIF4F complex [26] as illustrated in Fig. 9.1.

Dietary protein and amino acids have also been shown to be necessary to stimulate pancreatic protein synthesis at the translation initiation level in mice after 2 h of feeding [28]. This study demonstrates that when protein or leucine was removed from the diet, there was a strong inhibition of total protein synthesis and decreased polysomal fraction, with an increased eIF2α phosphorylation; the general controlled nonrepressed (GCN2) kinase was phosphorylated when leucine was not present. Dietary protein and amino acids have also been shown to stimulate pancreatic protein synthesis and pancreatic growth in rats [29] and mice [7] fed for several days. Branched-chain amino acids (BCAAs), particularly leucine, also stimulate the phosphorylation of 4EBP1 and S6K and the formation of the eIF4F complex in mice and rats, without the need for an increase in the hormones CCK and insulin [30]. A mechanism has been described for a direct stimulation of protein synthesis by amino acids through mTORC1 [26,30–32], and it seems that amino acids are necessary both as a signal and as a substrate for pancreatic digestive enzyme synthesis after a meal [28].

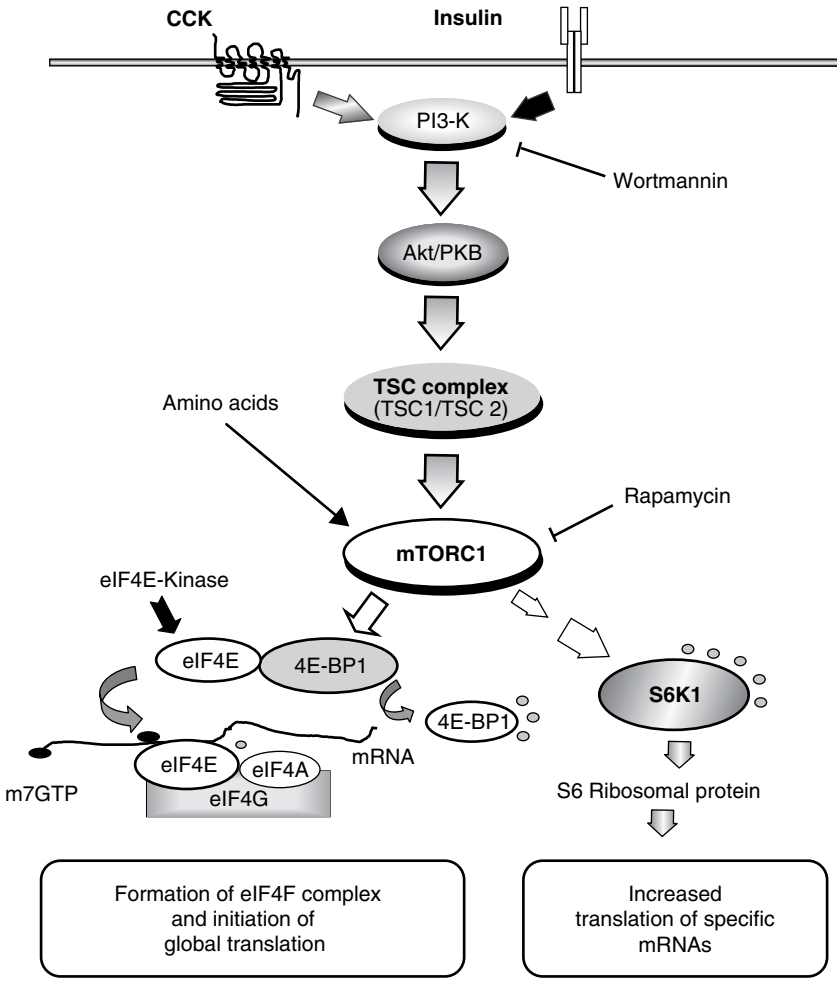

**Figure 9.1** CCK and insulin stimulate translational initiation through the P13K–PKB–mTORC1 pathway. mTORC1, which can be inhibited by rapamycin, phosphorylates the eIF4E-binding protein (4E-BP1) that allows the release of eIF4E and the formation of the eIF4F complex necessary for a global increase in translation. mTORC1 also phosphorylates S6K1 which is responsible for phosphorylating S6, thereby increasing the translation of a specific subset of mRNAs. CCK also increases the activity of an eIF4EK, leading to phosphorylation of eIF4E. Together, these effects lead to an increase in protein synthesis.

The effects of food can also be mediated by GI and systemic hormones and neurotransmitters. Their stimulatory mechanisms have been mainly studied in isolated pancreatic acini [33]. CCK, carbachol, insulin, and bombesin all stimulate the synthesis of total protein, trypsinogen, chymotrypsinogen, lipase, and amylase in isolated rat acini [34–36]. These *in vitro* studies demonstrate that CCK and insulin, at their stimulatory doses, have an additive effect on protein synthesis after 30 min, and that this effect is mainly at the translational level because it occurs without a change in mRNA levels and in the presence of actinomycin D [36,37]. Increased synthesis of both digestive enzymes and structural proteins was observed, although differences between individual proteins suggested nonparallel translational effects [37].

CCK stimulates protein synthesis in isolated rat acini and in the whole animal [38–40], by increasing the rate of translation initiation [38–41] and elongation [42], at concentrations that stimulate digestive enzyme secretion. Additionally, CCK or its analogue caerulein, activates the S6 kinase (S6K) [43,44] and the phosphorylation of eIF4E [40,41] and activates the formation of the eIF4F complex by stimulating the release of eIF4E from its binding protein 4E-BP1 and increasing the association of eIF4E with eIF4G [26,41]. These actions are summarized in Fig. 9.1. The activation of S6K, the formation of the eIF4F complex, and the activation of the elongation processes and eEF2 appear to be regulated through a rapamycin-sensitive pathway and to be downstream of phosphatidylinositol 3-kinase (PI3K) [39,42,43]. The calcium–calmodulin-activated phosphatase calcineurin is also involved in the activation of CCK-stimulated pancreatic protein synthesis and the regulation of the translational machinery [40]. As mentioned earlier,

insulin also stimulates protein synthesis in pancreatic acini *in vitro* [35] by activating the eIF4F complex formation, in a similar manner to CCK [39]. Insulin stimulates pancreatic digestive enzyme synthesis *in vivo*, after a meal. This has been demonstrated with the use of pancreatic acinar cell conditional insulin receptor (IR) knockout mice [44]. The activation of the Akt/mTORC1 pathway is reduced in the pancreas of these mice after 2 h of a meal feeding, and also the translational machinery and polysomal fraction. Additionally, the protein content of the stimulated pancreatic juice is reduced, but not the total pancreatic juice volume, compared with their littermate controls. This demonstrates that insulin is an important physiologic regulator of the pancreatic digestive enzyme synthesis and acinar cell homeostasis that could lead to pancreatic insufficiency during diabetes.

At concentrations of CCK and cholinergic analogues that inhibit secretion [33], protein synthesis is also inhibited [34,38,45]. In minced rabbit pancreas, however, only a decrease in protein synthesis was observed in response to CCK, and this was accompanied by a decrease in the number of polysomes [45].

### Inhibition of Pancreatic Protein Synthesis. Endoplasmic Reticulum (ER) Stress and Unfolded Protein Response (UPR)

*In vivo*, inhibition of pancreatic protein synthesis occurs during the development of acute pancreatitis [46]. This inhibition is accompanied by a reduction in the activity of the guanine nucleotide exchange factor eIF2B, an increase in eIF2α phosphorylation, and a decrease in the formation of the eIF4F complex [38,40,46] (Fig. 9.2). Additionally, this inhibitory effect appears to be calcium related, because the incubation of isolated acini in calcium-free media or with A23187 and thapsigargin to release intracellular $Ca^{2+}$ increases eIF2α phosphorylation and inhibits eIF2B activity. This suggests that pancreatic acinar cells adapt to short-term stress induced by reduction in calcium stores by inhibiting protein synthesis of pancreatic enzymes [38,45]. The ER-resident kinase (PERK) [47] mediates eIF2α phosphorylation in the exocrine pancreas [48,49] and activates the ER stress mechanisms. The inhibition of protein synthesis associated with high concentrations of CCK could therefore be an adaptive or protective mechanism in response to stress localized in the ER [38,46].

ER stress mechanisms are protective cellular responses to stress in the ER, due to an accumulation of unfolded or misfolded proteins in this cellular compartment that trigger the UPR [49]. ER stress and UPR mechanisms have been described in some experimental models of acute pancreatitis [46,50], in pancreatic acinar cell damage *in vitro* [51], and in induced pancreatic acinar cell damage due to alcohol abuse *in vivo* [52].

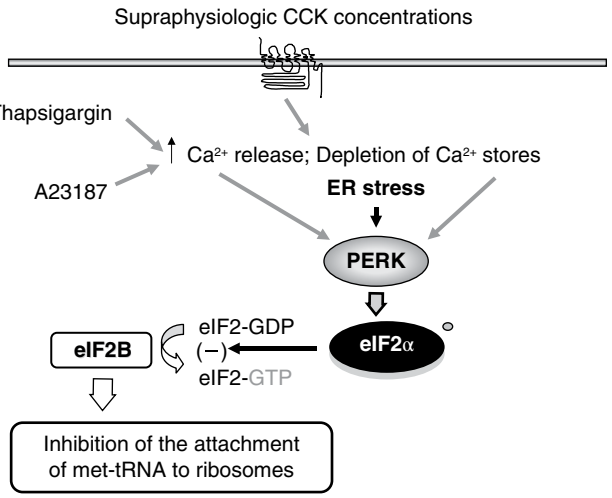

**Figure 9.2** Mechanism by which high concentrations of CCK and induction of ER stress inhibit initiation of translation. Depletion of intracellular $Ca^{2+}$ stores or other forms of ER stress activates a kinase (such as PERK), which phosphorylates eIF2α and thereby inhibits eIF2B. This inhibition results in a decrease in protein synthesis.

It is possible that all these highly regulated mechanisms of protein synthesis and associated ER stress are present in pancreatic cancer.

## Regulation of Pancreatic Growth

The pancreas arises embryologically as an outgrowth of the foregut that develops through a relatively undifferentiated duct-like state into acini, islets, and mature ducts under the influence of mesenchyme and a number of transcriptional regulators [53]. By birth, the pancreas has assumed its fully differentiated form and histology but continues thereafter to grow in parallel with body growth. In the adult animal, acinar and islet cells were originally assumed to be no longer dividing but in fact they both show a small but finite turnover that can be accelerated by hormones and diet. Hence the acinar and beta islet cells are considered to exist in the Go phase of the cell cycle rather than being terminally differentiated. Whether undifferentiated stem cells remain in the adult pancreas or if small duct cells can function as stem cells remains controversial.

In the exocrine pancreas, enhanced growth in response to hormones or diet can take the form of cellular hypertrophy in which protein increases in excess of DNA resulting in larger cells, or cellular hyperplasia marked by an increase in DNA resulting in more cells. Normally in hyperplasia, protein increases in parallel with DNA so the endpoint is normal-sized cells. In hypertrophy and hyperplasia, there is usually an increased total digestive

enzyme content in the pancreas, although the concentration relative to DNA or total protein may or may not change. Although not well studied, glandular atrophy can result from loss of cellular protein, as seen with protein-deficient diets [11], or from loss of cells, as seen with some forms of pancreatitis following apoptosis or necrosis. Two distinct types of *in vivo* growth to be discussed are adaptive growth in response to diet and hormones and regeneration following the loss of functional cells. The use of cell culture as a model for pancreatic growth will also be reviewed.

## Adaptive Growth in Response to Nutrients and Hormones

To insure adequate nutrient absorption, the amount and composition of digestive enzymes secreted by the pancreas must complement the size and macronutrient composition of a meal. Although the synthesis and secretion of digestive enzymes can increase with consumption of larger and/or more frequent meals, this capacity is finite. Another mechanism whereby the pancreas can adapt to increased feeding is through growth of the acinar cells. Both a high-protein diet and hyperphagia that occurs with cold exposure, pregnancy, and lactation are associated with pancreatic growth.

GI hormones released after a meal may contribute to the growth-promoting effects of feeding on the exocrine pancreas as CCK, secretin, and gastrin have all been shown to induce pancreatic growth [54,55]. The effects of CCK have been studied extensively in rodents and have been reviewed previously [56,57]. Direct administration of CCK or caerulein induces acinar cell growth *in vivo* [54,55,58] and *in vitro* [59]. Feeding a high-protein diet and especially synthetic or naturally occurring trypsin inhibitors, such as those found in raw soy flour, prevents feedback regulation of CCK secretion and culminates in maintained high concentrations of circulating CCK [60], which also stimulates pancreatic growth [61]. Oral trypsin inhibitor-induced pancreatic growth is blocked by coadministration of CCK antagonists [62] and is absent in CCK [63] and CCK-A receptor-deficient mice [64]. In the rat, CCK-stimulated growth is primarily through cellular hypertrophy, but with some hyperplasia, whereas in mice it is primarily through hyperplasia. In both cases, the hyperplasia involves DNA synthesis and replication of mature acinar cells [65]. Although CCK can mediate adaptive growth, it does not appear essential for growth during development and CCK or its receptors are not necessary in most studies for maintenance of normal pancreatic size. In contrast to CCK, the hormone secretin had little effect by itself but can potentiate the action of CCK [54].

More recently, information has emerged on intracellular pathways mediating pancreatic growth (Fig. 9.3). CCK is known to activate a number of intracellular pathways potentially related to growth, including an increase in intracellular $Ca^{2+}$, three MAPK pathways, and the PI3K–mTOR pathway [33]. Most of these pathways are activated in the pancreas in response to endogenous CCK release following feeding of camostat [66]. Pharmacologic and genetic evidence exists for three major intracellular pathways, calcineurin–NFAT, mTORC1, and ERK1/2, playing nonredundant roles in

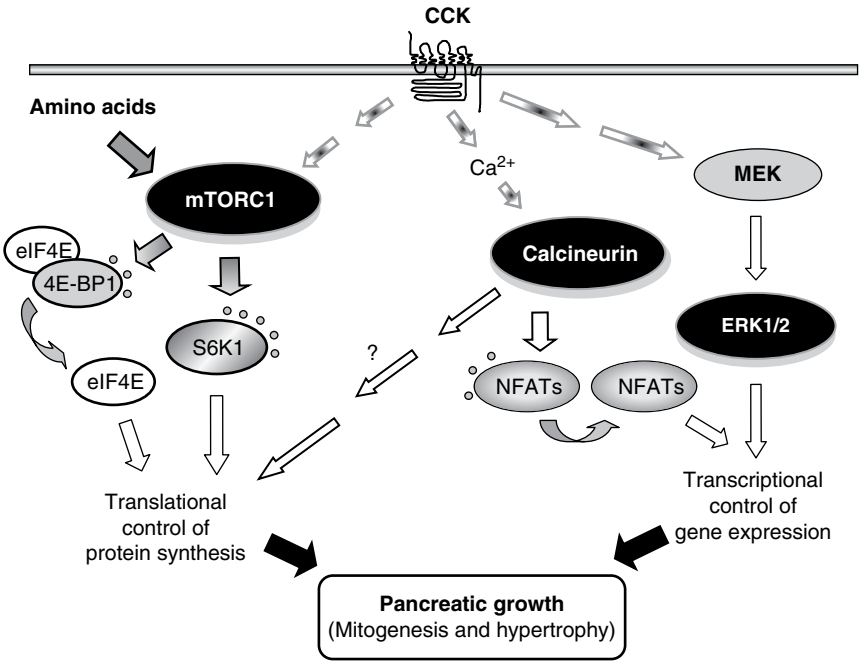

**Figure 9.3** Intracellular pathways through which CCK stimulates pancreatic growth. At least three pathways involving calcineurin–NFAT, mTORC1, and ERK1/2 have been shown to be necessary for growth of rodent pancreas either in vivo or in vitro. Inhibitors of all three pathways can block growth.

adaptive pancreatic growth. The calcineurin–NFAT pathway can be blocked pharmacologically with the calcineurin inhibitors FK506 and cyclosporin A and genetically by overexpression of *Rcan1* [63,67,68]. The mTORC1 pathway can be blocked with rapamycin [69] or by acinar cell-specific deletion of Raptor, an essential component of mTORC1 (S.J. Crozier, M.D. Sans, and J.A. Williams, unpublished data). The ERK pathway can be blocked with specific MEK inhibitors active *in vivo* such as PD-0325901 [70]. Blockage of each of these pathways blocks pancreatic adaptive growth induced by feeding camostat. These pathways are important regulators of mRNA transcription and translation and it is likely through modulation of these processes that CCK affects pancreatic growth by activating the cell cycle.

Polyamines have also been studied as mediators of pancreatic growth induced by CCK and other hormones [71]. The naturally occurring polyamines putrescine, spermidine, and spermine are normal cell components involved in protein and DNA synthesis. Biosynthesis of polyamines is initiated by ornithine decarboxylase and its inhibitor difluoromethylornithine inhibits pancreatic growth in response to CCK. However, there is no clear role for polyamines in pancreatic growth and it may be that they are simply a cellular component necessary for pancreatic growth similar to their role in intestinal adaptation and liver regeneration.

Growth of the pancreas in response to CCK administration is greatly diminished in rats fed a low-protein diet [72]. Conversely, consumption of large amounts of protein induces pancreatic hypertrophy in rodents [73], even in the presence of a CCK receptor antagonist [74] and in CCK-deficient mice [75]. Therefore, it appears that dietary protein both potentiates the effects of CCK on pancreatic growth and also stimulates pancreatic growth via CCK-independent mechanisms. These CCK-independent mechanisms are undoubtedly mediated, at least in part, by amino acids. Purified amino acids do not stimulate CCK secretion, yet ingestion of large quantities of amino acids stimulates pancreatic growth [74]. This action is mediated in large part by the mTORC1 pathway, which is activated by amino acids [7]. Interestingly, growth of the pancreas in mice fed a high-protein diet occurs predominately via cellular hypertrophy [75] whereas that associated with supraphysiologic levels of CCK, such as direct CCK administration and trypsin inhibitor feeding, in mice is primarily hyperplastic [63]. It may be that a threshold level of CCK exists, above which signal transduction pathways are activated that permit cell division following cellular hypertrophy.

Although less well studied, other hormones may also regulate pancreatic growth in response to meal feeding. Thyroid hormone, for instance, stimulates pancreatic growth *in vivo* when administered at high concentrations [76]; whether it does so at more physiologic concentrations has yet to be tested. Insulin stimulates protein synthesis in the pancreas and also growth of acinar-like AR42J cells *in vitro* [12]. Glucocorticoids can induce pancreatic hypertrophy in adult rats [77].

Activation of vagal nerve fibers to the pancreas during feeding stimulates the release of additional peptides associated with secretion of bicarbonate and digestive enzymes. Some of these neuropeptides may also play a role in the regulation of pancreatic growth and their effects have been reviewed previously [78]. In particular, vasoactive intestinal polypeptide (VIP) potentiates the effects of caerulein on pancreatic growth in a manner similar to secretin and gastrin-releasing peptide and bombesin stimulate pancreatic growth, although not as strongly as CCK.

## Regeneration

Despite the low rate of cellular turnover normally observed in the adult pancreas, studies in rodents have demonstrated its ability to regenerate in response to tissue injury. This has been studied both after pancreatitis and following surgical resection. Experimental pancreatitis induced by caerulein, arginine, bile salts, or ethionine leads to cell death by a combination of apoptosis and necrosis. The remaining acinar cells dedifferentiate and form tubular complexes that express both acinar and ductal characteristics and also some markers of embryonic pancreas. These cells divide and grow and eventually differentiate back into mature acinar cells [79–81]. At present, there is little definitive evidence for regeneration from stem cells.

Following surgical resection of 50–90% of the rat pancreas, the remnant pancreas increases in size and protein and DNA content, with the increase being greater after more complete resection [82]. However, the pancreas never regains its normal size and islets appear to regenerate to a greater extent than exocrine tissue. In some reports differentiated acinar cells are said to incorporate thymidine or show mitotic figures, whereas in other studies regeneration is reported to occur in the injured margin and show tubular complexes and express embryonic markers [83]. In mice, a 75% resection was followed by growth of the remnant by 40%, with evidence for proliferation of differentiated acinar cells [84].

Similarly to adaptive growth, dietary protein, CCK, and insulin play a significant role in the regeneration of exocrine cells following pancreatic injury. The pancreas is incapable of regeneration in rats fed a protein-free diet. Both exogenous and endogenous CCK enhance and CCK receptor antagonists slow the rate of pancreatic regeneration following pancreatitis [85]. There is also a significant decrease in the rate of pancreatic regeneration

in mice lacking the CCK-A receptor in the pancreas [86]. The importance of insulin is shown by the fact that in diabetic rats, CCK administration fails to induce pancreatic regeneration following pancreatitis unless exogenous insulin is also administered [87]. Pertinently, it has been demonstrated that the expression of IGF-1 mRNA is significantly increased following pancreatitis and resection, indicating that both insulin and IGF may be important in pancreatic regeneration.

The expression of cellular oncogenes that regulate the cell cycle and thereby control cellular proliferation rates is significantly increased in models of pancreatic regeneration [88,89]. Many genes associated with embryonic development, and whose expression is normally repressed in the adult, are re-expressed during pancreatic regeneration following pancreatitis [80]. Only a little is known of signal transduction pathways that mediate these changes in gene expression. The p42/p44 MAPK pathway, which modulates the expression of cell-cycle regulators, is activated in the regenerating pancreas [90]. Activation of the PI3K pathway has been shown to be necessary for pancreatic regeneration following resection, as inhibition of the pathway via pharmacologic inhibitors or siRNA severely diminished regeneration [84]. Moreover, the PI3K pathway activation in response to resection decreased with age and may contribute to the lessened regenerative capacity of the aged pancreas. Further identification of the signal transduction pathways, and also the factors modulating these pathways, will be important for improving our understanding of pancreatic regeneration.

### Growth of Pancreatic Cells in Culture

*In vitro* culture of differentiated or immortalized cells can be used as models for cell growth. Most pancreatic cancer cell lines, however, are undifferentiated and will not be considered here. Primary dissociated pancreatic cells, although not dividing, can be maintained in suspension culture under conditions such that they retain the differentiated phenotype or where they dedifferentiate and adopt a more plastic phenotype. When isolated acinar cells or acini are placed on an extracellular matrix such as collagen or matrigel, the cells will initiate division and remain viable for several weeks but almost invariably lose their differentiated appearance. CCK or its analogue caerulein can stimulate cell division and growth, as do insulin, epithermal growth factor (EGF), and other growth factors [59,91]. This model has been applied to evaluating which intracellular pathways mediate growth, with evidence for participation by Ras [92], PI3K/Akt [84], and MAPK pathways [93]. The dedifferentiated phenotype of cultured acinar cells was originally reported as duct like [94,95]. Subsequently, they were characterized as similar to precursor cells that can transdifferentiate into insulin-containing islet cells [96] and that the dedifferentiated cells can simultaneously express acinar, ductal, or beta-cell proteins. Another report showed retention of acinar cell phenotype with an altered medium containing a high amino acid level [97]. In a similar manner, pancreatic duct cells have been grown in monolayer culture. They retain their ion-transporting phenotype and have been used to study duct function. Their growth in culture is stimulated by EGF, TGFα, and insulin, inhibited by TGFβ, but not affected by secretion or other GI peptides [98].

Although no real differentiated pancreatic acinar cell line exists, considerable research has been carried out with AR42J cells, a rat cell line derived from a azoserine-induced tumor which under the influence of glucocorticoids assumes a more acinar phenotype [99]. However, these cells were subsequently shown also to have neuroendocrine properties and can even be driven toward an islet phenotype such that they appear more like an undifferentiated ductal epithelium. Their growth can be stimulated by CCK, gastrin, PACAP, and other peptides, but only to 25–30% and not after exposure to dexamethasone, which induces acinar differentiation but inhibits growth [99].

In summary, all the cultured pancreatic cells studied to date, although dividing and regulated by hormones, possess a relatively undifferentiated phenotype. Hence they are more a model for regenerating pancreas after pancreatitis than they are a model for diet- or hormone-driven acinar proliferation.

## Introduction

Fibrogenesis is defined as the development or production of fibrous tissue. In the healthy pancreas, fibrogenesis is a well-controlled, regulated process that is essential for regular turnover of extracellular matrix (ECM) in the parenchyma, thereby maintaining normal pancreatic architecture. In diseased states, however, this process is hijacked such that the fine balance between production and degradation of fibrous tissue is disrupted, leading to the deposition of excessive amounts of ECM proteins in the organ, eventually resulting in pathologic fibrosis.

Cellular and molecular mechanisms involved in pancreatic fibrogenesis have only begun to be understood since 1998, when methods were developed to isolate and culture pancreatic stellate cells (PSC), now established as key cells in the fibrogenic process, from rodent and human pancreas [1–3]. Interestingly, the presence of these cells in the pancreas was first reported by Watari et al. [4] in Japan a decade and a half earlier (in 1982), and confirmed by Ikejiri [5] in 1990. However, little was known of their function at the time. It was the subsequent development of techniques to isolate viable PSC from the pancreas that provided the much-needed *in vitro* tool that enabled researchers to interrogate the functions of these cells both in health and in pancreatic disease.

## Pancreatic Stellate Sells (PSC)

### PSC in Health

PSC are resident cells of the pancreas located around the basolateral aspects of acinar cells (Fig. 10.1a), blood vessels, and small pancreatic ducts [1,2] and also around and within pancreatic islets [6]. In the healthy pancreas, PSC make up a relatively small proportion (4–7%) of the total parenchymal cell population [1]. In their quiescent (non-activated) state, PSC store abundant vitamin A (retinoids) in their cytoplasm. This characteristic feature identifies a cell type that is part of a larger "stellate cell system" in the body, comprising retinoid storing cells in several other organs, including the liver, lungs, intestine, kidney, spleen, and adrenal glands [7]. This vitamin A storing capacity was exploited by Apte et al. [1] to develop the density gradient centrifugation method for the isolation of quiescent PSC from the pancreas. PSC in early culture exhibit a polygonal shape with abundant lipid droplets surrounding a central nucleus (Fig. 10.1b). It is the presence of these cytoplasmic vitamin A droplets, and also the expression of selective markers such as the intermediate filaments desmin, glial fibrillary acidic protein (GFAP), and nestin, and the neuroectodermal proteins neural cell adhesion molecule and nerve growth factor, that serve to differentiate PSC from fibroblasts (Fig. 10.2).

In addition to synthesizing ECM proteins (collagen types I–IV, fibronectin, and laminin) that constitute fibrous tissue, PSC also produce matrix metalloproteinases (MMP), the enzymes that degrade ECM proteins and their inhibitors TIMPs (tissue inhibitors of matrix metalloproteinases) [8]. Thus, in the healthy pancreas, PSC are thought to regulate normal ECM turnover by maintaining a fine balance between the production and degradation of ECM proteins. Interestingly, the role of PSC in the normal pancreas is not limited to regulation of matrix turnover. Additional postulated functions for PSC in the healthy pancreas include (i) acting as intermediary cells in cholecystokinin (CCK)-dependent exocrine pancreatic secretion in humans [9]; (ii) contributing to innate immunity via expression of toll-like receptors

(TLR 2, 3, 4, 5, 9), which recognize pathogen-associated molecular patterns (PAMP) [10,11]; PSC may thus actively protect the gland from initial injury [12]; and (iii) a role as progenitor cells (based on their transplantability, survival in circulation, ability to differentiate into other cell types, and expression of several stem-cell markers, including CD133, SOX9, nestin, and GDF3) [13,14].

## PSC in Disease

During pancreatic injury, PSC undergo a process of activation whereby they transform from their quiescent state to a myofibroblast-like phenotype characterized by loss of vitamin A lipid droplets, expression of the activation marker alpha smooth muscle actin (αSMA), and increased proliferation, migration, and ECM synthesis [15,16] (Table 10.1). The excessive production of ECM proteins by activated PSC outstrips the ability of the cells to degrade these proteins, ultimately leading to fibrosis of the gland. Activation of PSC can be caused by a wide range of factors, each of which is pertinent to pancreatic pathophysiology either as a factor that is upregulated/modulated during pancreatic disease or as a compound that is directly injurious to the gland. Thus, PSC are activated by alcohol and its metabolites, endotoxin, protease enzymes, oxidative stress, hypoxia, hyperglycemia, angiogenic factors and a variety of growth factors, cytokines, and chemokines, among others (Table 10.2). Notably, in addition to being activated by exogenous cytokines (released by surrounding acinar or inflammatory cells) via paracrine routes, PSC are capable of producing their own cytokines (transforming growth factor beta [TGFβ], connective tissue growth factor [CTGF], interleukins 8 and 15, CXCR1, monocyte chemotactic protein 1 [MCP1], and regulated on activation, normal T-cell expressed, and secreted [RANTES]), which can act on

**Table 10.1** Characteristics of quiescent and activated PSC phenotypes.

| Characteristic | Quiescent PSC | Activated PSC |
|---|---|---|
| Vitamin A lipid droplets | Present | Absent |
| α Smooth muscle actin | Absent | Present |
| Proliferation | Limited | Increased |
| Migration | Limited | Increased |
| Extracellular matrix production | Limited | Increased |
| Matrix metalloproteinases (MMP) and tissue inhibitors of matrix proteinases (TIMP) | Complement of MMP and TIMPs to maintain normal ECM turnover | Change in types of MMP and TIMPs to facilitate ECM deposition |
| Production of cytokines | Limited | Increased (PDGF, TGFβ, CTGF, IL-1, IL-6, IL-15) |
| Capacity for phagocytosis | Absent | Present |
| Proteomic analyses | Basal protein expression | Differential expression of proteins related to the cell cytoskeleton, cell metabolism, motility, growth, and invasion |

**Table 10.2** Pancreatic stellate cell activating factors.

| |
|---|
| Ethanol and its metabolites (acetaldehyde, fatty acid ethyl esters) |
| Inflammatory mediators (cytokines, growth factors, complement 5) |
| Proteases |
| Pigment epithelium-derived factor |
| Galectin 1 |
| Hyperglycemia |
| Parathyroid hormone-related protein (PTFrP) |

**Table 10.3** Pancreatic stellate cells: signaling pathways.

| Signaling pathway | PSC functions |
|---|---|
| Mitogen-activated protein kinase (MAPK) [30,93,94] | αSMA expression, proliferation, migration, ECM protein synthesis |
| Phosphatidylinositol 3-kinase (PI3K) [32] | Migration, proliferation, ECM protein synthesis |
| Protein kinase C (PKC) [94] | ECM protein synthesis |
| Hedgehog [95] | Migration |
| JAK-STAT [96] | Proliferation |
| Smads [97] | ECM protein synthesis |
| Rho, Rho kinase [98] | Actin cytoskeleton, stress fiber formation |
| Transcription factors (AP-1, NF κB, Gli-1) [95,99] | Activation, migration, proliferation, ECM protein synthesis |
| Wnt and β-catenin [100] | Proliferation, αSMA expression, cytokine expression |
| Peroxisome proliferator-activated receptor gamma (PPARγ) [12] | αSMA expression, proliferation, phagocytosis |
| Intracellular calcium modulation [33–35] | PSC activation |

the cells in an autocrine manner [17–20]. As a consequence, a process of perpetuated activation of PSC is set up, ensuring progression of fibrosis, even in the absence of the initial activation triggers.

In contrast to activating factors, quiescence of PSC has been shown to be induced by exposure to retinol and its metabolites [21,22], curcumin (a polyphenol found in turmeric) [23], melatonin, the anthraquinone derivative rhein [24], bone morphogenic protein (BMP) [25], troglitazone (a ligand for the peroxisome proliferator activated receptor PPARγ) [26], and calcipotriol (a vitamin D receptor ligand) [27]. Most recently, kinase inhibitors such as sorafenib, sunitinib, trametinib, and dactolisib have been shown to inhibit PSC proliferation and ECM synthesis [28,29]. Interestingly, trametinib also decreases the expression of two autocrine mediators of PSC activation, IL-6 and TGFβ [29].

Several intracellular signaling pathways that mediate PSC activation or quiescence have now been identified (listed and referenced in Table 10.3). It is important to

note that although numerous discrete pathways regulating PSC functions have been identified, there is significant cross-talk between the major signaling pathways, such that modulation of one can affect the functions of the other [30–32]. This built-in redundancy has to be taken into account during any development of novel therapies targeting PSC signaling pathways. Furthermore, studies have now indicated that a number of the signaling pathways described converge into a common secondary messenger system within the PSC, namely intracellular calcium [33–35]. Attention has also been focused in recent times on microRNA, which are small, noncoding RNA implicated in cell functions such as proliferation, differentiation, apoptosis, and protein synthesis. Significant differences between the microRNA profiles of quiescent cells and activated PSC have been reported, relevant to development and growth, movement, and survival of cells [36]. Other investigators have identified miR-15b and -16 as regulators of PSC apoptosis via their effects on the antiapoptotic factor Bcl-2 [37] and miR21 as a possible cofactor in connective tissue growth factor (CCN2)-mediated PSC activation [38].

The role of PSC in pathologic pancreatic fibrogenesis has been studied mainly with respect to three disease conditions of the gland—acute pancreatitis, chronic pancreatitis, and pancreatic cancer. Whereas the last two are characterized by the presence of abundant fibrous deposits within the pancreas, the first, acute pancreatitis, is well acknowledged as a self-limiting disease in a majority of patients. As described in the following, PSC play a critical role, not only in the pathologic fibrosis of chronic pancreatitis and pancreatic cancer, but also in the regeneration/repair of the pancreas after acute pancreatitis.

## Acute Pancreatitis

PSC proliferation is evident early in acute pancreatitis in response to the cytokines and chemokines secreted by damaged acinar cells and inflammatory cells [39]. Studies using chimeric models indicate that while the increased numbers of PSC observed in the inflamed pancreas are due predominantly to local proliferation of resident PSC, a small proportion (7–18%) of the PSC population may be derived from circulating bone marrow cells [40]. The activated PSC population produces increased ECM proteins that provide a scaffold and physical support for the regenerating ductal and acinar cells during the repair phase of acute pancreatitis. It is now well demonstrated that the ECM is critical for appropriate, integrin-mediated interactions between cell membranes and the surrounding matrix, which in turn is essential for cell differentiation and growth [41]. Indeed, using conditional β1-integrin knockout animals, it has been shown that the absence of integrin receptor expression on PSC results in reduced ECM production, hampering acinar cell–ECM interactions, resulting in acinar apoptosis and reduced proliferation [42].

PSC may also play a central role during recovery from severe necrotizing pancreatitis [43]. Pancreatic sections from patients with severe necrotizing pancreatitis exhibit hypercellular regenerative spheres comprising vascular granulation tissue, ductular cells, residual lobular elements, and stellate cells. Sprouting outwards from the margins of these spheres into surrounding tissue are pilot ductules lined by flattened epithelial cells and surrounded by a mantle of stellate cells. It has been speculated that this mantle of PSC provides the essential stimulus for proliferation of the cells lining the pilot ductules and for their differentiation into mature acinar and duct cells, thereby facilitating pancreatic regeneration.

An essential step for complete recovery of the gland from an acute inflammatory state to a normal pancreas is the removal of excess ECM within the gland and restitution of cell populations to their normal relative proportions. PSC play a role in fibrolysis via their capacity to produce the matrix-degrading enzymes MMP. Loss of excess PSC may occur via (i) apoptosis, (ii) reversion to quiescence, as is demonstrable upon treatment with the retinol metabolite all-*trans*-retinoic acid [21,22] or vitamin D receptor ligand calcipotriol [27]; and/or (iii) senescence, as reported by Fitzner et al. [44] in a model of dibutyltin chloride (DBTC)-induced pancreatitis.

## Chronic Pancreatitis

Chronic necroinflammation of the pancreas (chronic pancreatitis) is characterized histologically by abundant fibrosis that surrounds islands of atrophied acini and distorted pancreatic ducts [45]. Over the past 15 years, *in vitro* and *in vivo* studies have helped characterize the central role of PSC in this process.

The earliest studies involved histologic and immunohistochemical staining of pancreatic sections from patients with chronic pancreatitis [2,16]. Dual staining for collagen and the PSC activation marker αSMA (using Sirius Red stain and immunohistochemistry, respectively) demonstrated colocalization of both stains in the same cells, indicating the presence of activated PSC in fibrotic areas of the pancreas [16] (Fig. 10.2). More importantly, dual staining for αSMA and procollagen mRNA clearly demonstrated that activated PSC were the predominant source of collagen I in the fibrotic pancreas [16].

During chronic pancreatitis, PSC are likely activated by numerous factors, including (i) the profibrogenic growth factor TGFβ, which is found to be highly expressed in spindle-shaped cells within fibrotic areas and also in acinar cells adjacent to the areas of fibrosis (but not in acinar cells away from fibrotic areas), supporting the notion that TGFβ exerts paracrine and autocrine effects on PSC to stimulate cell activation [16]; (ii) platelet-derived growth factor (PDGF) – the receptor for this mitogenic and chemotactic factor is upregulated in fibrotic areas, thereby providing a possible mechanism for the observed increase in proliferation and migration of PSC to injured areas during pancreatic necroinflammation [16]; (iii) nerve growth factor (NGF), which has been demonstrated in PSC in areas of fibrosis, and which has been implicated in the pain of chronic pancreatitis via its ability to induce neurite growth [46]; and (iv) oxidative stress, as evidenced by increased staining of oxidant stress marker 4-hydroxynonenal [47].

Although studies with human tissue offer a point-in-time snapshot of the presence of activated PSC and relevant activating factors *in situ*, it is only through animal studies that chronological events in the development of fibrosis and the role of PSC in fibrogenesis have been able to be chronicled. Numerous different mouse and rat models of experimental chronic pancreatitis/pancreatic fibrosis have been reported in the literature (for a review, see [48]). Approaches to induce fibrosis in these models include (i) causing repetitive acute pancreatic injury (based on knowledge of the necrosis–fibrosis sequence of injury) by repeated injections of caerulein [49] or superoxide dismutase inhibitor [50]; (ii) injecting toxins into the pancreatic duct [16,51]; (iii) exposure of animals to chronic ethanol administration followed by secondary challenge with caerulein [52,53], cyclosporin [54], or endotoxin [11] (the last is considered to be a more physiologically relevant approach given the well-demonstrated increase in serum endotoxin levels in heavy drinkers [55]); (iv) transgenic methods involving overexpression of cytokines or profibrogenic factors such as IL-1β, TGFβ, and heparin-binding EGF-like growth factor (HB-EGF) [56,57]. Rats developing spontaneous chronic pancreatitis (WBN–Kob rats [58]) and type 2 diabetes (Goto–Kakizaki rats) [6] have also been used.

Space limitations preclude a detailed discussion of the described models. However, the overall results of all of the studies indicate that known PSC-activating factors (TGFβ, PDGF, oxidant stress, etc.) are upregulated early during pancreatic injury, leading to PSC activation (as evidenced by proliferation and increased ECM synthesis). The increased numbers of PSC are mainly sourced from the resident PSC population, although a small fraction (5–18%) may be derived from pluripotent circulating bone marrow cells [59]. As mentioned earlier, the ability of activated PSC to secrete endogenous cytokines that act on the cells via an autocrine loop helps to perpetuate PSC activation, ultimately resulting in pathologic fibrosis.

Whereas the majority of the described models were focused on the role of PSC in fibrosis of the exocrine pancreas, recent reports suggest a role for PSC in the fibrosis of endocrine pancreas also. Studies with rodent models of diabetes (Goto–Kakizaki rats [6] and db/db mice [60]) have demonstrated activated PSC within fibrotic areas in and around the islets of Langerhans. PSC have been shown to inhibit insulin secretion by beta cells and also to stimulate beta-cell apoptosis; these detrimental effects of PSC on beta cells are aggravated by hyperglycemia [61]. Indeed, repeated caerulein injections have been reported to cause more severe chronic pancreatitis in hyperglycemic mice than in normoglycemic mice [62]. These findings suggest the presence of a positive feedback loop between PSC and islet cell function and support an active role for PSC in the diabetes of chronic pancreatitis.

## Reversal of Pancreatic Fibrosis

The advances made over the past decade in our understanding of PSC biology, particularly with regard to their key roles in the fibrosis of chronic pancreatitis, have underpinned recent research efforts to develop targeted approaches to inhibit the process of PSC activation, so as to prevent, retard, and/or reverse the fibrogenic process, thereby limiting disease progression. To date, most of these novel treatments have been utilized mostly in experimental models and involve (i) inhibition of profibrogenic growth factors TGFβ and tumor necrosis factor alpha (TNFα) [63–65]; (ii) antioxidants such as vitamin E [66], ellagic acid, a plant polyphenol [67], and salvianolic acid, a herbal medicine [68]; (iii) protease inhibitors [69]; (iv) modulation of signaling molecules (e.g., troglitazone binding to the peroxisome proliferator receptor gamma, PPARγ [26]; retinoic acid-induced PSC quiescence via suppression of the Wnt–catenin pathway [22]); (v) inhibition of collagen synthesis by targeted treatment of PSC with collagen siRNA [70]; (vi) an anthraquinone derivative Rhein [24] and a flavonoid, apigenin [71]; (vii) a prostacyclin analogue ONO-1301, which inhibits proinflammatory and profibrogenic cytokine production [72]; and (viii) in the case of alcoholic pancreatitis, withdrawal of alcohol administration [73]. This list of potential treatments is an exciting step forward in the field, one that is expected to drive the development of clinical trials that can assess the efficacy of such approaches in the treatment of human chronic pancreatitis.

## Pancreatic Cancer

Pancreatic ductal adenocarcinoma (PDAC) is characterized by an abundant stromal/desmoplastic reaction that surrounds tumor elements. This fibrotic stroma comprises extracellular matrix proteins including collagen type I, fibronectin, and laminin, noncollagenous factors such as glycoaminoglycans (e.g., hyaluronan), glycoproteins, and proteoglycans, and several cell types, including stellate cells, endothelial cells, neural elements and immune cells. Studies with human pancreatic cancer sections involving dual staining for PSC-selective markers and *in situ* hybridization for collagen mRNA, have now unequivocally established that PSC are the major source of the fibrosis of pancreatic cancer [74] (Fig. 10.3). Furthermore, activated PSC have been identified surrounding the earliest (premalignant) lesions of pancreatic cancer, namely pancreatic intraepithelial neoplasms (PanIN), indicating that PSC activation is an early feature in carcinogenesis [75]. Interestingly, an association has been reported between the extent of activated PSC in the stroma and poor clinical outcome (as assessed by overall survival) [76,77].

It is increasingly evident that the role of PSC in pancreatic cancer extends beyond merely producing the fibrotic stroma. Using *in vitro* (cocultured PSC and cancer cells) and *in vivo* (subcutaneous xenografts, orthotopic implants, genetically engineered models) approaches, a close bidirectional interaction between PSC and cancer cells has been identified, which facilitates local tumor growth and distant metastasis (for a review, see [78]). Pancreatic cancer cells induce PSC activation, as evidenced by increased proliferation, ECM production, and migration. These effects are mediated by factors such as TGFβ, fibroblast growth factor (FGF), PDGF [79], cyclooxygenase 2 (COX-2, the enzyme involved in conversion of arachidonic acid to prostaglandin) [80], and trefoil factor 1 (TFF1, a stable secretory protein that is upregulated in pancreatic cancer but not expressed in the normal pancreas) [81]. In turn, PSC significantly increase pancreatic cancer cell proliferation, while at the same time inhibiting their apoptosis, thereby increasing cancer cell survival. PSC also stimulate cancer cell migration, an effect that is associated with enhanced epithelial–mesenchymal transition (EMT) of cancer cells (as demonstrated by increased expression of mesenchymal markers such as Snail and vimentin associated with a corresponding decrease in the expression of epithelial markers such as E-cadherin) [82]. In addition, PSC have been shown to induce stemness in cancer cells—such a stem-cell niche is thought to be responsible for the well-known propensity of pancreatic cancer for recurrence [83]. Ikenaga et al. [84] identified a subset of cancer-associated PSC that have significantly more aggressive effects on cancer cell migration and proliferation than the parent population. This PSC subset exhibits increased expression of CD10 (a cell membrane-associated matrix metalloproteinase), which is capable of degrading basement membrane, thereby facilitating invasion into surrounding tissue and also into blood vessels. PSC-induced cancer cell proliferation is mediated, at least in part, by PDGF [85], while hepatocyte growth factor (HGF) plays a role in PSC-induced cancer cell migration [86]. Other candidate factors that require further study as possible

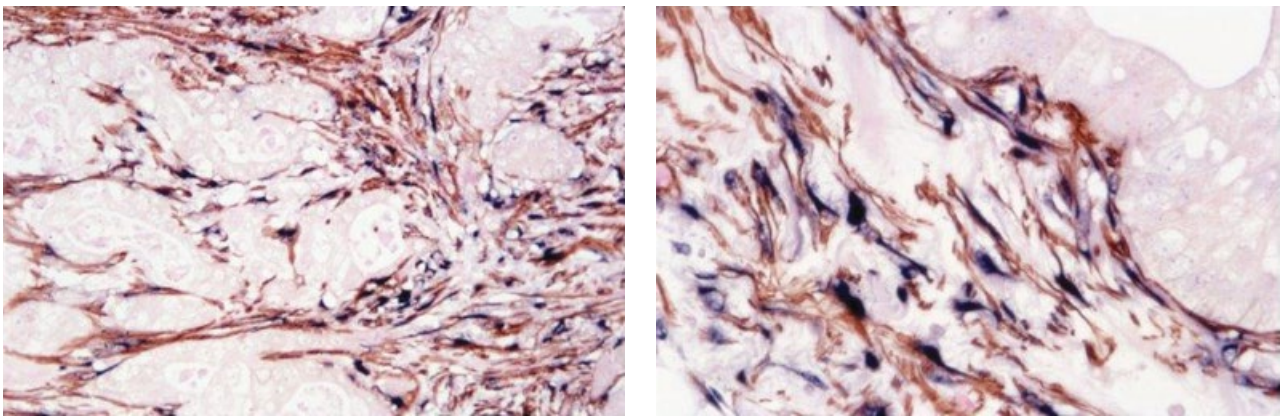

**Figure 10.3** Low- and high-power views of a human pancreatic cancer section dual stained for alpha smooth muscle actin (αSMA) and collagen mRNA: immunostaining for αSMA (brown) combined with *in situ* hybridization for collagen mRNA (blue) reveals colocalization of the two stains in stromal areas of the section with no staining in tumor cells. This pattern of staining indicates that pancreatic stellate cells are the main source of collagen in pancreatic cancer stroma. *Source:* Apte et al. 2004 [74]. Reproduced with permission of Wolters Kluwer Health.

mediators include insulin-like growth factor (IGF), epithermal growth factor (EGF), TGFβ, and other proinflammatory cytokines. Interactions of PSC with other cell types in the stroma, such as endothelial cells (influencing angiogenesis), immune cells (facilitating immune evasion), and neuronal cells, are being increasingly described, but are beyond the scope of this chapter (for a review, see [87]).

The fibrotic stroma is thought to contribute to chemoresistance by acting as a physical barrier to the penetration of drugs to the cancer cells. However, accumulating data indicate that PSC may also directly influence the response of cancer cells to chemotherapeutic agents via the production of stromal-derived factor 1α (SDF-1α), which acts on its receptor CXCR4 on cancer cells to phosphorylate downstream signaling pathways including mitogen-activated protein kinase (MAPK) and phosphatidylinositol 3-kinase (PI3K) in cancer cells. This induces the production of IL-6 by cancer cells, which exerts an autocrine effect to protect the cells from gemcitabine-induced apoptosis [88]. PSC themselves have been shown to survive chemoradiation and to exhibit an even more activated phenotype post-treatment, a feature that may enable the cells to induce proliferation of residual cancer stem-cell niches, thereby aiding cancer recurrence [89].

Although the weight of evidence to date supports a facilitatory role for PSC in pancreatic cancer progression, this tumor-permissive function of PSC has been brought into question by two recent studies reporting that conditional depletion of αSMA myofibroblasts [90] or targeting a specific signaling pathway (hedgehog pathway) [91] in mouse models of pancreatic cancer paradoxically resulted in reduced survival of animals. These discrepant findings may be explained by the possibility that the impact of PSC on cancer behavior is a dynamic and stage-dependent process. The presence of activated PSC at the earliest stages of pancreatic cancer (PanIN) may represent a protective reaction within the gland as the fibrosis laid by the PSC attempts to sequester the malignant cells from the normal pancreas. As the disease progresses, cancer cells can overcome this "protective" barrier and recruit PSC to their own advantage, converting them into "helper" cells.

Therapeutic targeting of PSC and the microenvironment to improve pancreatic cancer outcome have attracted significant attention in recent years. These studies have mostly involved preclinical models of pancreatic cancer, although a few have progressed to early clinical trials, with encouraging, albeit modest, results. An exhaustive discussion of this work is not within the scope of this chapter (for reviews, see [87,92]). However, given that (i) targeting cancer cells alone has failed to improve patient outcome for several decades and (ii) the influence of the stroma on cancer biology is becoming increasingly clear, there is general agreement in the field that it would be reasonable to consider measures to modulate PSC behavior as novel treatment options for pancreatic cancer.

## Conclusion

In summary, it is now unequivocally established that the cells responsible for fibrogenesis in the pancreas are pancreatic stellate cells (PSC). In health, PSC maintain a fine balance between ECM production and degradation, thereby ensuring normal ECM turnover in the gland. Accumulating evidence suggests that PSC may also have additional roles in the healthy pancreas as progenitor cells, immune cells, and intermediary cells in CCK-regulated pancreatic exocrine secretion. In diseased states, PSC are transformed into an activated myofibroblast-like state, producing excessive amounts of ECM proteins. When the activation of PSC is limited, as in resolving acute pancreatitis, PSC can aid the regenerative/repair process. However, perpetuated activation of the cells, as seen in chronic pancreatitis and pancreatic cancer, ultimately leads to pathologic fibrosis. Notably, it is now becoming increasingly evident that PSC have functions beyond the fibrotic process in both chronic pancreatitis and pancreatic cancer. In chronic pancreatitis, PSC have been shown to promote islet (beta) cell dysfunction, whereas in pancreatic cancer, PSC interact closely with cancer cells and other stromal cells such as endothelial cells and immune cells to influence cancer progression. Understanding the biology of these multifunctional PSC will underpin the development of novel therapeutic approaches for difficult-to-treat fibrotic diseases of the pancreas such as chronic pancreatitis and pancreatic cancer.

# Fibrogenesis of the Pancreas: The Role of Macrophages

*Aida Habtezion*

*Division of Gastroenterology and Hepatology, Stanford University School of Medicine, Stanford, CA, USA*

## Introduction

Macrophages are cells of the innate immune system and are highly efficient phagocytic cells that play a central role in tissue homeostasis, infection, inflammation, wound repair, and healing [1]. In addition to their phagocytic abilities, although not as efficient as their counterpart myeloid-derived dendritic cells, macrophages are also capable of antigen processing and can play an important role in promoting adaptive immune responses [2]. In disease states, however, macrophages can contribute to pathogenic roles that promote chronic inflammation and cancer [3]. Improved molecular and cellular techniques have led to the appreciation of phenotypic and functional macrophage diversity and a better understanding of their heterogeneity and highly dynamic nature with the capacity to respond readily to environmental changes.

Chronic pancreatitis is associated with pancreatic stellate cell activation and fibrosis. Both human and animal model studies show that macrophages are one of the major immune cell infiltrates in chronic pancreatitis [4–6]. Experimental model findings also support the recruitment of these myeloid cells early on during disease development, suggesting an important role for macrophages in fibrogenesis. Ongoing destruction of the exocrine pancreas associated with chronic inflammation and activated pancreatic stellate cells leads to the development of fibrosis. Management of chronic pancreatitis with its progressive fibrosis that gradually replaces the organ remains a clinical challenge. In addition, patients with chronic pancreatitis have an increased risk of developing pancreatic cancer [7].

Pancreatic ductal adenocarcinoma (PDAC), the most common and lethal form of pancreatic cancer, is also associated with a dense stromal reaction where fibrosis surrounds tumor areas [8]. Interestingly, macrophages are also the major immune cell infiltrate in PDAC and also in most solid tumors [9]. Tumor-associated macrophages (TAM) have distinct gene transcript profiles [10]; however, at least phenotypically, TAM resemble those infiltrating fibrotic areas in chronic pancreatitis and other fibrotic diseases. These observations suggest that similar mechanism(s), at least in part, are probably involved in both benign and malignant-associated fibrogenesis and analogous approaches potentially can target macrophages with goals of modulating fibrotic areas. This chapter focuses on the role of macrophages in fibrosis associated with chronic pancreatitis (independent of etiology) and pancreatic cancer based on the available evidence and body of literature.

## Macrophages

Macrophages are highly efficient phagocytic myeloid cells discovered over a century ago by the Nobel Laureate Ilya Metchnikoff [11]. Circulating monocytes derived from bone marrow myeloid progenitors enter tissues and undergo differentiation into either macrophages or dendritic cells depending on the presence of local growth factors, cytokines, and exogenous or microbial signals [12]. Macrophages represent a highly functionally diverse and heterogeneous population and as a result are involved in health and many diseases [13,14]. Unlike terminally differentiated cells, they have the ability to respond to changes in environmental signals and alter their phenotypic and functional characteristics [15]. As a result, macrophages are highly diverse, dynamic, and a population with a high degree of plasticity that enables them to adjust to physiologic and pathologic changes.

Companion website: www.wiley.com/go/beger/thepancreas

Although macrophages exist along a functional and dynamic continuum, classically (M1 or type 1)- and alternatively (M2 or type 2)-activated macrophages are generally accepted as those on the extreme or opposite side of this continuum [13,14]. Other studies classify macrophages according to their functional role such as proinflammatory, profibrotic, proresolution or prowound healing, proresolving, and tissue regenerating [16–19]. For the purpose of this chapter, we will use the classically and alternatively activated (M1/M2) terms based on the general and common uses of these terminologies in the literature. Classically activated macrophages (M1) develop due to inflammatory signals such as IFNγ or lipopolysaccharide (LPS) and as a result are associated with T helper (Th) type 1 immune responses and are involved in effector or proinflammatory functions. In contrast, the alternatively activated macrophages (M2) develop in response to Th2-type responses (cytokines such as IL-4 and IL-13) and are associated with immunosuppression, tissue repair, and wound healing [20].

M2 macrophages have been further subdivided into M2a, M2b, M2c, and M2d (also known as tumor-associated macrophages or TAM) [14,21,22] This subdivision is also based on gene, surface receptor, and cytokine expression (Fig. 11.1). M2a are induced by factors such as IL-4, IL-13, or IL-10 and are associated with antiparasitic, allergic, and Th2 responses, and have been termed "tissue reparative and wound healing" [13,20,23]. M2a are also associated with fibrosis. M2b (induced by IL-1, LPS, immune complexes or ICs) and M2c (induced by IL-10 and TGFβ) are generally referred to as "regulatory" with pro- and anti-inflammatory properties, respectively [23–25]. M2c are also associated with tissue remodeling, fibrosis, and tumor promotion [23]. Relevant to the pancreas, chronic injury can lead to a dysregulated macrophage wound-healing response and development of pathologic fibrosis that impairs normal tissue function [26]. M2d or TAM, induced by tumor-enriched factors such as colony-stimulating factor 1 (CSF-1) and IL-6, promote tumor growth, invasion, and metastasis [27].

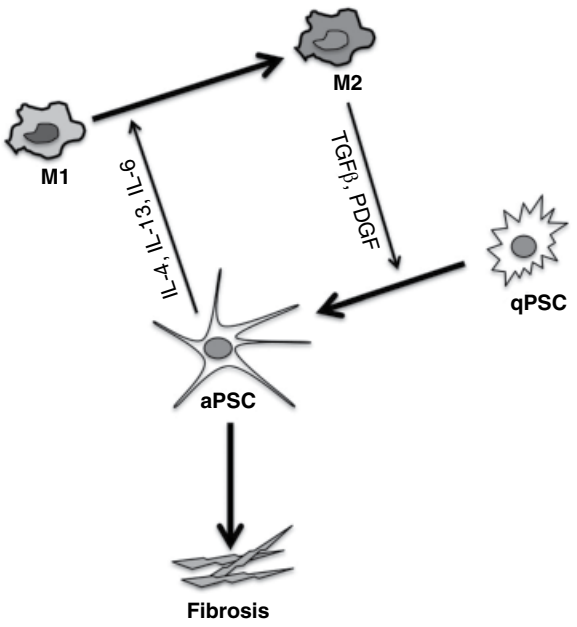

**Figure 11.1** Macrophage–pancreatic stellate cell (PSC) interaction in promoting fibrogenesis [35]. Activated (a) and quiescent (q) PSC; classically (M1) and alternatively (M2) activated macrophages. PDGF, platelet-derived growth factor; TGFβ, transforming growth factor beta.

## Origin and Characteristics of Pancreatic Macrophages

Experimental models using congenic mouse strains have allowed the separate tracing of donor and host cells in cell transfer studies. In addition, the use of bone marrow chimeras, parabiosis (conjoined animals in order to assess turnover of cells), and yolk sac or embryogenic cell transfers has allowed investigators to determine macrophage ontogeny in different tissues. Prior to the establishment of bone marrow, primitive hematopoiesis originating from yolk sac progenitor cells takes place (in the mouse embryo: E7.5) [28]. Interestingly, lineage-tracing analysis showed that adult brain-specific macrophages (microglia) are derived exclusively from the primitive yolk sac precursors [29]. In contrast, although yolk sac- and fetal liver-derived macrophages are present in the neonatal intestine, they do not persist into adulthood [30], suggesting that although the intestine is seeded by embryonic precursors, intestine macrophages are replenished by bone marrow-derived monocytes from the circulation throughout adulthood. The differences in brain and intestinal macrophage ontogeny highlight environment and context dependence, where recruitment of monocytes to the intestine, for example, is largely dependent on the presence of microbiota [30].

Although bone marrow and yolk sac-derived macrophages appear similar, Schulz et al. showed that although the transcription factor Myb was necessary for the development of monocytes and macrophages derived from hematopoietic stem cells or bone marrow, it was dispensable for the development of yolk sac-derived macrophages [31]. They also investigated macrophage origin in multiple tissue sites and found that a significant proportion of the pancreatic macrophages were derived from primitive hematopoiesis or yolk sac. More recently, Calderon et al. investigated the origin and characteristics of pancreas macrophages in the mouse in more detail [32]. In the steady state, the pancreas macrophages were long lived with minimal exchange with blood monocytes.

Notably, macrophages in the interacinar parenchyma were distinct in origin and phenotype compared with those in the islets of Langerhans. Macrophages in the interacinar parenchyma were of alternatively activated phenotype or M2 and composed of two subgroups, one derived from yolk sac and the other from bone marrow precursors. Macrophages in the islets of Langerhans were derived from bone marrow stem cells but had minimal exchange with circulating monocytes and had a profile of classically activated macrophages or M1. These findings highlight and underscore the heterogeneity of the macrophage lineage not only in different organs but also within the microenvironment of a single tissue such as the pancreas. Nevertheless, under myeloablative conditions, pancreas-resident macrophages, regardless of their site of origin or microenvironmental location, were replaced with donor bone marrow-derived monocytes [32], indicating that under inflammatory conditions, circulating monocytes are likely to play an important role in reconstituting the tissue macrophages.

## Role of Macrophages in Chronic Pancreatitis-Associated Fibrosis

Immune cell infiltrates are observed in fibrous areas of the pancreas in patients with chronic pancreatitis [33]. Macrophages are the most abundant myeloid cells in the inflamed pancreas in chronic pancreatitis [4,5,34]. Macrophages with alternatively activated profiles are found in high numbers in the fibrosis area and the vicinity of activated pancreatic stellate cells [5,35]. A marked increase in immune cell infiltrate has been reported in patients with alcohol-related chronic pancreatitis [36]. Using histologic staging of the pancreas of alcoholic patients, it was proposed that alcoholic chronic pancreatitis was initiated via a cytokine-mediated interaction between macrophages and myofibroblasts as a result of tissue injury [37]. In addition, the potential role of macrophages in fibrosis was demonstrated *in vitro* by LPS-activated macrophages that stimulated pancreatic stellate cell activation and collagen and also fibronectin synthesis [38]. Activation of pancreatic stellate cells was also observed when cocultured with macrophage cell lines [39].

Similar to findings in the human pancreas, macrophages are also present in the vicinity of areas of fibrosis in experimental models of chronic pancreatitis [6,35]. Unlike in acute pancreatitis, where classically activated macrohages (M1) are dominant, chronic pancreatitis is dominated by alternatively activated macrophages (M2) [35]. Coculture of pancreatic stellate cells with M2- as opposed to M1-polarized macrophages significantly upregulates stellate cell fibrosis genes. Moreover, pancreatic stellate cells were shown to secrete Th2 cytokines in culture and influence macrophage polarization toward M2. In addition, alternatively activated macrophages (M2) were also more efficient than classically activated macrophages (M1) at activating pancreatic stellate cells, indicating that a feed-forward process and interaction between pancreatic stellate cells and macrophages exist in chronic pancreatitis (Fig. 11.2).

The functional significance of alternative macrohpage polarization in fibrogenesis is also emphasized by the fact that blockade of macrophage IL-4 receptor signaling via genetic and pharmacologic means inhibits progression of experimental chronic pancreatitis-associated fibrosis *in*

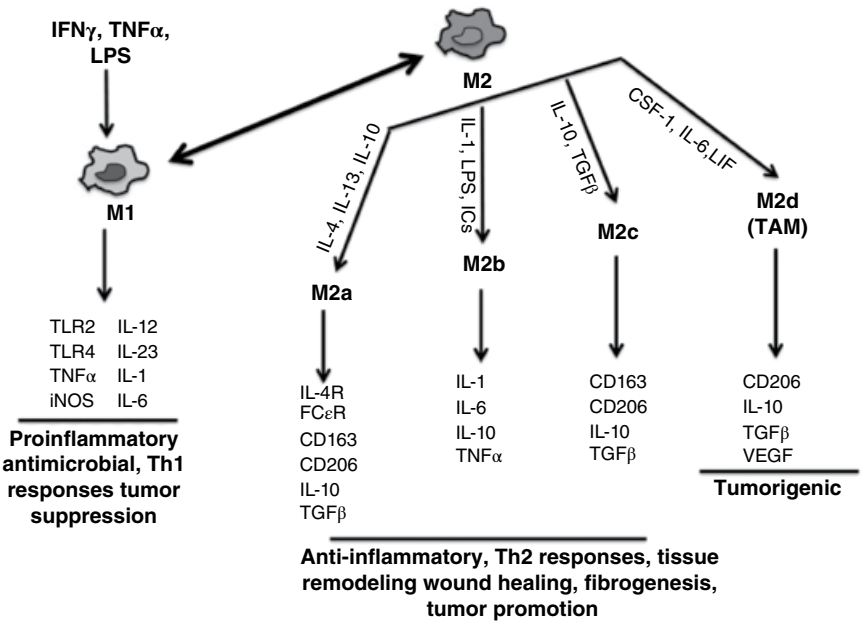

**Figure 11.2** Macrophage phenotypic and functional heterogeneity [3,10,13,20,23,25]. The diagram depicts stimulating conditions that induce M1 and M2 functional subtypes that upregulate unique receptor and cytokine expressions. CD206, mannose receptor; FCεR, high-affinity IgE or Fc epsilon receptor; IC, immune complexes; iNOS, inducible nitric oxide synthase; IL, interleukin; M1, classically and M2, alternatively activated macrophage subsets; CSF-1, colony-stimulating factor 1; LIF, leukemia inhibitory factor; LPS, lipopolysaccharide; Th, T helper; TAM, tissue-associated macrophage; TLR, toll-like receptor; TGFβ, transforming growth factor beta; TNFα, tumor necrosis factor alpha; VEGF, vascular endothelial growth factor.

*vivo* [1]. Moreover, inhibition of IL-4 receptor signaling using peptide-targeting IL-4/IL-13 also was effective in decreasing the progression of fibrosis in established disease. This mechanism offers a potential therapeutic target that alters macrophage–pancreatic stellate cell interaction and alter the natural progression of fibrosis, at least as observed in animal models of chronic pancreatitis. The IL-4 receptor pathway and blocking peptide findings were also consistent with *ex vivo* experiments that used primary human macrophages and pancreatic stellate cell cocultures, demonstrating potential future translation to clinical application [6]. However, future clinical studies are crucial to test the validity and efficacy in patients with chronic pancreatitis.

Addition of alcohol feeding to caerulein treatment in a model of chronic pancreatitis had a combined effect on the upregulation of macrophage arginase-1 expression [40]. Arginase-1 is a urea cycle enzyme, which converts L-arginine into L-ornithine and urea, and is generally accepted as a protypic M2 marker [13]. L-Ornithine is thought to enter polyamine and collagen synthesis, thus promoting fibrosis and wound healing [41]. Hence alcohol likely further promotes fibrosis, at least in part, via induction of arginase-1 expressing alternatively activated macrophages. Many studies have demonstrated the importance of nuclear factor kappa light-chain enhancer of activated B cells (NFκB) activation in pancreatitis. Sustained activation of NFκB results in chronic pancreatitis [42,43]. The contribution of macrophages is further emphasized by the requirement for myeloid and not acinar NFκB activation in promoting fibrosis in experimental chronic pancreatitis [44].

Macrophages contribute not only to fibrogenesis but also to the remodeling of fibrotic areas. Macrophages, in particular alternatively activated or M2-like macrophages, were shown to be critical in degrading and remodeling collagen scaffolds in models of skin fibrosis [45]. Other tissue model systems have also shown that macrophages produce metalloproteinases and other enzymes that degrade the fibrotic extracellular matrix and thus facilitate the resolution of fibrosis [17,46,47]. Further investigations are needed to identify conditions and define mechanisms that lead to the opposing roles of macrophages in fibrosis generation and degradation. These studies are likely to offer methods via which fibrosis can be modulated to alter chronic pancreatitis-associated fibrosis progression.

## Role of Macrophages in Pancreatic Cancer-Associated Fibrosis

A strong desmoplastic reaction surrounds PDAC areas and poses a major therapeutic challenge [8,48]. Juxtatumoral stroma is enriched by tumor-infiltrating macrophages and fibroblasts, highlighting the significance and pathogenic role of macrophages in PDAC [49]. Macrophages are major immune cells infiltrating many solid tumors and their presence is associated with cancer prognosis. In fact, an increase in PDAC-infiltrating macrophage burden is associated with a poor patient outcome [50]. Consistent with the profibrogenic role of M2, increased tumor infiltration with M2-polarized macrophages was associated with shorter survival, whereas the presence of M1-polarized macrophages was associated with longer survival in patients with PDAC [51].

Increases in extracellular matrix protein were observed with progression of pancreatic cancer and correlated with increases in myofibroblasts and macrophages in both human and mouse PDAC studies [39]. In that report, *in vitro* coculture findings suggested cross-regulation between macrophages and pancreatic stellate cells. In another study, immune-targeted therapy (antibody-based CD40 agonist) in experimental models of PDAC led to the re-education of macrophages, immune activation, and altered tumor stroma that were associated with improved response to chemotherapy [52,53]. These studies suggest that targeting tumor-infiltrating macrophages is likely to alter fibrogenesis in pancreatic cancer and improve chemotherapy response.

## Conclusion

Macrophages need to be evaluated in the context of the environment and settings owing to their heterogenity and dynamic nature. Alternatively activated macrophages play an important role in matrix synthesis and degradation, making these cells an attractive future target for modulating fibrosis in pancreatic diseases. Experimental models so far have elucidated the critical role played by macrophages in fibrogenesis and the interaction of macrophages especially with pancreatic stellate cells to promote fibrosis. Studies have shown that pancreatic stellate cells and alternatively activated macrophages influence fibrogenesis in a feed-forward process. Recent studies have highlighted the dynamic nature of macrophages, although more studies are needed to understand the natural course of fibrotic pancreatic diseases and macrophage heterogeneity during disease development and progression. Moreover, studies are needed to understand macrophage behavior and pancreas-specific regulators of macrophage function during mild versus severe inflammation and during early and late disease. The ability of macrophages to be reprogrammed, sense environmental signals, and interact with and impact pancreatic stellate cell behavior makes them a suitable candidate to target in order to alter fibrogenesis.

# Insulo–Acinar Relationship

*Keiko Shiratori and Kyoko Shimizu*

*Departments of Internal Medicine and Gastroenterology, Tokyo Women's Medical University School of Medicine, Tokyo, Japan*

## Introduction

The pancreas consists of two separate organ systems—the exocrine pancreas and the endocrine pancreas—both of which arise from a primordial outgrowth of the primitive gut. The pancreatic islets are interspersed throughout the acini of the pancreatic exocrine tissue. Pancreatic exocrine secretion is highly regulated by several regulatory peptides and neurotransmitters [1–4]. Islet hormones directly reach acinar cells through the insulo-acinar portal system [5–8], and they play important roles in the regulation of acinar cell function. Based on morphologic and hemodynamic studies of the islet–acinar portal system and physiological regulation of acinar cell function by islet peptides, Williams and Goldfine [9] proposed the novel concept of an "insulin–pancreatic acinar axis." However, since many other peptides released by the islets and neuropeptides released by the nerve terminals in the islets have recently been shown to influence exocrine function, the term "islet–acinar axis" appears to be more appropriate [10,11]. Moreover, because a functional relationship between islet cells and duct cells has been demonstrated, a newer concept, called an "acinar–duct–islet axis," is now being considered [12].

## Structural Relationships Between Pancreatic Islets and Exocrine Pancreas

The normal human adult pancreas contains about 1 million islets scattered throughout the organ, consisting of 2–3% of the gland. One islet contains an average of about 5000 endocrine cells, of which there are four major types: those that synthesize and secrete insulin and amylin (β cells), those that synthesize and secrete glucagon (α cells), those that synthesize and secrete somatostatin (δ cells), and those that synthesize and secrete pancreatic polypeptide (PP) and adrenomedullin (PP/F cells). These account for 68%, 20%, 1%, and 2%, respectively, of the cells in pancreatic islets. Another type of endocrine cells, ghrelin-producing cells, have recently been found in islets and named "ε cells" [13,14]. All islets contain β cells and δ cells, whereas α cells are almost exclusively present in islets located in the tail, body, and superior part of the head of the pancreas, and PP cells are mainly observed in islets in the head of the pancreas. Because no capsule or basement membrane surrounds the islets, they are in close contact with pancreatic acinar cells.

Acini located around the islets are called peri-insular acini, and are recognized by the presence of larger cells containing larger nuclei and more abundant zymogen granules than remote acini, which are called tele-insular acini. The constant high concentrations of islet hormones conveyed from the islets to the acinar parenchyma may be responsible for the morphological and functional characteristics of the peri-insular acini [10,11,15]. The islets are densely innervated by both central nervous system and autonomic nervous system. Many neuropeptides and neurotransmitters have been found to be involved in the regulation of islet hormone release.

All islet cell types differentiate from precursor cells present in the epithelial lining of the expanding ductal system [16]. Anatomical and functional associations between islets and ducts have been suggested to exist in the adult pancreas as well as in the fetal pancreas [17,18]. Recent immunohistochemical studies have demonstrated expression of insulin, glucagon, somatostatin, and PP in adult human pancreatic duct cells [19], and Yu et al. [20] demonstrated widespread occurrence of insulin-producing acinar β cells in the adult human pancreas

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

and coexpression of both amylase and insulin in the acinar β cells. The acinar–duct–islet axis is thought to play an important role in the differentiation and development of endocrine cells [12].

## Insulo-Acinar Portal System

The arterial blood supply to the pancreas predominantly flows first to the islets and then via the islets to the exocrine portion of the gland. Lifson et al. [21] found that 11–23% of pancreatic blood flow in the rabbit pancreas flows directly to the islet, whereas the other 77–89% flows directly to the acini (Fig. 12.1). A capillary-like microvascular connection between the endocrine and exocrine portions of the pancreas has been identified in various mammals. Fujita and colleagues confirmed the existence of an "insulo-acinar portal system" by electron microscopic studies of the pancreas of humans and other mammals [5–7]. Pancreatic intralobular arteries give off branches to the islets in the form of an afferent vessel that divides into a capillary glomerulus within the islets, and numerous efferent vessels extend into the surrounding exocrine pancreas to form an insulo-acinar portal system [5–8]. The capillaries from the exocrine tissue coalesce into a venule, and all of the efferent islet blood flows into acinar capillaries before leaving the pancreas. Thus, the exocrine pancreas receives a large part of its blood supply via the islets, and islet hormones reach the acinar cells in high concentrations via this insulo-acinar portal system, with the peri-insular acini being exposed to particularly high concentrations of the islet hormones. Because pancreatic ducts are surrounded by a vascular plexus that is supplied by venous blood from the acini [22], ductal cells are also exposed to high local concentrations of islet hormones.

## Regulation of Pancreatic Exocrine Secretion by Islet Hormones

### Insulin

Insulin secreted by the β cells in the islets plays a pivotal role in the regulation of pancreatic exocrine secretion. Insulin stimulates basal amylase secretion and potentiates secretagogue-stimulated amylase secretion. Many studies have shown that exogenous insulin potentiates cholecystokinin (CCK)-stimulated amylase secretion [23–26]. Although glucose clamping has been shown to inhibit secretin-stimulated pancreatic secretion, there have been several conflicting reports concerning the effect of hyperglycemia on pancreatic secretion [27–30]. Berry and Fink [27] used the euglycemic hyperinsulinemic clamp technique in a study on innervated and denervated dog pancreata and reported finding that insulin inhibited secretin-stimulated pancreatic bicarbonate secretion. The inhibitory action of exogenous insulin on

secretin-induced pancreatic bicarbonate secretion in dogs has been shown to be mediated by a cholinergic mechanism [27,29]. Lam et al. [31] demonstrated that basal pancreaticobiliary secretion in humans is also reduced by hyperglycemia and euglycemic hyperinsulinemia, and that CCK-stimulated secretion is reduced only in the presence of hyperglycemia. Pretreatment with atropine abolished the exogenous insulin-induced increase in pancreatic secretion despite persistent hypoglycemia [32], suggesting that the increase might be mediated by vagal cholinergic activation induced by hypoglycemia.

Saito et al. [23] clearly showed that the endogenous insulin released in response to glucose infusion of a perfused rat pancreas significantly potentiated pancreatic secretion in response to CCK. Iwabe et al. [33] demonstrated that intravenous glucose infusion increased intravenous CCK- and intraduodenal casein-stimulated pancreatic secretion in rats. An important role of endogenous insulin was clearly shown in the studies conducted by Lee et al. [34–36] in which they immunoneutralized insulin with a specific antiserum. They found that intravenous administration of anti-insulin serum to rats resulted in significant depression of pancreatic secretion in response to ingestion of a meal (Fig. 12.2) and to intravenous administration of secretin and CCK [34]. Pancreatic exocrine secretion stimulated with secretin, CCK, or a combination of both in isolated perfused rat and dog pancreata was also inhibited by anti-insulin serum [35,36]. Anti-insulin serum infusion also increased the somatostatin and PP levels in the portal venous efferent vessels, and co-infusion of both anti-somatostatin and anti-PP serum abolished the inhibition of pancreatic secretion induced by anti-insulin serum. These results indicated that the suppression of pancreatic secretion by anti-insulin serum may in part be mediated by local release of somatostatin and PP [36]. Insulin binds its own receptor on the acinar cell, which leads to stimulation and potentiation of amylase secretion by various mechanisms [37–40].

## Glucagon

The effect of glucagon on pancreatic secretion in early studies using extracted glucagon was controversial, because the extracted glucagon was contaminated by a variety of unidentified biologically active peptides. Although biologically active synthetic glucagon showed no stimulatory effect of glucagon on pancreatic secretion [41], the inhibitory action of glucagon on pancreatic secretion *in vivo* has been shown [42,43] and may be indirect and related to stimulation of somatostatin release by glucagon [42]. von Schonfeld and Muller [44] demonstrated that CCK-stimulated amylase secretion in the isolated perfused rat pancreas is unaffected by exogenous glucagon but that it is inhibited by arginine-released endogenous glucagon, and that immunoneutralization with glucagon antibodies blocks the inhibitory effect of endogenous glucagon released in response to arginine.

## Somatostatin

Somatostatin is present in islet δ cells, the intestine, and nerve terminals. It has an inhibitory action on exocrine pancreatic secretion in the islet–acinar axis [45], but the mechanism of the inhibitory effect has been debated. One of the proposed mechanisms is that as a paracrine messenger somatostatin directly inhibits acinar cell function by binding to the somatostatin receptors on the acinar cells, and another is an indirect mechanism in which somatostatin inhibits the release of secretin, CCK, and insulin. In an experiment performed on the isolated perfused rat pancreas, Muller et al. [46] showed that the role of somatostatin in the regulation of exocrine pancreatic secretion is mediated by its effect on pancreatic α and β cells. Somatostatin receptors (SSTR2) have been shown to be located on α and β cells in humans [3]. A neuron-mediated mechanism for somatostatin's regulation of pancreatic exocrine secretion has been suggested,

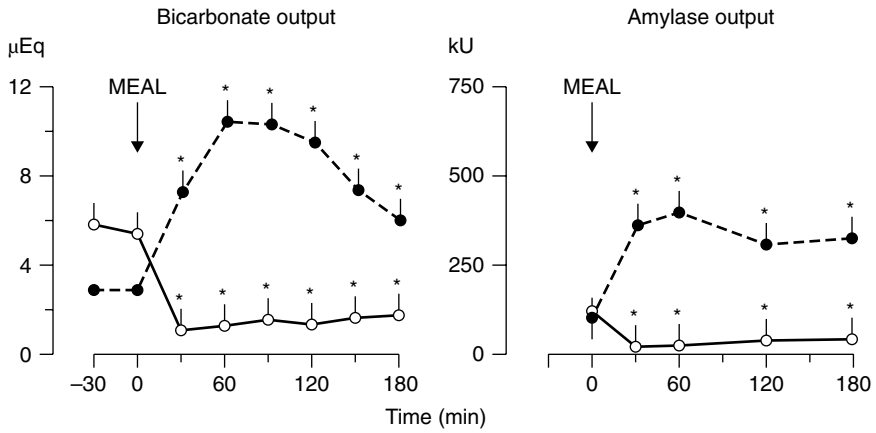

**Figure 12.2** Effects of normal rabbit serum (closed circles) and anti-insulin serum (open circles) on pancreatic secretion of bicarbonate and amylase in response to a test meal in rats [34]. Immunoneutralization with anti-insulin serum resulted in complete suppression in bicarbonate and amylase output in response to ingestion of a meal.

because somatostatin does not inhibit enzyme secretion in either isolated arterially perfused preparations or acinar cells *in vitro*.

## Pancreatic Polypeptide

PP is secreted by the PP cells of the pancreatic islets and released into the circulation after a meal. In the fasting state, endogenous PP is released cyclically and its release is closely linked to the cyclic migrating motor complex (MMC) of the duodenum [47–49]. Immunoneutralization of circulating PP in dogs has been found to result in a significant increase in pancreatic exocrine secretion in the interdigestive state as well as in the postprandial state [49]. Intravenous administration of PP inhibits both basal and stimulated pancreatic secretion of amylase and bicarbonate. However, PP has failed to suppress CCK-stimulated amylase secretion by either isolated rat pancreatic acini or pancreatic lobules preparations [50]. Thus, the inhibitory action of PP on amylase secretion may be achieved indirectly through its inhibitory effect on insulin secretion. Recent studies have shown that PP inhibits somatostatin and glucagon release [51,52], and that PP receptors are present on the α cells of both mouse and human pancreatic islets [52].

## Ghrelin

Ghrelin is a 28-amino-acid peptide that was initially discovered in the stomach and later found to be produced in the pancreas. Ghrelin-producing cells have been named ε cells [14], and their presence has been confirmed in both fetal and adult human pancreas [53]. Lai et al. [54] detected ghrelin and its receptor at both the protein level and mRNA level in acinar cells of the rat pancreas, suggesting that ghrelin regulates exocrine functions by a paracrine and/or autocrine mechanism. Ghrelin has been found to be a potent inhibitor of pancreatic amylase secretion in rats *in vivo* and in pancreatic lobules *in vitro* [55], and ghrelin has been shown to stimulate pancreatic secretion via a vagal cholinergic pathway [56]. Several studies have shown that ghrelin inhibits insulin release in humans, rats, and mice and by clonal β cells [53]. These findings indicate that the ghrelin released in the islets may act as a paracrine inhibitor of insulin secretion.

## Amylin

Amylin is a 37-amino-acid peptide hormone that is co-secreted with insulin by pancreatic β cells in response to nutrient stimuli [57]. Amylin is an effective and potent inhibitor of stimulated pancreatic enzyme secretion. Young et al. [58] reported *in vivo* dose–response relationships in the inhibitory effects of amylin on CCK-stimulated amylase and lipase secretion in rats. Neither inhibitory effect was observed in AR42J cells nor isolated pancreatic acini. Thus, the inhibitory effect of amylin on pancreatic secretion appears to be the result of an indirect mechanism or is possibly mediated by an extrapancreatic mechanism.

## Pancreastatin

Pancreastatin is a 49-amino-acid peptide that was first isolated and purified from porcine pancreas [59]. Chromogranin A is the prohormonal precursor of pancreastatin. Pancreastatin appears to be localized in the α, β, and δ cells of the islets and it inhibits insulin release induced by various physiological and hormonal stimuli [59,60]. Efendic et al. [61] found that pancreastatin inhibits arginin-induced somatostatin secretion *in vivo* in rats and potentiates arginine-induced glucagon release in the isolated perfused pancreas. Pancreastatin has been shown to have an inhibitory effect on exocrine pancreatic secretion stimulated by ingestion of a meal, CCK-8, and central vagal nerve stimulation *in vivo* in rats [60,62]. However, CCK-stimulated amylase secretion by isolated rat pancreatic acinar cells is unaffected by pancreastatin [62]. The inhibitory effect of pancreastatin seems to be mediated by presynaptic modulation of acetylcholine release by the vagal system [62]. A recent clinical study has reported elevated pancreastatin levels and overexpression in patients with type 2 diabetes [63].

## Peptide YY

Peptide YY (PYY) is a 36-amino-acid peptide that was originally isolated from the porcine intestine [64], and immunoreactive PYY has been detected in α and PP cells in rats [65]. PYY has been shown to have an inhibitory effect on secretin- and CCK-stimulated pancreatic secretion in cats [64], and PYY secretion stimulated by ingestion of a meal and duodenal oleate administration has been demonstrated in dogs and rats [66]. Two receptors, PYY1 and PYY2, are known to mediate physiological actions of PYY. PYY2 receptors have been demonstrated on guinea pig pancreatic acini [67]. The inhibitory effect of PYY on pancreatic secretion in dogs has been reported to be mediated by PYY2 receptors [68], and in isolated perfused rat pancreas by PYY1 receptors [69].

## Galanin

Galanin is a 29-amino-acid peptide that was originally isolated from porcine upper intestine [70]. The presence of galanin has been immunohistochemically demonstrated in the neural elements of the pancreas of several

species including humans [71,72]. Baltazar et al. [73] also detected galanin-like immunoreactivity in islet endocrine cells, and demonstrated colocalization of galanin and insulin. Galanin has been shown to influence pancreatic islet secretion, most notably by inhibiting insulin secretion. The colocalization of galanin and insulin suggests an autocrine interaction between these two hormones. Although the first study showed an inhibitory effect of galanin on amylase secretion in isolated rat pancreatic acinar cells, numerous subsequent studies have found neither an inhibitory effect nor a stimulatory effect. Barreto et al. [74] reported that galanin inhibits caerulein-stimulated amylase secretion by acting on cholinergic neurons and/or islet cells via galanin receptor 2 and thereby regulates insulin release.

### Adrenomedullin

Adrenomedullin is a multiregulatory peptide that was discovered by Kitamura et al. [75]; it is expressed in a wide variety of tissues. Adrenomedullin has been demonstrated in the pancreatic islets in mammals, including humans, and has been found to colocalize with PP in islet PP/F cells [76]. Adrenomedullin receptors have been detected in β cells. Adrenomedullin has been shown to inhibit insulin secretion in a dose-dependent manner both in isolated rat islets and in rats *in vivo* [77]. Tsuchida et al. [78] demonstrated specific adrenomedullin binding sites on rat pancreatic acini and a dose-dependent inhibitory effect of adrenomedullin on CCK-stimulated amylase release from acini. A recent study showing overexpression of adrenomedullin in pancreatic cancer has indicated that adrenomedullin may be a biomarker for early diagnosis of pancreatic cancer [79].

### Pancreatic Stone Protein and Regenerating Pancreas

A sequence comparison has been shown that the pancreatic stone protein (PSP) identified in pancreatic stones and the regenerating protein (Reg) identified in regenerating islets are identical [80]. PSP/Reg has been shown to be predominantly synthesized by acinar cells, and neither pancreatic duct dells nor islet cells seem to contribute significantly to its production. Kimura et al. [81] showed that PSP/Reg mRNA is expressed in the acinar cells of normal human pancreas and pancreatic cancer cells. PSP/Reg expression is associated with β-cell growth and proliferation during islet regeneration. Increased serum PSP levels have been reported in patients with acute and chronic pancreatitis, pancreatic cancer, and type 2 diabetes [82,83]. PSP may be useful as a predictor of pancreatic exocrine and endocrine diseases.

### Cholecystokinin

CCK binds to the CCK-A receptors and regulates gallbladder contraction and pancreatic exocrine secretion [1]. It is also a neuropeptide that binds to the CCK-B receptors and regulates anxiety, satiety, and other behaviors. CCK-producing cells were identified in rat pancreatic islets [84], and further study showed that CCK is expressed in the pancreatic β cells of rats [85]. CCK-A receptors have also been detected immunohistochemically in the β and α cells of rats, pigs, and humans [86]. A stimulatory effect of CCK on insulin secretion has been demonstrated in mice, in diabetic rats, and in humans with type 2 diabetes. CCK has been shown to protect β-cell mass in rats and mice with streptozotocin (STZ)-induced diabetes [85,87]. Islet-derived CCK may have an important paracrine/autocrine effect in protecting β cells from apoptosis and mitogenesis [86]. The effects of CCK on the exocrine pancreas were thought to be almost exclusively mediated by enteropancreatic reflexes [1,88,89] because human pancreatic acini are now known to lack functional CCK-A receptors [90].

## Pancreatic Exocrine Function and Diabetes Mellitus

### Pancreatic Exocrine Function in Patients with Diabetes

Pancreatic exocrine dysfunction is well known in patients with type 1 and type 2 diabetes [91,92]. Chey et al. [93] observed reduced amylase secretion in response to injection of CCK–secretin in 36% of 50 patients with diabetes and 77% of juvenile patients with diabetes. Vacca et al. [94] reported an abnormal secretin test in 73% of 55 patients with diabetes on insulin therapy, and Lankisch et al. [95] demonstrated pancreatic exocrine insufficiency in 43% of 53 patients with insulin-dependent diabetes. A multicenter study conduced in 1021 German patients with diabetes by Hardt et al. [96] showed normal concentrations of fecal elastase-1 in 59.3% of the patients and much lower concentrations in 22.9%, and there was a significant difference in the prevalence of reduced fecal elastase-1 concentrations between the type 1 group (51%) and the type 2 group (35%). Ewald et al. [97] reported that fecal elastase-1 concentrations were inversely correlated with diabetic duration and $HbA_{1c}$ levels, and that both C-peptide levels and body mass index (BMI) were positively correlated with fecal elastase-1 concentrations.

### Pancreatic Exocrine Function in Experimental Animal Models of Diabetes

Shimizu et al. [98] observed impaired basal and CCK-stimulated pancreatic exocrine secretion in rats with STZ-induced diabetes and restoration of pancreatic

secretion in response to administration of the thiazolidine derivative troglitazone, a peroxisome proliferator-activated receptor γ (PPARγ) agonist, even though the insulin content of the pancreas was unaffected. Troglitazone has been shown to reduce insulin resistance and increase pancreatic weight and pancreatic enzyme content in WBN/Kob rats and OLETF rats, which spontaneously develop diabetes and chronic pancreatitis [99,100]. Thus, the insulin resistance of peripheral tissues as well as the amount of circulating insulin affects pancreatic exocrine function. Patel et al. [101] observed decreased CCK-8-evoked amylase secretion in rats with STZ-induced diabetes and in acinar cells isolated from such rats, and suggested that the reduced amylase secretion might be due to reduced cytosolic free calcium concentrations and amylase gene expression, and not to gene expression of the CCK-A receptor in pancreatic acinar cells. Korc et al. [102] clearly demonstrated decreased pancreatic amylase mRNA in rats with STZ-induced diabetes, and that insulin reversed this effect and induced a selective increase in amylase mRNA in the pancreas. It has recently been suggested that reduced adenosine triphosphate (ATP) and nicotinamide adenine dinucleotide phosphate (NADPH) production in mice with STZ-induced diabetes may contribute to the development of exocrine insufficiency [103].

## Introduction

The association of the overuse of alcohol with pancreatitis was first reported in the medical literature in 1815 [1,2] with subsequent more systematic analyses being made by Freidreich in 1878 [3] and Fitz in 1889 [4]. Over the past 100 years or so, considerable effort has been expended in exploring the clinical and epidemiological features of alcoholic pancreatitis and possible cofactors in the disease as well as mechanisms whereby alcohol (ethanol) may be directly injurious to the pancreas. (Note: In this text, the words "alcohol" and "ethanol" are used interchangeably.)

Alcoholic pancreatitis represents a clinical paradox. On the one hand, the risk of developing the disease increases with the amount of alcohol consumed, suggesting direct toxic effects of alcohol on the pancreas. On the other hand, only a minority (5% or less) of heavy drinkers develop the disease, suggesting a role for individual susceptibility factors.

## Epidemiology

In Western countries, alcohol ranks with gallstone disease as a major cause of acute pancreatitis, and is the major cause of chronic pancreatitis. There has been variation in attribution rates among different studies [5–8]. This variation most likely relates to the background alcohol consumption of the population under study, the types of institutions surveyed (e.g., private facility vs. county or Veterans Affairs facilities in the United States), the difficulties associated with eliciting an accurate alcohol consumption history and the growing awareness of possible cofactors in the disease (e.g., smoking).

For a long time, acute alcoholic pancreatitis and chronic alcoholic pancreatitis were considered separate diseases [9]. It is now generally recognized that they a part of the same continuum. There is good clinical [10,11] and experimental evidence [12,13] that repeated attacks of pancreatic necroinflammation lead to chronic pancreatitis (the necrosis–fibrosis sequence).

With respect to the amount of alcohol consumption required to produce pancreatitis, there has been confusion. Episodic binge drinking or the isolated alcoholic debauch rarely, if ever, causes pancreatitis [14]. However, with regard to the common situation of chronic alcohol intake, an early study suggested that the risk of developing pancreatitis was linear, even at relatively low (social) levels of consumption [15]. Later studies have suggested that there is a threshold above which pancreatitis is more likely to occur [6,16,17]. Most clinicians, basing their views on clinical experience, would agree that the diagnosis is not made in the absence of chronic heavy alcohol consumption (80–100 g of alcohol per day for at least 5 years). However, alcoholic pancreatitis is now emerging as a polyfactorial/polygenic disease (see later), so that lesser amounts of alcohol consumed may be responsible for the phenotype. It is clear that more work needs to be done on this concept.

## Pathogenesis

### Large Duct Theories

Historically, studies of pathogenesis of alcoholic pancreatitis centered first on the sphincter of Oddi and the large pancreatic ducts. This work was inspired by the observations of Opie with respect to gallstone pancreatitis. The biliary–pancreatic reflux, duodeno-pancreatic

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

reflux, and obstruction–hypersecretion theories gradually lost support because of a failure of consensus on the effects of alcohol on sphincter of Oddi motility, the effect of alcohol on pancreatic secretion, and other factors. These so-called "large duct" theories have been discussed in greater detail elsewhere [18].

## Small Duct Theory

In the 1970s, attention moved to the small pancreatic ducts, due predominantly to the landmark research of Henri Sarles and his colleagues in Marseilles. This group proposed that the initial event in alcoholic pancreatitis was the deposition of protein plugs in small pancreatic ducts, leading to local injury and possible upstream effects as a result of obstruction of pancreatic secretion [9]. These plugs are the forebears of pancreatic intraductal calculi, a major feature of chronic alcoholic pancreatitis. The major problem with Sarles' theory was the uncertainty as to whether these protein plugs were primary or secondary lesions. The plugs contain the readily precipitable protein lithostathine S1, formed from lithostathine by autocatalysis or hydrolysis by trypsin [19]. Since alcohol predisposes to premature activation of trypsinogen to trypsin in acinar cells [20], prior upstream events may precede plug formation. Nonetheless, the work of Sarles and colleagues was important in suggesting that ductular dysfunction may play a role in the pathogenesis of alcoholic pancreatitis, especially as they provided the initial suggestion (via sweat electrolyte studies) that cystic fibrosis transmembrane conductance regulator (CFTR) dysfunction may play a role [9].

## Direct Cellular Effects of Alcohol on the Pancreas

From the 1980s, attention focused on the direct effects of alcohol on pancreatic acinar cells, then from around 2000, on pancreatic stellate cells, and, most recently, on pancreatic duct cells. The results of these studies, conducted largely in rodents, are depicted in Fig. 13.1.

It should be remembered that there is no satisfactory model of alcoholic pancreatitis. In experimental animals, alcohol by itself induces a number of changes that

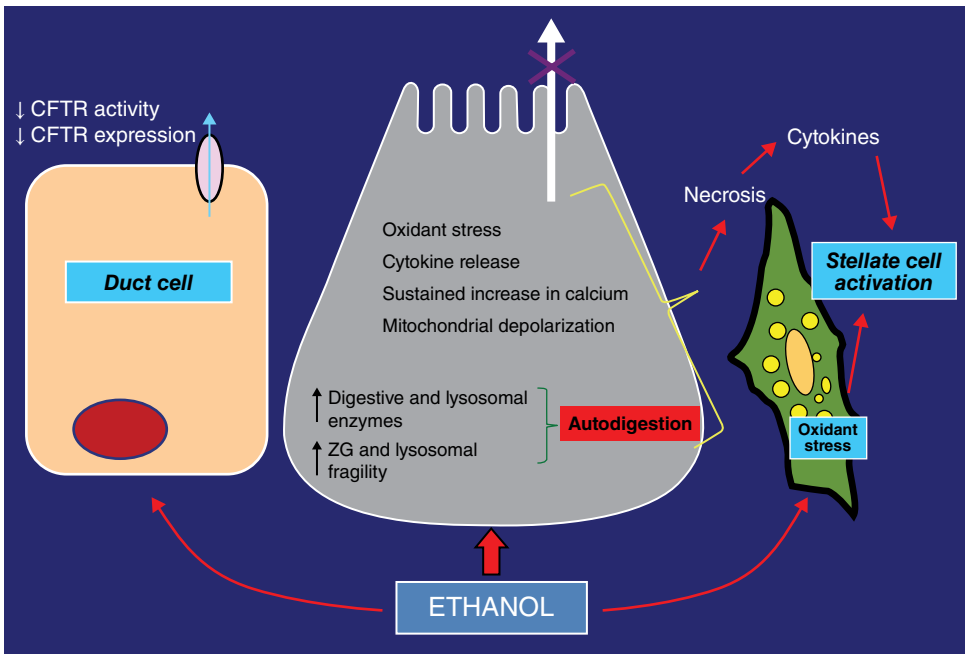

**Figure 13.1** Effects of alcohol and its metabolites on the acinar cell, duct cell, and stellate cell of exocrine pancreas. Ethanol induces an increase in digestive and lysosomal enzyme synthesis in the acinar cell, while at the same time decreasing exocytosis and impairing organelle stability. These effects predispose the cell to premature intracellular enzyme activation and autodigestion. Ethanol metabolism within the cell leads to oxidant stress, which damages subcellular membranes, proteins, and nucleic acids. In addition, ethanol causes a sustained increase in intracellular calcium, leading to mitochondrial depolarization and cell death. The ethanol-induced injury to the acinar cell also results in the release of cytokines by the cell, which can subsequently damage neighboring cells. Ethanol impairs duct cell function by decreasing CFTR expression and activity. With regard to the pancreatic stellate cell (PSC), ethanol and its metabolites and oxidant stress activate "PSCs" leading to production of excessive amounts of extracellular matrix proteins. Cytokines released from acinar cells can also activate "PSCs" via paracrine pathways, while cytokines synthesized by "PSCs" themselves can further activate the cells in an autocrine manner, leading to progressive fibrosis, even in the absence of the initial trigger. ZG, zymogen granule.

predispose the pancreas to autodigestion, necroinflammation, and fibrosis, but that are insufficient to cause overt pancreatitis. However, coadministration of an additional "hit," such as bacterial endotoxin, produces pancreatitis. This will be discussed in greater detail later.

#### Metabolism of Alcohol by the Pancreas

Many of the direct effects of alcohol on the pancreas are a consequence of the metabolism of alcohol (ethanol) by the gland via oxidative and nonoxidative pathways.

The oxidative pathway of alcohol metabolism involves sequential oxidation by alcohol dehydrogenase (ADH) to acetaldehyde and then to acetate via acetaldehyde dehydrogenase (ALDH). Catalase in peroxisomes can also metabolize ethanol to acetaldehyde but its activity is thought to be low as it is determined by the availability of its substrate hydrogen peroxide ($H_2O_2$). Additionally, cytochrome P450 2E1 (CYP2E1) can metabolize ethanol at high concentrations to acetaldehyde and this is enhanced by enzyme induction following chronic ethanol exposure [21]. Both ADH and CYP2EI have been identified in pancreatic tissue (catalase is ubiquitous) [22–24]. The oxidative pathway results in depletion of antioxidant defenses (mainly glutathione) and the production of reactive oxygen species capable of disruption of membranes, proteins, and DNA.

The nonoxidative pathway involves esterification of ethanol with free fatty acids (FFA) to form fatty acid ethyl esters (FAEE). The enzymes catalyzing this reaction are FAEE synthases. There appears to be no one enzyme responsible for this reaction, and carboxyl ester lipase (CEL) and triglyceride lipase have been implicated. It has been reported that the pancreas has the highest FAEE synthesizing capacity of any parenchymal organ [25].

FAEE are believed to exert toxicity via:

- direct perturbation of biological membranes following intercalation and
- a transport shuttle mechanism with local release of FFA resulting in disturbance of intracellular membrane function with decreased lysosomal stability (see later) and altered intracellular calcium homeostasis with resultant calcium overload, mitochondrial dysfunction, and cell death.

The pancreatic acinar cell possesses the enzymatic machinery for both oxidative and nonoxidative ethanol metabolism, with the former representing the major pathway for alcohol metabolism [22–24] in rats. Kinetic studies using rat pancreatic acini suggest that ethanol is metabolized in acinar cells predominantly by class III (high $K_m$) ADH [22,23]. However, a recent study has reported that the predominant class of ADH in human pancreatic acini is ADH I, with ADH III contributing little to pancreatic alcohol oxidation [26]. These disparate findings may reflect species differences and the relative magnitudes of the oxidative and nonoxidative pathways in human pancreatic tissue remain to be determined. However, even in rat pancreatic acinar cells, where oxidative metabolism of ethanol seems to dominate, the contribution of the nonoxidative pathway cannot be discounted because FAEE are produced in sufficient amounts to produce local injury [27]. Interestingly, pharmacologic inhibition of the FAEE synthase CEL ameliorates alcohol-induced pancreatic damage in mice [28].

Rat pancreatic stellate cells (PSC) can also oxidize alcohol to acetaldehyde via a pyrazole-sensitive (class I) ADH [29]. These observations are well supported by a recent study reporting activity of an ADH class I isozyme, namely ADH1C, in quiescent human PSC which was inhibited by pyrazole [26]. Interestingly, this study also showed that the expression of ADH1C was increased in activated human PSC in chronic pancreatitis [26]. The capacity of PSC for nonoxidative ethanol metabolism is yet to be determined.

#### Effects of Ethanol on Pancreatic Acinar Cells

Chronic alcohol administration to rodents results in a number of changes in acinar cells which may predispose the cells to injury. *In vitro* and *in vivo* approaches have now established that ethanol and its metabolites exert multiple effects on acinar cells, including:

- an increase in intracellular levels of digestive enzymes (trypsin, chymotrypsin, and lipase) mediated, at least in part, by increases in their respective mRNA levels [30] and possibly also by decreased secretion secondary to acetaldehyde-induced apical microtubule disruption [31] and inhibition of binding of secretagogues to their receptors [32];
- an increase in lysosomal enzyme content [20,30];
- decreased stability of lysosomes mediated by accumulation of FAEE and cholesteryl esters (transesterification products of FAEE) in the cells [27,33];
- decreased zymogen granule stability [34], possibly mediated by an ethanol-induced reduction of GP2 [35], the predominant protein in zymogen granule membranes that is responsible for zymogen granule shape and membrane stability.

Taken together, the effects of alcohol on lysosomes and zymogen granules create a situation whereby there is an increased potential for contact between trypsinogen and lysosomal hydrolases, with subsequent generation of active trypsin, leading to activation of an intracellular digestive enzyme cascade and autodigestion.

Other effects of alcohol on pancreatic acinar cells include the following:

- FAEE cause a sustained rise in intracellular calcium levels via stimulation of calcium release from endoplasmic reticulum following stimulation of inositol trisphosphate ($IP_3$) receptors and defective clearance of cytosolic calcium via inhibition of $Ca^{2+}$-ATPase pumps in plasma membrane and endoplasmic reticulum. The sustained rise in calcium levels subsequently causes mitochondrial overload and cell death [36].
- The transcription factors NFκB and AP-1 (which are important regulators of cytokine expression) are induced by alcohol and acetaldehyde as well as by FAEE [22].
- The unfolded protein response/endoplasmic reticulum (ER) stress and autophagy are two homeostatic mechanisms for maintaining cellular integrity in all cells. Recent studies have demonstrated that chronic alcohol consumption induces ER stress [37] and impaired autophagy [38] in pancreatic acinar cells.

#### Effects of Ethanol on Pancreatic Stellate Cells

PSC are the principal source of collagen and other extracellular matrix proteins in the fibrosis of chronic alcoholic pancreatitis. PSC are directly activated upon exposure to ethanol [29,39]. This activation is thought to be mediated via the metabolism of alcohol to acetaldehyde and the subsequent generation of reactive oxygen species within the cells [29].

PSC are also activated by inflammatory cytokines (released during pancreatic necroinflammation) and, in turn, produce their own inflammatory cytokines resulting in an autocrine loop allowing perpetuation of activation even after the initial insult has been removed [40–44].

#### Effects of Ethanol on Pancreatic Duct Cells

Inspired by the original observations of Sarles et al. [9] on pancreatic intraductal abnormalities and sweat electrolytes in patients with chronic alcoholic pancreatitis (see earlier), Maleth et al. [45] have recently examined the effect of ethanol on CFTR function. In recently abstinent alcoholics and in acutely drinking alcoholics with very high blood alcohol concentrations, CFTR function (as determined by sweat chloride concentration) was impaired, but this was not the case in normal individuals with acute consumption of alcohol. In addition, it was found that in duct cells isolated from alcoholic pancreatitis tissue, CFTR expression was decreased at both mRNA and membrane protein levels, with evidence of impaired posttranslational processing. In *in vitro* experiments using duct cell lines and tissue from mice and guinea pigs, ethanol decreased CFTR mRNA as well as membrane CFTR levels and stability; these effects were reported to be mediated by nonoxidative metabolites of ethanol.

## Individual Susceptibility to Alcoholic Pancreatitis

Despite the substantial experimental evidence supporting direct toxic effects of alcohol and its metabolites on the pancreas, it is well established that only a minority of people with alcoholism develop clinically evident pancreatitis [46,47], suggesting that an additional factor is required to induce the disease in heavy drinkers. The search for this cofactor/susceptibility factor/trigger factor/second "hit" has prompted many studies, as summarized in Table 13.1.

Ideally, studies into individual susceptibility to alcoholic pancreatitis should compare alcoholics *with* the disease and alcoholics *without* the disease so that the index and the control groups differ in only one variable (i.e., the presence or absence of pancreatitis). This has not always been the case, with several studies using only the healthy population as a control group.

Many susceptibility factors have been examined to date. These can best be classified as being environmental or hereditary. Environmental factors include diet, amount and type of alcohol consumed, the pattern of drinking, smoking, obesity, lipid intolerance, and endotoxemia. Hereditary factors include genes relevant to alcohol metabolism, digestive enzymes and their inhibitors, proinflammatory cytokines, oxidant stress, and cystic fibrosis [8,48,49].

#### Environmental Factors

##### *Dietary Factors*

There is no clear evidence that dietary factors play a role in individual susceptibility to alcoholic pancreatitis [50]. This is certainly true with respect to macronutrients [50]. Properly controlled studies of dietary micronutrients, antioxidants, and other micronutrients are yet to be performed.

##### *Beverage Type and Periodicity of Drinking*

Similarly, there is no evidence that the type of alcoholic beverage consumed plays any part in susceptibility to alcoholic pancreatitis [50], although it must be acknowledged that the congeners of alcoholic beverages have not been studied exhaustively.

Additionally, it has not been established that the periodicity of drinking is a susceptibility factor in this disease [50]. Although there have been occasional reports implicating binge drinking, most patients imbibe alcohol at high levels constantly from one day to the next, prior to the initial presentation.

**Table 13.1** Individual susceptibility to alcoholic pancreatitis.

| Factor | Association | |
|---|---|---|
| Drinking pattern | No | Wilson et al., 1985 [50] |
| Beverage type | No | Wilson et al., 1985 [50] |
| | Yes | Nakamura et al., 2003 [95] |
| Diet | No | Wilson et al., 1985 [50] |
| Smoking | Yes | Lowenfels et al., 1987 [96] |
| | No | Haber et al., 1993 [97] |

[a] Studies that did not include alcoholics without pancreatitis as controls.

### *Smoking*

The role of smoking as a trigger factor for alcoholic pancreatitis has been a particularly contentious subject [51,52]. This is largely because the vast majority of heavy drinkers are also smokers, making it difficult to demonstrate unequivocally an independent role for smoking in the initiation of pancreatitis. Law et al. [53] concluded that smoking is independently associated with chronic pancreatitis, after adjusting for alcohol and other risk factors. However, the authors acknowledged that the retrospective nature of the study made it difficult to stratify accurately the extent of smoking and alcohol use. Furthermore, the study population included patients with chronic pancreatitis with a variety of etiologies; only a small proportion of the study subjects could be classified as heavy drinkers.

Although the role of smoking as an initiating factor in alcoholic pancreatitis remains uncertain, there is evidence to suggest that it may facilitate the progression of the disease as evidenced by the accelerated development

of pancreatic calcifications and endocrine dysfunction in patients with alcoholic pancreatitis who smoke [54].

#### *Obesity*

Another recently explored risk factor for alcoholic pancreatitis is obesity. Using a prospectively recruited cohort of patients with alcoholic chronic pancreatitis and age- and sex-matched healthy subjects as controls, Ammann et al. [55] reported that obesity prior to onset of chronic pancreatitis, defined as body mass index (BMI) greater than 30, was fivefold more frequent in patients with alcoholic chronic pancreatitis compared to healthy controls, but had no effect on disease progression. However, as obesity is highly prevalent in asymptomatic alcoholics compared to the general population [56], the lack of an appropriate control group (alcoholics without pancreatitis) in the Ammann study [55] precludes any definitive conclusions regarding obesity as a susceptibility factor for the development of alcoholic pancreatitis.

#### *Lipid Intolerance*

Alcohol abuse can cause hypertriglyceridemia and hypertriglyceridemia is a known cause of acute pancreatitis, at least at very high levels of serum triglycerides. These facts have led to speculation that those alcoholics who develop pancreatitis do so via the development of hypertriglyceridemia. However, when postprandial lipid tolerance was studied in patients with alcoholic pancreatitis (index group) no difference was found compared with a control group comprising alcoholics without pancreatitis [57]. This study emphasized the importance of appropriate controls in studying susceptibility to alcoholic pancreatitis.

#### *Endotoxin*

Serum endotoxin levels are increased in alcoholics, even after a single binge, most likely due to an alcohol-induced increase in gut permeability permitting translocation of gram-negative bacteria (such as *E. coli*) across the mucosal barrier and decreased clearance of endotoxin by Kupffer cells in the liver [58,59]. Recently, Forsyth et al. [60] have shown that alcohol increases the permeability of Caco-2 intestinal epithelial cell monolayers via CYP2E1-induced oxidant stress, which in turn induces the circadian clock proteins CLOCK and PER2.

Experimental studies support the concept of bacterial endotoxin (lipopolysaccharide [LPS]) as a promising susceptibility factor for alcoholic pancreatitis. A study by Vonlaufen et al. [61] has provided convincing evidence that endotoxin (LPS) challenge in alcohol-fed rats initiates overt pancreatic injury and also stimulates progression to chronic disease manifesting as acinar atrophy and fibrosis. Importantly, this effect was abrogated in TLR4 (Toll-like receptor 4, LPS receptor) knockout rodents [62], demonstrating the specificity of the effects of LPS on pancreatic cells.

Further work is needed to determine whether genetic polymorphisms pertinent to the alcohol-induced hyperpermeability/endotoxin paradigm may explain individual susceptibility to alcoholic pancreatitis (see later).

In summary, in terms of environmental factors, a clear and single susceptibility factor for alcoholic pancreatitis remains to be identified.

### Hereditary Factors

#### *Polymorphisms of Alcohol-Metabolizing Enzymes*

Alcohol toxicity is most likely to depend on its metabolism generating toxic metabolites such as acetaldehyde, FAEE, and reactive oxygen species. Increased or decreased activities of alcohol-metabolizing enzymes (ADH, ALDH, CYP2E1, FAEE synthases) may result in the accumulation of toxic metabolites and tissue damage (see earlier).

ADH and ALDH are the major enzymes of oxidative alcohol metabolism in the body. There are multiple ADH and ALDH enzymes encoded by different genes which can exist as several allelic variants. These variants can influence rate of metabolism and their distribution varies between ethnic groups as well as different tissues in the body [21].

Based on amino acid sequence and structural similarities, human ADH enzymes are now classified into five classes. The three class I enzymes (ADH1A, ADH1B, and ADH1C) are the major contributors to ethanol clearance in the liver [21].

There are two main groups of ALDH enzymes: cytosolic ALDH1 and mitochondrial ALDH2. ALDH2 is the major enzyme responsible for the oxidation of acetaldehyde to acetate [21].

Most attention to ADH-mediated metabolism/damage in alcoholic pancreatitis has been centered on the *ADH1B* gene. In Asian populations, the *ADH1B*2* allele predominates and encodes for the more active β2-ADH subunit that produces acetaldehyde at a much faster rate than the more common *ADH1B*1* allele (wild-type) [63,64]. Several Japanese studies have demonstrated that the frequency of the *ADH1B*2* allele is increased in patients with alcoholic pancreatitis compared to alcoholics without pancreatitis [64–66]. In the Japanese population, a decreased frequency of the *ADH1B*1* allele has also been reported, suggesting that this allele "reduces vulnerability" [66,67].

A recent meta-analysis of eight case–control studies evaluating the association of ADH1B, ADH1C, and ALDH2 variants in alcoholic pancreatitis found a higher risk for carriers of the *ADH1B*2* allele and a lower risk for the *ALDH2*2* allele (coding for a metabolically nearly inactive protein) in Asian patients [68]. In non-Asian

subjects, the *ADH1C*2* allele was associated with decreased risk [68].

Genetic polymorphisms have been described in the promoter region as well as in intron 6 of the *CYP2E1* gene, some of which are associated with altered function [69]. However, no polymorphism has been associated with alcoholic pancreatitis in studies of alcoholics without pancreatitis as controls.

#### *Mutations of FAEE Synthase Enzymes*

One study reported a positive association between the risk of developing alcoholic pancreatitis and a polymorphism of the gene for one of the candidate FAEE synthase enzymes, CEL, in Japanese subjects [70]. The investigators employed alcoholics without pancreatitis as controls. The functional significance of this polymorphism has not yet been elucidated, and the study findings have not been corroborated in a study involving European subjects [32,71]. A more recent study has reported an association between a hybrid allele of the CEL gene (*CEL-HYB*) and alcoholic chronic pancreatitis [72]; however the controls used were healthy subjects and not alcoholics without pancreatitis. Based on *in vitro* studies using HEK293 cells, the authors report that the resulting CEL-HYB protein may play a role in cell injury by impairing autophagy [72].

#### *Trypsinogen Gene Mutations*

The landmark report of Whitcomb et al. [73] in 1996 implicating a mutation in the cationic trypsinogen gene (R122H) in hereditary pancreatitis greatly strengthened the notion that trypsin may be central to the pathogenesis of pancreatitis. Certainly this discovery inspired a great amount of work into the pathogenesis of hereditary pancreatitis, and a number of other mutations were subsequently described.

Using a similar candidate gene approach, studies in alcoholic pancreatitis have largely been negative. A protective variant (G191R) of the anionic trypsinogen gene *PRSS2*, which results in a form of trypsin that is easily degraded, was reported to be significantly less common in patients with alcoholic chronic pancreatitis compared to healthy controls, but the prevalence of this variant in alcoholics without pancreatitis was not tested [74].

Most recently, the results of two large genome-wide association studies (GWASs), one from North America [75] and the other from Europe [76], have been published. A significant association in the *PRSSI/PRSS2* locus at 7q34 was detected (rs10273639). This single nucleotide polymorphism (SNP) is located in the 5′ promoter region of *PRSS1* and may affect expression of the trypsinogen gene. Both investigating teams found a decrease in alcoholic pancreatitis risk with rs10273639. This association was not observed in nonalcoholic chronic pancreatitis, nor in patients with alcoholic liver disease, although, the investigators did not study a control group of "healthy" alcoholics (i.e., those without pancreatic or liver disease). The functional significance of rs10273639 awaits clarification.

#### *Claudin 2 Mutations*

A second association of alcoholic pancreatitis was revealed by the aforementioned GWASs [75,76], involving the *CLDN2–RIPPLY1–MORC4* locus (Xp23.3, SNPs rs7057398 and rs12688220). *CLDN2* encodes claudin 2, a tight junction protein. The authors again found a decreased risk of alcoholic pancreatitis associated with the *CLDN2* locus SNP rs12688220. The functional significance of this *CLDN2* SNP remains unclear.

In chronic pancreatitis tissue sections, claudin 2 is expressed in duct cells and acinar cells and there is aberrant expression along the basolateral membrane of acinar cells in the presence of the high-risk SNP [75]. There is an intriguing possibility that the SNP reported influences the function of claudin 2 in the intestine, influencing intestinal permeability and the possibility of endotoxemia in those alcoholics susceptible to pancreatitis (see earlier). Upregulation of pore-forming claudin 2 has been implicated in increased intestinal permeability in Crohn's disease [77].

#### SPINK 1 *Mutations*

An association between mutated *SPINK1* and alcoholic pancreatitis has also been described. The N34S mutation, a c.101A > G transition leading to substitution of asparagine by serine at codon 34, was found in 5.8% patients with alcoholic pancreatitis, compared to 1.0% alcoholic controls without pancreatitis [78]. A more recent study on Romanian patients has reported that 5% of patients with ACP had the N34S mutation compared to 1% of healthy controls [79]. A recent meta-analysis found a significant association of the N34S mutation with alcoholic pancreatitis with an odds ratio of 4.98 (95% confidence interval: 3.16–7.85) but the association was the weakest among categories analyzed, including tropical pancreatitis, idiopathic chronic pancreatitis, and hereditary pancreatitis [80]. Since the N34S mutated human *SPINK1* does not show any altered trypsin inhibitor capacity, the functional consequences of this mutation are unclear.

#### *Chymotrypsin Gene Mutations*

Chymotrypsin C (CTRC) is a minor isoform of chymotrypsin. In a German study, in individuals with idiopathic or hereditary chronic pancreatitis, various CTRC variants have been found and the two most frequent variants were detected in 3.3% of pancreatitis patients but only in

0.7% of controls [81]. In individuals with alcoholic pancreatitis both variants have been detected more often (2.9%) than in patients with alcoholic liver disease (0.7%) [81]. In a Chinese population more CTRC variants were detected in chronic pancreatitis patients but the overall frequency of mutations was 2.3% and thus lower than in the European study [82].

#### CFTR *Mutations*

*CFTR* mutations have been implicated in a subset of patients with idiopathic pancreatitis [83,84]. In addition, it has been demonstrated, in both animal and human studies, that CFTR expression and function are impaired by alcohol [45]. However, there is an overall lack of evidence implicating *CFTR* mutations in the pathogenesis of alcoholic pancreatitis. A small study from Brazil showed that patients with alcoholic pancreatitis showed a higher frequency of the T5/T7 genotype in the noncoding region of thymidines in intron 8, suggesting reduced transcription of the *CFTR* gene [85]. Clearly additional and larger studies are needed.

#### *Other Hereditary Factors*

A number of other hereditary factors have also been examined as possible triggers for alcoholic pancreatitis. These include blood group antigens [86,87], HLA serotypes [88], $\alpha_1$-antitrypsin phenotypes [89], genotypes of the cytokines transforming growth factor β (TGF-β) [90], tumor necrosis factor α (TNF-α) [90], interleukin 10 [90], and interferon γ [90], and genotypes of detoxifying enzymes such as UDP-glucuronosyl transferase (*UGT1A7*) [91,92] and glutathione *S*-transferase [93]. Most studies have failed to show any association with alcoholic pancreatitis, although one recent study has reported a positive association between the risk of developing alcoholic pancreatitis and fucosyl transferase (FUT2) nonsecretor status as well as with ABO blood group B status [94]; further work is awaited.

## Summary

Since the first association of alcohol excess with pancreatitis more than 200 years ago, understanding of the disease "alcoholic pancreatitis" has undergone considerable conceptual refinement. Although alcohol excess remains a central and definitional component of the disease phenotype, it is clear that the disease is multifactorial/polygenic and that further work is needed to tease out the various pathogenetic components and their interrelationships.

## Introduction

Many authorities have contributed to our understanding of the link between the biliary tree and acute pancreatitis over the years (Table 14.1), but none more so than Eugene Opie, a pathologist at the Johns Hopkins Hospital in Baltimore, who wrote:

> During whatever stage of the disease operation is performed the condition of the bile passages is important and may offer an imperative indication for interference. The common bile duct should be examined so far as it is possible, and bearing in mind the mechanism by which a small calculus may produce the lesion, the operator should, if feasible, exclude the possibility that a stone is still lodged in the diverticulum of Vater. If such impaction should be found, removal of the calculus is essential in order to prevent further destruction of the pancreas. The temporary lodgement of a calculus within the diverticulum may produce an extensive pancreatic lesion, yet, finally expelled into the duodenum the stone may no longer be demonstrable either at operation or autopsy. Hence in a considerable number of cases the gallbladder will be found to be filled with gallstones, even though the bile ducts are free. The stones may be of such size that any one of them lodged at the orifice of the common duct might divert bile into the pancreatic duct [30].

This demonstrates both his understanding of the pathophysiologic mechanism of acute pancreatitis (i.e., the passage of gallstones and their lodgement at the ampulla of Vater) but also the importance of removal of such stones for the prevention of further attacks. Claude Bernard had previously shown that injection of bile and sweet oil into the pancreatic duct of dogs caused peritonitis, but he failed to connect this with the development of pancreatitis [12]. Lancereaux, in 1899, suggested that a stone in the lower main bile duct might obstruct the main pancreatic duct and allow penetration of microorganisms into the pancreas [16], but again did not link this to the development of acute pancreatitis. Instead it was Opie who finally linked gallstones with the pathogenesis of acute pancreatitis [17].

## Etiology of Gallstone Pancreatitis

It is now widely accepted that gallstone-associated pancreatitis results from the passage of stones through the sphincter of Oddi, into the duodenum (Fig. 14.1a,b). In a landmark study, Acosta and Ledesma analyzed the feces of patients with gallstones and pancreatitis [24]. They identified stones in the feces of 94% of patients with gallstone-associated pancreatitis but in only 8% of patients with uncomplicated biliary colic without pancreatitis. There are essentially three hypotheses to account for how gallstones induce acute pancreatitis: (i) common channel, (ii) duodenal reflux, and (iii) ductal hypertension.

### Common Channel Hypothesis

Opie described the discovery of a stone impacted at the ampulla of Vater in a common biliary/pancreatic channel of a patient who had died of acute pancreatitis [17]. He suggested that reflux of bile into the pancreatic duct may have been the precipitating cause of acute pancreatitis.

| Prognostication | J.H. Ranson et al. [25] | 1974 |
| First randomized trial controlled by prognostic stratification | C.W. Imrie et al. [26] | 1978 |
| Endoscopic stone extraction in acute pancreatitis | M. Classen et al. [27] | 1978 |
| First randomized trial of ERCP/sphincterotomy | J.P. Neoptolemos et al. [28] | 1988 |
| Ductal hypertension hypothesis | M.M. Lerch et al. [29] | 1993 |

Experimentally, Opie was able to demonstrate that forcible injection of bile into the pancreatic ducts of dogs did indeed induce inflammation of the pancreas, a finding that has been confirmed by other investigators [31]. It has become apparent, however, that no more than two-thirds of the population have such a common ductal channel [32,33] and in many cases this is so short that a stone obstructing the common bile duct would also obstruct the pancreatic duct. Nevertheless, common channels are found more commonly among patients with biliary acute pancreatitis than in the general population [34]. Even in the absence of a significant anatomic common channel, however, it is possible that passage of a stone may cause a functional common channel in some patients by causing a stenosis of the ampulla of Vater [35]. This assumes that bile reflux is the trigger for pancreatitis, even though at normal pressures bile is not injurious to the pancreas [36]. The pressure in the pancreatic duct is, in fact, normally two to three times higher than that in the bile duct and would therefore tend to favor reflux of pancreatic secretions into the biliary tract rather than vice versa [37,38].

## Duodenal Reflux Hypothesis

A second potential mechanism of pancreatitis induced by the passage of gallstones invokes the reflux of duodenal content into the pancreatic duct. This is a

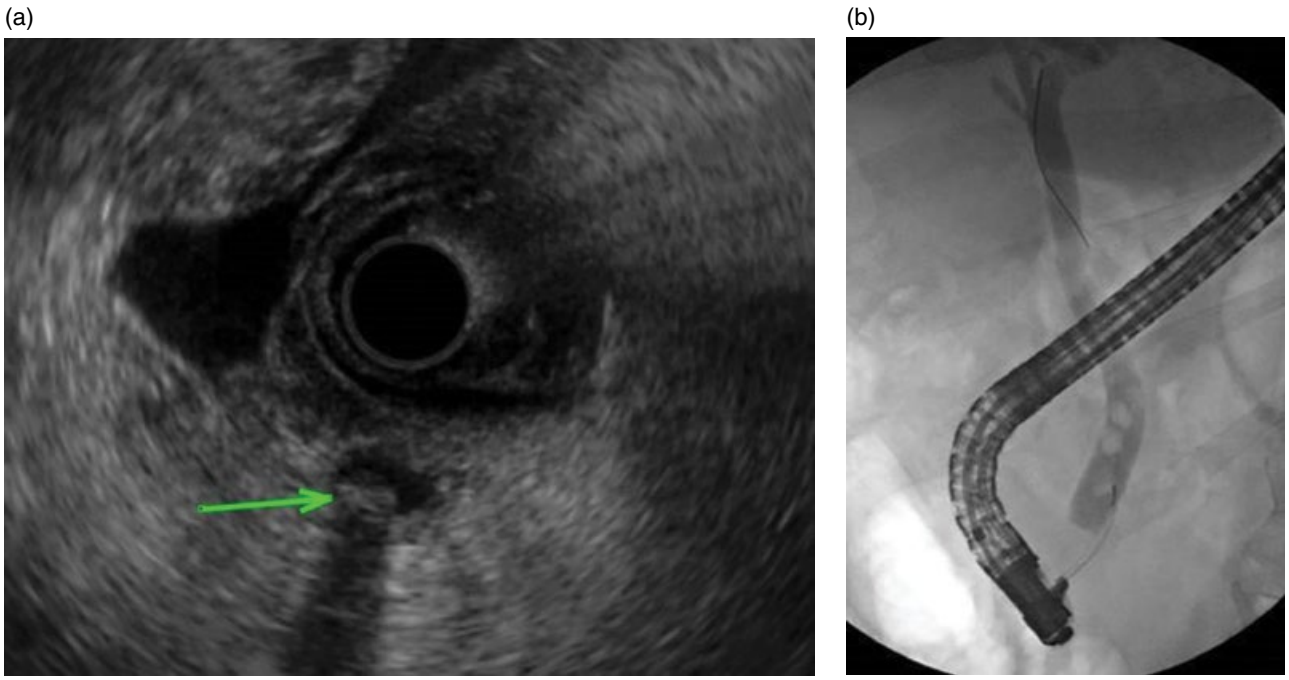

**Figure 14.1** A 78-year-old man presented with mild acute pancreatitis with a normal bilirubin but elevated liver enzymes alkaline phosphatase and gamma-glutamyltransferase. Transabdominal ultrasound was unhelpful, but endoscopic ultrasound demonstrated at least one stone in the common bile duct (a). Several stones were removed at subsequent endoscopic retrograde cholangiopancreatography (b).

mechanism that has been utilized in experimental studies on dogs [39] in which a closed duodenal loop is created. The subsequent development of pancreatitis appears to be due to reflux of contents since it may be prevented by ligation of the pancreatic duct [40–42]. This does have an infrequent parallel in humans in that obstruction of the afferent loop after Polya gastrectomy or gastroenterostomy may occasionally cause acute pancreatitis [43,44], however, the normal pancreatic duct is protected by several mechanisms to prevent this occurrence (i.e., the oblique course of the duct, the sphincter of Oddi, and the mucosal folds around the opening) [45]. Passage of a gallstone may allow reflux of duodenal contents either directly at the time of passing or later by damaging the sphincter mechanism, but surgical sphincterotomy at endoscopic retrograde cholangiopancreatography (ERCP) is usually protective against further episodes of biliary pancreatitis and does not appear to predispose to pancreatitis due to duodenal reflux [46–48]. In cases of pancreatitis due to duodenal obstruction, not only is there duodeno-pancreatic reflux but this also occurs at a high pressure, and it is likely that ductal hypertension is at least as significant as the duodenal content. It is possible to induce pancreatitis experimentally in rats by infusion of isotonic saline solution alone (M Brady, unpublished data).

## Ductal Hypertension Hypothesis

Lerch et al. evaluated the effect of obstruction at different sites in the pancreaticobiliary ductal tree on the development of pancreatitis in opossums [29]. They showed that obstruction of the main pancreatic duct alone is sufficient to induce pancreatitis in this animal model and that separate ligation of the common bile duct or ligation of the common biliopancreatic channel did not affect the severity of disease caused. Other studies have shown that continued stimulation of secretion in the presence of an obstructed pancreatic duct exacerbates the damage [49], but that relief of the obstruction ameliorates the severity of pancreatitis [50]. Obstruction of the pancreatic duct in the presence of continued stimulation of secretion induces pancreatic ductal hypertension. Ductal hypertension would also be generated by several of the other, less common, causes of acute pancreatitis, such as ampullary tumors, helminthic infestations, and ERCP. Indeed, injection of many compounds into the pancreatic duct at supraphysiologic pressure is sufficient to induce acute pancreatitis [31], but it is likely that the pressure of injection is of more significance than the precise chemical compound used.

The mechanism by which increased ductal pressure leads to pancreatitis has been the subject of much debate over the years. It has been generally assumed that it acts either by causing rupture of small pancreatic ductules

and extravasation of secretions into the interstitium of the gland with subsequent activation of enzymes, or by prevention of discharge of secretions from the acinar cells into the ductal space with consequent intracellular changes. Since the first observable changes after duct ligation occur within the acinar cells rather than in the interstitium or periductally, the latter would seem more likely. High pressure within the acinar lumen may impair both exocytosis of zymogens and $Ca^{2+}$ extrusion from the apical plasma membrane [51]. Disruption of the plasma membrane and its transport channels also impairs the restoration of normal $Ca^{2+}$ levels after physiologic cholecystokinin (CCK) stimulation, and CCK stimulation is known to compound the effects of ductal obstruction [50,52]. It is known that disruption of acinar $Ca^{2+}$ signaling is a key early event in the initiation of intra-acinar enzyme activation [53] and $Ca^{2+}$ signaling is indeed disrupted by experimental duct obstruction [54,55]. $Ca^{2+}$ signals may also be disrupted by the uptake into acinar cells of bile acids, which thereby induce cell death [56,57]; this may compound the effect of obstruction if a common biliopancreatic channel does exist.

## Two-phase Hypothesis of Gallstone Acute Pancreatitis

These three proposed pathogenetic mechanisms are not mutually exclusive, and may compound each other, as is the case with biliopancreatic reflux in the presence of ductal obstruction and hypertension. Indeed, obstruction alone often leads to biliary complications rather than pancreatitis, and therefore a two-phase hypothesis has been proposed to explain the development of acute pancreatitis [58]. Initially, the passage of a gallstone in a patient with a common pancreatobiliary channel induces acute pancreatitis, but migration of the stone allows free drainage of activated pancreatic enzymes and the pancreas can recover, resulting clinically in a mild attack of acute pancreatitis. Such is the case for the majority of attacks of acute pancreatitis. In a minority, however, further obstruction to the flow of activated enzyme-rich pancreatic juice results in exacerbation of the pancreatic damage and a severe attack of pancreatitis. Secondary obstruction may be due to:

- edema of the head of the pancreas or ampulla after passage of a gallstone;
- repeated transient obstruction due to passage of multiple small stones;
- a large stone impacted in the distal main bile duct causing compression of the main pancreatic duct which lies alongside;
- impaction of a larger stone at the ampulla of Vater itself.

The first and second phases of this mechanism may be separated by minutes, hours or days, but the hypothesis implies that there may be a window of opportunity in some patients in which to prevent further obstruction and avert a severe attack of pancreatitis.

## Other Causes of "Biliary" Acute Pancreatitis

Although biliary acute pancreatitis is often equated with pancreatitis secondary to gallstones, and in reality most often is, a number of other less common etiologies cause pancreatitis via a similar mechanism and should be considered in the same category (Box 14.1). Biliary sludge is almost certainly not a cause of pancreatitis but is a common finding in patients with acute pancreatitis due to reduction in gallbladder motility (see later). As with gallstones, the essential pathophysiologic mechanism is obstruction to the pancreatic duct at the level of the ampulla of Vater.

Cholesterolosis has been described as affecting 11% of gallbladders removed at surgery [59]. In most cases, cholesterol polyps were found in association with gallstones, but in one study of 55 cases with cholesterolosis alone, 27 (55%) presented with recurrent acute pancreatitis, suggesting that cholesterol polyps themselves may cause transient pancreaticobiliary obstruction (Fig. 14.2). A larger, more recent series, however, of 6868 patients who had undergone cholecystectomy, found no association between cholesterolosis and acute pancreatitis [60].

Biliary sludge is a mixture of particulate matter that precipitates from bile, generally consisting of cholesterol monohydrate crystals, calcium bilirubinate, and other calcium salts embedded in mucin [61] (Fig. 14.3). Biliary sludge often coexists with gallstones [62] and it is

questionable whether the formation of sludge represents an early stage of gallstone formation. Biliary sludge has been reported as causing acute pancreatitis in 3.1% of cases [63], although whether this is due to sludge per se or to associated microlithiasis is difficult to judge. A study performed by Lee et al. assessed 86 patients who had been diagnosed with "idiopathic pancreatitis" and found evidence of biliary sludge in the majority (67%). Although the presence of biliary sludge was not shown to have a causal relationship, its presence was predictive for recurrent episodes of acute pancreatitis [64].

ERCP, with or without sphincterotomy, is associated with the development of acute pancreatitis in up to 7% of cases [65]. Factors associated with an increased risk were a history of previous ERCP-induced pancreatitis (odds ratio [OR] 5.4), suspected sphincter of Oddi dysfunction (OR 2.6), female gender (OR 2.5), biliary sphincter balloon dilatation (OR 4.5), difficult cannulation (OR 3.4), pancreatic sphincterotomy (OR 3.1), and one or more injections of contrast into the pancreatic duct (OR 2.7).

Biliary surgery has been infrequently linked with acute pancreatitis, usually after exploration of the main bile duct. In a study of 1041 patients undergoing surgery for gallstones, Vernava et al. [66] found three cases of pancreatitis following cholecystectomy in 842 patients (0.35%) but nine cases of pancreatitis after 199 bile duct explorations (4.5%), of whom three patients died. Operations involving transduodenal bile duct exploration are especially likely to trigger acute pancreatitis. In one study, 23 of 208 patients died following transduodenal exploration of the main bile duct [67].

Parasites may cause acute pancreatitis by obstruction of the ampulla of Vater, either by inducing the formation of gallstones or by direct infestation of the main pancreatic duct. Such causes are unusual in Western countries but common in parts of Africa and Asia where the commonest pathogens are *Ascaris*, *Clonorchis sinensis*, echinococcal hydatid disease, *Giardia*, and malaria [68–72].

Tumors at or around the level of the ampulla of Vater may present as acute pancreatitis in around 6% of cases [73–76]. More proximal lesions have also been reported as presenting with acute pancreatitis, possibly due to ampullary obstruction by tumor fragments or mucoid secretions [77]. There are a few anecdotal reports of sclerosing cholangitis as a cause of acute pancreatitis [78,79].

Sphincter of Oddi dysfunction, either dyskinesia or organic stenosis, may present as recurrent acute pancreatitis [80], although many patients with sphincter dyskinesia also have gallstones, and there is some evidence that dyskinesia is more common in patients with gallstones [81].

## Epidemiology of Biliary Acute Pancreatitis

Between 3% and 8% of patients with symptomatic gallstones develop acute pancreatitis [82,83], representing an increase in relative risk of developing pancreatitis for

patients with gallstones of up to 35 times that of the general population. Around 80% of patients will have a mild attack, 20% will have a severe attack, and 5% will die as a result of acute biliary pancreatitis (ABP) [84]. Like gallstones in general, gallstone pancreatitis is more common in women than in men and tends to occur in an older age group than pancreatitis due to alcohol ingestion [85]. The precise incidence varies with the population prevalence of gallstones [86] but ranges from 150 to 420 per million population in Western countries [87–89].

The development of gallstone acute pancreatitis is related to the size and number of the gallstones present. Patients with gallstones who present with acute pancreatitis tend to have smaller stones, in larger numbers, and with preserved gallbladder motility when compared with patients with otherwise symptomatic gallstones without pancreatitis [90]. Such criteria would obviously favor migration of small stones from the gallbladder into the biliary tree. This study also suggested that patients with pancreatitis had a higher concentration of mucin in their bile than patients with gallstones causing other symptoms. Higher mucin levels appear to correlate with the number of gallstones, suggesting that mucin encourages stone formation. A further study also showed a correlation with the diameter of the cystic duct, again in keeping with the passage of stones from the gallbladder into the biliary tree [91]. In a study of 528 patients with gallstones, those presenting with pancreatitis had smaller stones ($3 \pm 1$ mm) than those with obstructive jaundice ($4 \pm 1$ mm), acute cholecystitis ($8 \pm 1$ mm), or asymptomatic stones ($9 \pm 1$ mm; $P = 0.01$) [92].

In most series, gallstones account for approximately 60% of cases of acute pancreatitis [87,88,93,94]. Detailed studies of patients with "idiopathic" acute pancreatitis, however, suggest that a high proportion of these cases are due to microlithiasis, which may be detected by endoluminal ultrasound if performed early enough after the onset of disease. Such studies suggest that up to 80% of "idiopathic" cases are actually due to gallstones [64,95–99] (Fig. 14.4).

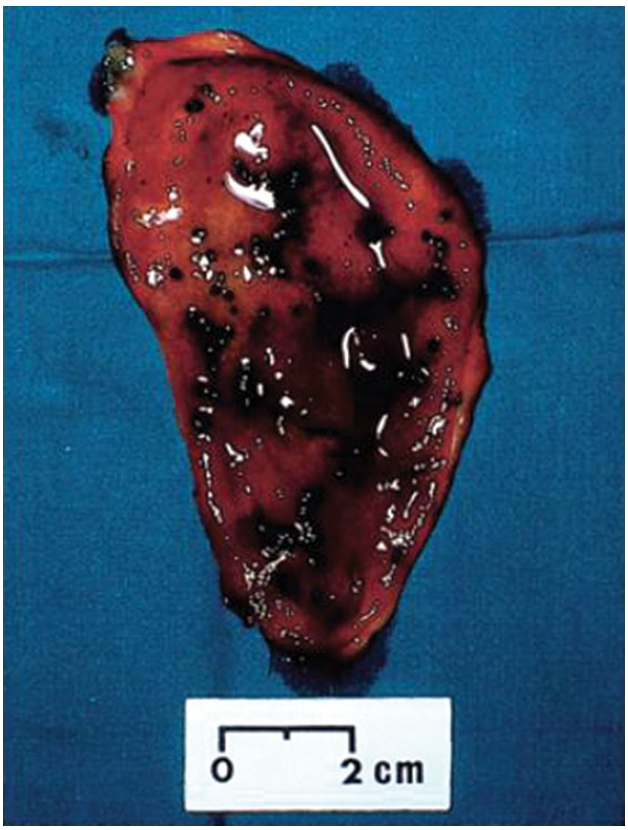

**Figure 14.4** A gallbladder specimen containing microlithiasis that had been missed by all investigations, including bile crystal analysis and endoscopic retrograde cholangiopancreatography.

## Confirmation of Gallstones as the Cause of Pancreatitis

It is important to confirm the presence of gallstones in acute pancreatitis in three distinct clinical settings:

1) during the acute phase in a patient with prognostically severe pancreatitis in whom early ERCP and sphincterotomy may be of therapeutic benefit;
2) in the convalescent phase, to identify patients in whom laparoscopic cholecystectomy and/or endoscopic sphincterotomy (ES) will prevent further attacks;
3) in the identification of patients with microlithiasis or cholesterolosis who may have previously been deemed "idiopathic" but who may also benefit from cholecystectomy.

Although transabdominal ultrasound is the investigation of choice for gallbladder stones, with an overall accuracy in excess of 95%, in the setting of acute pancreatitis it is much less accurate, detecting stones in only 70–80% of cases [100,101]. It is even less satisfactory in the detection of main bile duct stones, even in the absence of acute pancreatitis, with a sensitivity of 19–55% [102]. Endoluminal ultrasound is much more sensitive for ductal stones, even in acute pancreatitis, with sensitivity and overall accuracy of 93% and 85%, respectively [103]. Endoluminal ultrasound is also useful for the detection of other causes of acute pancreatitis, such as small periampullary tumors or anatomic anomalies. Historically, ERCP has been the gold standard for the detection of main bile duct stones but has now been largely superseded by endoluminal ultrasound, which is becoming much more widely available. When required, subsequent ERCP may be employed for therapeutic purposes, but diagnostic ERCP with its

**Table 14.2** Accuracy of three separate systems in predicting gallstones as the cause of acute pancreatitis.

| Predictive analysis | System 1 (%) | System 2 (%) | System 3 (%) |
|---|---|---|---|
| Correct prediction | 74 | 76 | 71 |
| Sensitivity | 75 | 74 | 62 |
| Specificity | 74 | 78 | 80 |
| Positive predictive value | 79 | 82 | 80 |
| Negative predictive value | 69 | 70 | 62 |

Based on serum values within 48 hours of onset in 391 consecutive patients, of which 220 (56%) were due to gallstones.
System 1: alanine transaminase (ALT)/aspartate transaminase (AST) >60 IU/L.
System 2: one of the following; alkaline phosphatase >225 IU/L, ALT/AST >60 IU/L, bilirubin >40 μmol/L.
System 3: three or more of the following: female, amylase >4000 IU/L, ALT/AST >100 IU/L, alkaline phosphatase >225 IU/L.

associated morbidity and mortality is no longer necessary in many cases [104,105].

It has been proposed that the serum lipase/amylase ratio may be used to differentiate alcoholic and biliary causes of acute pancreatitis, but this has not proved useful in practice [106]. Instead, elevated levels of serum transaminases (alanine transaminase [ALT] or aspartate transaminase [AST]) have proven to be better predictors of gallstones if measured within 48 hours of the onset of the attack. In a comparison of two multifactorial systems with serum AST/ALT alone, the latter proved to be equally accurate in the prediction of gallstones, correctly predicting the etiology in 74% of cases [107] (Table 14.2).

## Clinical Features

Gallstone pancreatitis tends to follow an acute intermittent disease pattern, with individual attacks being clinically very similar to those of other etiologies [86]. Bacteremia and ascending cholangitis are more common in association with gallstones than with other nonobstructive causes, however [108,109].

As well as increased susceptibility to infection, some studies have shown a higher mortality rate among patients with gallstones compared with other causes of pancreatitis [110]. This study showed a mortality rate of 13% among patients with gallstones compared with 3% for alcohol-induced cases. This may partly be explained by the higher average age of the patients in the gallstone group, as 75% of the fatalities were in patients aged over 60, but this study also revealed a generally more severe disease course among patients with gallstones. A separate study [111] showed mortality rates of 5.3% for alcohol-induced pancreatitis, 10% for biliary pancreatitis, and 5.5% for other etiologies. However, these differences were not statistically significant.

## Treatment of Acute Biliary Pancreatitis

ERCP ± ES has been employed in order to relieve biliary obstruction in ABP since 1973. The landmark randomized controlled trial (RCT) performed by Neoptolemos et al. demonstrated early ERCP ± ES in ABP significantly improved patient outcome, and the continuing utility of ERCP in decompressing biliary obstruction is without question, however there is still much controversy regarding the patients who are most likely to benefit from this intervention.

Several RCTs have been conducted to compare conservative management of ABP versus early ERCP ± ES (within 72 hours) and have yielded conflicting results [28,77,112–115]; subsequent meta-analyses have not clarified the situation. The most contemporary Cochrane database systematic review conducted by Tse and Yuan concluded that there was no significant difference between mortality, or local and systemic complications between different intervention groups [116]. The most recent meta-analysis performed by Burstow et al. included 1314 patients (662 conservative management vs. 652 ERCP ± ES) and showed no significant difference in mortality between the two groups, even when subgroup analysis was performed for mild/severe ABP, but did demonstrate a significant reduction in ABP-related complications in the ERCP ± ES group (OR 0.43, 95% confidence interval 0.27–0.68, $P = 0.0001$) [117].

There appears to be clear international consensus on the role of immediate ERCP ± ES in ABP and cholangitis (grade 1A/B evidence, strong agreement) from the American Gastroenterology Association (AGA), American College of Gastroenterologists, British Society of Gastroenterologists (BSG), International Association of Pancreatologists, American Pancreatic Association, and Japanese guideline 2015 [94,118–121]. The BSG also recommend ERCP in ABP of suspected gallstone etiology with predicted or actual severe pancreatitis.

There is mounting evidence to support the theory that it is not necessarily the severity of ABP that should determine the urgency of ERCP intervention, but the duration of the biliary obstruction [28,115] and the most recent Japanese 2015 guidelines reflect this by recommending early ERCP ± ES in ABP in the presence of complications such as cholangitis or when a prolonged passage disorder is suspected (grade 1A evidence, strong agreement) [121].

Further clarity on patient selection for ERCP following ABP requires further data from high-quality RCTs with key focused questions around the main areas of

controversy. The Dutch Pancreatitis Study Group intend to perform such a study, assessing early ERCP ± ES versus conservative management in an assessor-blinded multicenter trial of patients with ABP who are randomized within 24 hours of presentation.

### Timing of Cholecystectomy Following Acute Biliary Pancreatitis

Without treatment of gallstones the risk of recurrent attacks following a single episode of ABP is in the region of 30% [122,123] and the average delay before the second attack in one series was 108 days [124]. Another study has reported an incidence of 8% within 4 weeks of the first attack [125]. Additional complications include cholecystitis, cholangitis, and recurrent biliary colic.

Unfortunately, despite these figures, and both International Association of Pancreatology and national guidelines [94,126,127] supporting cholecystectomy within the same index hospital admission, or the AGA and the BSG suggesting early "interval" surgery (within 2–4 weeks of discharge), long delays before cholecystectomy are still reported. The lack of international consensus has been reflected in the outcomes of several national level audits performed across Europe and the United States. Reports vary, but patients wait on average at least 6 weeks for a cholecystectomy following a mild ABP attack, and in the United Kingdom a recent study highlighted that nearly one-third of patients had not undergone definitive treatment for gallstones at 1 year following pancreatitis attack [128,129].

Delay in definitive surgical treatment in patients who are surgical candidates appears to originate from the perceived risk of complications of cholecystectomy such as conversion to an open procedure or a bile duct injury due to challenging dissection and distorted anatomy from peripancreatic inflammation and edema [129].

The same-admission versus interval cholecystectomy for mild gallstone pancreatitis (PONCHO) trial was published in the *Lancet* in 2015 [130]. This multicenter, parallel-group, assessor-masked, randomized controlled superiority trial is the first RCT to assess same-admission cholecystectomy (recommended by international guidelines) and the more commonly practiced interval cholecystectomy as demonstrated by audit. This study showed that same-admission cholecystectomy significantly reduces the number of gallstone disease-related readmissions compared to interval cholecystectomy. There were minimal complications seen in either group. It is now recommended that all patients admitted with a mild attack of ABP should receive a cholecystectomy during their index admission.

# Genetic Factors in Acute Pancreatitis

*Zachary Zator and Georgios I. Papachristou*

*University of Pittsburgh Medical Center, Pittsburgh, PA, USA*

## Introduction

Acute pancreatitis is a clinical syndrome characterized by injury to the pancreas that invokes an acute inflammatory response, which leads to a range of potential local and systemic complications, typically resolving over time [1]. The premature activation of trypsinogen, or similarly the failure to eliminate active trypsin, is the most important mechanism of pancreatic injury. Not only does trypsin regulate the activity of other digestive enzymes, but it can also cross-activate the immune system directly [2]. This trypsin-mediated process can be influenced by genetic variations; indeed, the 1996 discovery of the gain-of-function mutations in the cationic trypsinogen gene (*PRSS1*) serves as the prototypical example [3]. Following pancreatic injury, an inflammatory response cascade is initiated. Dysregulation or variation of the inflammatory response is likely important in determining severe clinical course and systemic complications.

Several clear examples of the importance of genetic variability in susceptibility and severity of acute pancreatitis have been reported. The prototype susceptibility genes include not only *PRSS1*, but also the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene [4]. Loss-of-function mutations in the pancreatic secretory trypsin inhibitor gene (*SPINK1*) [5] have also been identified as susceptibility factors. The prototype disease-modifier gene is the monocyte chemotactic protein-1 (MCP-1) [6], which demonstrates a promoter variant that significantly increases severity of disease. Multiple genes have been associated with progression to chronic pancreatitis, including variants in chymotrypsin C (*CTRC*), calcium-sensing receptor (*CASR*), and claudin 2 (*CLDN2*). These are addressed more completely in Chapter 47.

More research is needed to understand the complex interactions between additional genetic factors and the immune response, which, in clinical practice, may turn out to be the most important factors. This chapter highlights specific genetic variants, with prototype mutations being emphasized.

## Genetic Susceptibility Factors

Factors that increase the likelihood of pancreatic injury determine susceptibility to acute pancreatitis, especially when genetic and environmental risk factors overlap in the same patient [7]. The pancreas is divided into different anatomic and functional compartments that are predisposed to different types of injury [2]. Certain genetic factors are directly linked to the proper function of either the acinar cell or duct cell compartments, and it is useful to understand them in context of these compartments (Table 15.1).

### Acinar Cell-Associated Susceptibility Factors

Calcium dysregulation appears to be the pathway for triggering acute pancreatitis in acinar cells [8]. Intracellular hypercalcemia can lead to damage in any cell, but it is especially dangerous within acinar cells because of the high concentrations of trypsinogen [9,10]. When calcium occupies the calcium-binding domains of the trypsinogen molecule it results in both trypsinogen activation and prevents its degradation. Therefore, any factors that increase the entry of calcium into the acinar cell, increase calcium release from intracellular stores, disrupt calcium reuptake, or diminish calcium removal from the acinar cell enhance susceptibility to acute pancreatitis.

**Table 15.1** Genetic factors involved in the pathogenesis of acute pancreatitis.

| | |
|---|---|
| **Susceptibility factors** | |
| Acinar cell-associated | *PRSS1* mutations (R122H, N29I, A16V, R122C) |
| | *SPINK1* polymorphisms (N34S, P55S) |
| | *CLDN2* |
| Duct-associated | *CFTR* mutations ($CFTR^{sev}$/$CFTR^{m-v}$) |
| | Bicarbonate conductance: R74Q, R75Q, R117H, R170H, L967S, L997F, D1152H, S1235R, and D1270N |
| | Calcium homeostasis mutations |
| | *CASR* |
| | *CTRC* (G60G, R254W) |
| **Modifying factors** | |
| Proinflammatory cytokines | MCP-1 polymorphisms (−2518G allele) |
| | TNF-α polymorphisms (−1031C and −863A alleles) |
| | IL-8 polymorphisms (−251A allele) |
| Other | GST polymorphisms (*GSTT-1*A*) |
| | HSP70 |

Any genetic alteration that affects the calcium-dependent regulatory domains of the trypsinogen molecule can potentially increase the risk of unregulated pancreatic injury.

Although both environmental and metabolic risk factors can increase susceptibility to acute pancreatitis through an acinar cell-associated mechanism, the presence of any of these risk factors alone does not necessarily trigger acute disease [8]. Indeed, most people who are exposed to pancreatitis-associated extrinsic risk factors, such as excessive alcohol consumption, will never develop acute pancreatitis [11]. This observation applies to individuals with significant genetic risk as well [12,13]. Thus, the convergence of several risk factors is required to develop an episode of acute pancreatitis [7]. The risk of acute pancreatitis is dependent on the balance between environmental/metabolic stressors and the strength of protective counter-mechanisms, which are linked to genetic variations of their translated products [2,7]. Thus, the magnitude of an extrinsic stressor that is required to trigger acute pancreatitis appears to be reduced in proportion to the effect of genetic polymorphisms related to the mechanisms protecting the pancreas from injury. The prototype acinar cell susceptibility gene is the one that codes for cationic trypsinogen, *PRSS1*.

### Cationic Trypsinogen: *PRSS1*

Hereditary pancreatitis is characterized by acute recurrent or chronic pancreatic injury, typically inherited in an autosomal dominant pattern and most commonly attributed to mutations in the gene (serine protease 1, *PRSS1*) coding for cationic trypsinogen. PRSS1 is a prototypic serine protease with two globular domains connected by a single side-chain. Pancreatic acinar cells synthesize trypsinogen, which is activated to trypsin on cleavage of a short exposed peptide chain called trypsinogen activation peptide (TAP). Enterokinase or a second trypsin molecule can cleave TAP, allowing for the transformation of trypsinogen to active trypsin. Trypsin then activates most of the inactive pancreatic digestive enzymes in the duodenum. Trypsin can also inactivate trypsin by attacking the arginine residue coded by codon 122 (R122) in the side-chain. Trypsin has two calcium-binding domains, one at the activation site and one at the autolysis site, and nearly all the mutations associated with hereditary pancreatitis affect one of these two calcium-regulated sites.

The cationic trypsinogen gene, *PRSS1*, was the first pancreatitis susceptibility gene to be discovered, and mutations within *PRSS1* are associated with hereditary pancreatitis. This rare autosomal dominant disorder has a high but variable disease penetrance (~80% by age 20 years). It usually presents in childhood at a median age of 10 years with recurrent episodes of acute pancreatitis [12–14]. After these repeated episodes of acute pancreatitis, about half of these patients progress to some degree of chronic pancreatitis [13,15]. Furthermore, approximately 40% of patients with chronic pancreatitis develop pancreatic cancer [13,16]. The R122H and N291 mutations are the most common pancreatitis-associated mutations in *PRSS1* [2,3,17].

The first *PRSS1* mutation to be identified was the arginine-(R)-(CGC) → histidine-(H)-(CAG) substitution in codon 122 (R122H) [18]. Arginine 122 is the initial site of hydrolysis of trypsin by trypsin itself. In the case of the *PRSS1* mutation, the arginine to histidine substitution renders trypsin resistant to fail-safe autolysis. As a consequence, trypsin activation can lead to prolonged trypsin survival inside the acinar cells, which in turn can result in acute pancreatitis. Interestingly, a 2009 Korean study found that 40% of patients with hereditary pancreatitis (and zero controls) carried the R122H mutation, but there were no other variants reported in this population with hereditary pancreatitis [19].

More than 20 *PRSS1* mutations have been discovered, such as A16V and N291 in Caucasians and the D162D variant in Chinese populations [20]. Most are gain-of-function mutations that cause either premature/excessive trypsin activation or failure of autolysis. Despite

sharing a common genetic mutation, family members may exhibit clinical symptoms and complications that range across a broad spectrum. This wide variation in phenotype and incomplete penetrance suggests that additional modifying environmental and/or genetic factors are involved in the pathogenesis of hereditary pancreatitis [21,22].

#### Serine Protease Inhibitor Kazal Type 1: *SPINK1*

The pancreatic secretory trypsin inhibitor (PSTI) directly inhibits the premature activation of trypsinogen. It is encoded by the serine protease inhibitor Kazal type 1 (*SPINK1*) and expressed in acinar cells during acute inflammation. SPINK1 is a 56-amino-acid acute-phase protein that directly blocks the active catalytic site of trypsin. The proportion of SPINK protein to its RNA has been shown to range from less than 1:1000 in the normal pancreas to at least 6:1 in the inflamed pancreas [22]. This indicates that *SPINK1* expression is rapidly increased *after* pancreatic injury, and therefore likely plays a role in limiting the extent and duration of an attack by inhibiting trypsin. These findings also fit with the observation that the pattern of SPINK1 in the blood after surgery or severe inflammation is that of an acute-phase reactant [23,24].

Although several mutations have been identified in the *SPINK1* gene, the N34S haplotype is the most prevalent throughout the world and is found in 1–3% of the general population [25]. *SPINK1* gene mutations are found in 25–50% of cases of idiopathic chronic pancreatitis in children [26,27] and tropical chronic pancreatitis [28–31]. However, these mutations are only found in a few percent above controls in sporadic acute pancreatitis [32]. It follows that *SPINKI* mutations alone are not sufficient to cause acute pancreatitis. This matches the observation that those with a high-risk *SPINK1* haplotype actually have a low risk of developing pancreatitis (<1%) [25,27].

Among those who develop pancreatic disease associated with *SPINK1* mutations, the phenotype is widely variable [33]. The risk and severity of pancreatitis appears to be similar between subjects with heterozygous, homozygous, or compound heterozygous genotypes, suggesting that the genetics underlying the disease state is complex [27] and likely related to other susceptibility factors. This observation matches the notion that *SPINK1* is only necessary when there is excessive trypsin activation upstream. Although the *SPINK1* N34S haplotype has been proposed to enhance susceptibility to acute pancreatitis, the frequency of the high-risk haplotype is relatively low (7.8% of patients and 2.6% of controls) [32]. Furthermore, *SPINKI* mutations increase susceptibility to recurrent acute [34] and chronic pancreatitis both as an autosomal recessive disorder and as part of non-Mendelian complex traits [7], but do not appear to be a major risk factor for sentinel acute pancreatitis.

### Duct-Associated Susceptibility Factors

Acute pancreatitis can originate from delayed or blocked drainage of the pancreatic duct. This is illustrated most clearly by gallstone pancreatitis, which is the most common cause of acute pancreatitis in adults [35,36]. However, there are additional important duct-associated factors that can contribute to the development of acute pancreatitis.

The acinar cells are connected to the duodenum by the pancreatic duct system. The pancreas duct lumen has an elevated calcium concentration, but in a state of physiologic homeostasis, premature activation of trypsinogen within the pancreatic duct is prevented by a high pH, the presence of trypsin inhibitors, and the rapid evacuation of activated enzymes from the duct [2].

The pancreatic duct cell differs from many other types of epithelial cells in its expression of a combination of ion channels and transporters. The primary apical (luminal) ion channel of the duct cell is CFTR [37], which is permeable to chloride and, to a lesser degree, bicarbonate [38,39]. The continuous entry of bicarbonate into the duct cell is facilitated by a sodium–bicarbonate cotransporter on its basolateral surface [40]. Simultaneously, minimal chloride permeability on the basolateral surface results in bicarbonate being the dominant diffusible anion within the duct cell. In this setting, a concentration gradient across the apical membrane favors bicarbonate secretion [41]. This ion secretion is dependent on CFTR, so any alterations in CFTR function can potentially limit fluid secretion from the duct. Failure to flush the pancreatic duct is a susceptibility factor for acute pancreatitis, and *CFTR* mutations represent the prototype genetic defect.

#### Cystic Fibrosis Transmembrane Conductance Regulator: CFTR

CFTR is an anion channel present in the plasma membranes of epithelial cells in multiple organs (i.e., lungs, small bowel, and pancreas) [42], and mutations in the gene encoding CFTR can cause pancreatitis, even in the absence of phenotypic cystic fibrosis. Pancreatic acinar cells secrete a protein-rich fluid, which is diluted and alkalinized by the duct epithelium as it flows through the pancreatic duct. This is accomplished by CFTR-mediated bicarbonate excretion [43]. Brisk bicarbonate secretion is critical for maintaining a high pH so that trypsin remains inactive [44]. This secretion must also rapidly and efficiently flush digestive enzymes out of the pancreatic duct against any distal resistance. Failure of the duct cells to secrete bicarbonate anions increases susceptibility to

acute pancreatitis [45]. Furthermore, it is suggested that *CFTR* mutations also augment the inflammatory response, predisposing to severe disease [46].

*CFTR* mutations were first identified in 1989, and since then, more than 2000 variants in *CFTR* have been identified. Although the functional role of many of these variants remains unknown, several patterns have emerged to define *CFTR*-associated pancreatitis. For example, severe mutations in both copies of the *CFTR* gene ($CFTR^{sev}/CFTR^{sev}$) result in the complete loss of CFTR function and the classic cystic fibrosis phenotype [42]. As the pancreas is one of the first organs to fail in cystic fibrosis, children affected by cystic fibrosis typically develop pancreatic insufficiency from infancy [43]. Pancreatic histology in cystic fibrosis shows all the features of chronic pancreatitis (i.e., parenchymal fibrosis and atrophy, ectatic pancreatic ducts), as well as scattered ducts that are dilated and obstructed by protein-rich material [7].

Another pattern is that of "atypical" cystic fibrosis in those with incomplete involvement of the classically affected organs, including the pancreas [47]. These patients are often compound heterozygotes, having one $CFTR^{sev}$ allele plus one mild variable CFTR mutation ($CFTR^{m\text{-}v}$), or homozygotes with two mild alleles. $CFTR^{m\text{-}v}$ mutations reduce CFTR function to 10–30% of normal levels [42] and the risk of chronic pancreatitis is increased 40–80 times over that in the general population [43]. An important example, the *CFTR* p.R75Q variant, results in defective bicarbonate secretion with preservation of chloride secretion, increasing the risk for chronic pancreatitis without the classic cystic fibrosis phenotype [48,49]. In addition, the heterozygous *CFTR* mutation confers a moderate risk (3–4 times) of chronic pancreatitis over that of the general population, which is typically heightened by concomitant mutations (*SPINK1*, etc.) [48,50,51].

Finally, there is a group of *CFTR* variants that result in the selective deficiency of bicarbonate conductance through CFTR (CFTRBD). A recent study identified nine variants (CFTR R74Q, R75Q, R117H, R170H, L967S, L997F, D1152H, S1235R, and D1270N) that were associated with an increased risk of recurrent acute pancreatitis and chronic pancreatitis without an increase in lung disease [52].

## Multiple Genetic Defects and Susceptibility

Because of the multiple complementary protective mechanisms that exist at each site of potential pancreatic injury, the risk of developing acute or recurrent acute pancreatitis is quite low. As illustrated above, genetic mutations can disrupt these protective mechanisms or alter key regulatory sites, increasing the risk of pancreatitis when environmental or metabolic insults are present. Indeed, patients with multiple genetic predispositions are at increased risk for pancreatic injury [7], and in a multistep pathologic process, the probability of a late effect is dependent on the presence and severity of more proximal effects [53].

It has been hypothesized that *SPINK1* could, in fact, act as a disease-modifier gene [28,54]. This is supported by the observation that the *SPINK1* N34S haplotype is relatively common, although there is no associated specific phenotype. Furthermore, the severity of disease is similar between patients with homozygous and heterozygous genotypes. A small study of subjects with $CFTR^{sev}/CFTR^{m\text{-}v}$ genotypes, a subgroup of whom also had *SPINK1* mutations [55], led to the hypothesis that defects in these gene products may act synergistically to increase the risk of pancreatitis. A subsequent study confirmed that a subset of patients with idiopathic pancreatitis and abnormal *CFTR* genotypes had an excess of *SPINK1* mutations [56]. Pancreatitis risk is increased 10-fold in individuals with a *SPINK1* mutation, 40-fold in individuals with *CFTR* compound heterozygosity, and 500-fold in individuals who have both [43].

Patients with an isolated mutation in the calcium-sensing receptor gene (*CASR*), manifested as hypocalciuric hypercalcemia, tend to have elevated serum calcium levels, which represent a risk factor for acute pancreatitis. It has been observed that those patients with both *CASR* and *SPINK1* mutations develop chronic pancreatitis [57], likely a consequence of recurrent acute pancreatitis [2]. Thus, the combination of genetic defects affecting serum calcium levels (*CASR*) and trypsin inhibition (*SPINK1*) leads to subclinical recurrent acute and chronic pancreatitis.

The above findings support the concept that pancreatitis can be a complex genetic disorder. In addition, mutations in immune-modulating genes appear to modify the severity and complications of acute pancreatitis.

### Genetic Modifying Factors

The intensity of the inflammatory response rather than the degree of pancreatic injury seems to determine the severity of acute pancreatitis, as those with seemingly mild pancreatic injury sometimes develop severe acute pancreatitis, whereas other subjects with profound pancreatic injury might have a relatively mild course [58]. Thus, there appear to be other factors determining the extent of the immune response after initial pancreatic injury.

### Cytokine Polymorphisms

Alteration in the expression of regulatory cytokines/chemokines through genetic variations can affect the inflammatory response to pancreatic injury. A clear example of this is seen with MCP-1, a key chemokine in the regulation of inflammation, which is released by mononuclear cells to attract additional monocytes, lymphocytes, mast cells, and eosinophils. A single-nucleotide polymorphism in the distal regulatory region of the MCP-1 gene (G → A) at position −2518 results in a significantly greater MCP-1 response to inflammatory stimuli than the wild-type sequence [59].

In preliminary studies, the *MCP-1* – 2518A/G polymorphism predicted that the physiologic response to pancreatitis would be severe and associated with death [6]. Among 77 prospectively studied subjects with pancreatitis and 116 controls, the G allele was present in 87% of patients with severe pancreatitis, 45% of those with mild pancreatitis, and 43 % of controls. The presence of the G allele significantly increased the risk of severe acute pancreatitis from any cause about sevenfold (~40%), whereas subjects with an AA genotype had a low risk of severe acute pancreatitis (~5%). Supporting these findings, a group from Italy recently found that among patients with acute pancreatitis, recurrent acute pancreatitis, chronic pancreatitis, and controls, those with evidence of pancreatic inflammatory disease had significantly higher serum MCP-1 levels [60].

The acute inflammatory response is a highly regulated process, with proinflammatory and anti-inflammatory factors interacting in sequential and coordinated ways. Indeed, a number of cytokines that regulate the local inflammatory response in acute pancreatitis have been studied, including tumor necrosis factor α (TNF-α), interleukin 1 (IL-1), IL-8, and IL-10 [61]. TNF-α, the earliest cytokine to be released, is a principal mediator of immune responses to endotoxin. Multiple groups have evaluated the association between pancreatitis and the −308G > A and −238G > A polymorphisms in the TNF-α gene, finding variable associations between these mutations and disease severity [62–67]. A recent meta-analysis [68] found that neither susceptibility nor severity of pancreatitis was altered by the presence of these TNF-α polymorphisms, but more research in individual populations is needed. A subsequent study reported that TNF-α promoter variants do not alter susceptibility to acute pancreatitis, but rather the TNF-α expression-enhancing −1031C and −863A alleles significantly increase the risk of progression to multisystem organ failure [69].

IL-8 is a proinflammatory chemokine produced by macrophages and other cells, which attracts neutrophils to the site of inflammation. Polymorphisms in the gene encoding IL-8 appear to be associated with a more severe course of acute pancreatitis [70]. A recent meta-analysis [71] with a total of 1220 patients with acute pancreatitis and 1351 controls examined the relationship between interleukin gene polymorphisms and acute pancreatitis. It showed that there was a significant association between the IL-8 – 251 T/A (rs4073) polymorphism and an increased risk for developing acute pancreatitis.

## Progression to Chronic Pancreatitis

Chymotrypsinogen C is a calcium-dependent serine protease that autodigests trypsinogen in a protective manner. It follows that loss-of-function mutations in the *CTRC* gene can disrupt this mechanism and lead to pancreatic injury [72–75]. Groups from Asia and Europe have identified rare *CTRC* variants, such as R254W and K246_R25del, that are associated with chronic pancreatitis, but the specific associations have been difficult to replicate [72,76–78]. These rare variants exist in the North American population, but at a lower frequency than elsewhere. Although they are strongly associated with chronic pancreatitis, the variant G60G (c.180 T) is not associated with recurrent acute pancreatitis, suggesting that *CTRC* modifies the risk of progression to chronic pancreatitis but is not a susceptibility gene for acute pancreatitis [79].

Claudin 2 is a highly regulated tight junction protein forming cation-selective ion and water channels between endothelial cells, normally expressed between pancreatic acinar and islet cells. The high-risk claudin 2 locus, located on the X-chromosome with variant rs12688220, acts as a disease modifier and is associated more with chronic than with recurrent acute pancreatitis. It is also strongly associated specifically with alcoholic chronic pancreatitis [80–82].

## Future Directions

With our expanding knowledge of the genetics of acute pancreatitis, a system is required to integrate all this information and to determine strategies for rapid identification of patients at risk of severe acute pancreatitis. New, patient-specific strategies must be developed so that this knowledge can be applied in a way that minimizes morbidity and mortality from severe acute pancreatitis.

# The Role of the Intestine and Mesenteric Lymph in the Development of Systemic Inflammation and MODS in Severe Acute Pancreatitis

*Alistair B.J. Escott[1], Anthony R.J. Phillips[2], and John A. Windsor[1]*

[1] *Department of Surgery, University of Auckland, Auckland, New Zealand*
[2] *Applied Surgery and Metabolism Laboratory, School of Biological Sciences and Department of Surgery, University of Auckland, Auckland, New Zealand*

## Introduction

Acute pancreatitis is a protean disease of unpredictable course [1]. Its severity and outcome are primarily determined by local and systemic factors, such as the presence of infected (peri)pancreatic necrosis (e.g., "acute necrotic collections" and/or "walled off necrosis") and persistent end-organ dysfunction (e.g., cardiovascular, pulmonary and/or renal failure) [2]. The pattern of this organ dysfunction is broadly similar across many different severe diseases, suggesting common drivers for the multiple organ dysfunction syndrome (MODS) [3]. This pattern appears valid for acute pancreatitis [4,5].

The aim of this chapter is to review the evolving understanding of the intestine's role in the development of MODS, to look at the evidence for the gut–lymph concept in promoting MODS in acute pancreatitis, and to discuss the potential to translate this to clinical treatment.

## Role of the Intestine and Mesenteric Lymph in Multiple Organ Dysfunction Syndrome

The concept that the intestine drives critical illness was developed in the 1960s when bacterial endotoxin was demonstrated in the systemic circulation of patients with infective and noninfective severe diseases [6]. This gave rise to the bacterial translocation hypothesis, where gut organisms were thought to cross the intestinal barrier to create a "septic-like state" [7]. In the 1980s the "gut motor" hypothesis expanded this concept to acknowledge the contribution of changes in the intestinal flora and the increased permeability of the gut barrier, postulating that bacterial pathogens and endotoxins enter the systemic circulation from the portal venous system [8]. This was largely discredited when it was not possible to prospectively demonstrate bacteria in the portal vein or systemic circulation in patients with major trauma [9]. A further concept was advanced where neutrophil priming occurred in the mesenteric circulation and that this contributed to both local gut injury and distant organ injury [10–12]. This was the basis of the second-hit hypothesis, which implicates the intestine but does not rely on a direct bacterial role.

Using experimental models of hemorrhagic shock and trauma Deitch and colleagues introduced the concept that mesenteric lymph could cause distant organ failure. They suggested that primed neutrophils and other intestine-derived toxic factors were the mediators of MODS, and that this occurred in association with increased gut permeability but independent of bacterial translocation [13]. Deitch went on to demonstrate that these intestine-derived factors were transported by thoracic duct lymph to reach the systemic circulation to promote systemic inflammation and organ dysfunction [13,14]. He termed this the "gut–lymph hypothesis" [15]. Lung injury mediated by hemorrhagic shock-conditioned mesenteric lymph was key to validating this concept in the experimental setting. Ligation of the mesenteric lymph duct before hemorrhagic shock prevented lung injury in a rodent model, whereas division after shock but prior to resuscitation partially prevented lung injury [16]. It was found that mesenteric lymph from these rats was cytotoxic to endothelial cells and increased permeability to both a monolayer of endothelial cells and lung tissue, whereas portal vein plasma did not [16,17]. The early failure of lung function [3–5] has also been demonstrated in experimental models of burns [18], shock [19], and sepsis

[20] and acute pancreatitis [21]. Furthermore, ligation of the mesenteric or thoracic duct ligation in these different models has been shown to prevent neutrophil priming [22], reduce red blood cell deformity [23,24], reduce cardiac dysfunction [25–27], protect against renal injury [28], and increase adenosine triphosphate (ATP) and ATPase renal activity [29].

The gut–lymph concept is best understood in relation to the anatomy of the mesenteric/thoracic lymphatics [30]. Mesenteric lymph drains from the intestine and mesentery to the cisterna chyli and then ascends through the mediastinum in the thoracic duct. Almost 75% of thoracic duct lymph arises from the abdomen and pelvis [31]. The thoracic duct lymph drains into the internal jugular or subclavian veins on the left side of the neck, immediately upstream of the heart, lungs, and kidneys, the organs most often involved in MODS. It is noteworthy that this lymph does not enter the portal venous system and it bypasses the liver and its detoxification processes (Fig. 16.1).

## Role of the Intestine in Severe Acute Pancreatitis

Although there has been interest in how intestinal injury contributes to the severity of acute pancreatitis for more than two decades, the gut–lymph concept has only recently been considered of potential relevance [32]. The mechanism of injury to the intestine in acute pancreatitis is multifactorial. Splanchnic vasoconstriction is a key mechanism (Fig. 16.1), and is the reflex response to hypovolemia; this can be profound in severe acute pancreatitis with substantial retroperitoneal third space fluid loss. The microanatomy of the intestinal mucosa makes it particularly prone to ischemic injury. The villous tip readily becomes ischemic due to the countercurrent flow of oxygen via the rich capillary network between the parallel artery and vein [33]. This is further compounded with fluid resuscitation because the intestine is the last organ to be reperfused and is subject to ischemia–reperfusion injury. This ischemic injury can be compounded by the use of nonselective inotropes in persistently hypotensive patients. Intestinal ischemia is related to the severity of acute pancreatitis [34], and a lower gastric intramucosal pH ($pH_i$) has been noted in patients admitted to intensive care than those who remain on the ward. $pH_i$ is also correlated with the risk of mortality [35,36]. Ischemic injury to the intestine is also known to contribute to the breakdown of protective mucus [37], which is compounded by the action of pancreatic proteases [38,39]. The ischemic environment also induces mucosal atrophy, mitochondrial dysfunction [40], oxidative stress, and cell death. Interestingly the mitochondrial dysfunction witnessed early in acute pancreatitis appears to be selective to the pancreas, lung, and jejunum, with relative sparing of the liver, heart, and kidneys [40].

As with other acute and critical diseases, there is strong evidence for intestinal dysfunction in acute

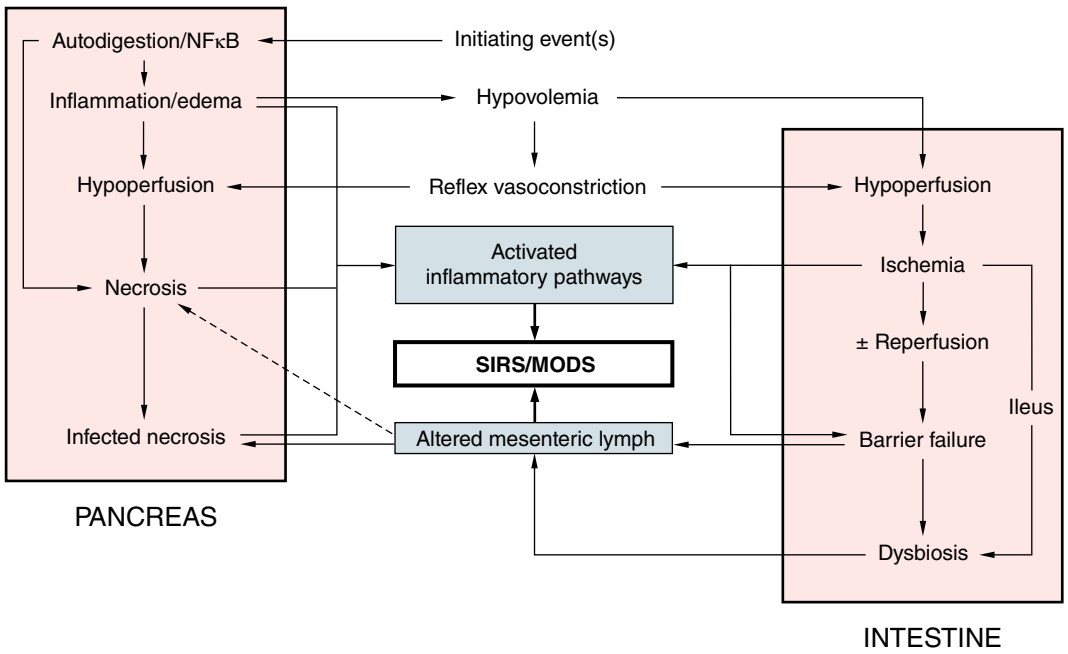

**Figure 16.2** A summary of the complex interactions between the pancreas and the intestine in the development of systemic inflammation (SIRS) and multiple organ dysfunction (MODS) in the pathogenesis of severe acute pancreatitis. *Source:* Adams et al. 2017 [51].

pancreatitis (Fig. 16.2), and it is estimated to occur in 60% of patients [41]. Clinically this dysfunction can be evident as an ileus (dysmotility) [42], feeding intolerance [43], and, at the severe end of the spectrum, nonocclusive intestinal ischemia [44,45]. There is clear clinical evidence that increased intestinal permeability to enterally administered polyethylene glycol is associated with the risk of MODS in acute pancreatitis [46]. Increased urinary intestinal fatty acid-binding protein, a marker of intestinal mucosal injury, has been correlated with the severity of acute pancreatitis [34,47]. The depletion of immunoglobulin G (IgG) anti-endotoxin antibodies, indicative of exposure to endotoxin and "gut barrier failure," is strongly associated with the development of organ failure and death in severe acute pancreatitis [48]. The administration of enteral nutrition, rather than starvation or parenteral nutrition, has been clearly associated with a reduction in infections, complications, and mortality in patients with acute pancreatitis [49], giving rise to the concept of "gut rousing" in seeking to maintain and improve intestine function [50].

## Altered Gut–Lymph Composition in Acute Pancreatitis

There is a significant body of experimental evidence that in critical diseases such as hemorrhagic shock, sepsis, trauma, and burns, mesenteric lymph undergoes significant compositional change [13]. Comparable evidence in acute pancreatitis is only now emerging. A canine model of acute pancreatitis with thoracic duct cannulation demonstrated that a significant proportion of pancreatic amylase and lipase is transported via thoracic duct lymph but not absorbed from the peritoneum from pancreatic ascites [52]. A rodent model of acute pancreatitis revealed a profound change in the proteome of mesenteric lymph [53]. Of the eight proteins exhibiting a significant increase in mesenteric lymph, seven were pancreatic proteases, and the increase was up to 40-fold. Despite this there was no commensurate increase in antiproteases. Lipase generates free and unsaturated fatty acids in mesenteric lymph, which are directly toxic to umbilical vein cells [54]. These exhibit systemic toxicity and are associated with MODS [55]. The lymph profile of noncoding microribonucleic acid (miRNA) is altered in acute pancreatitis, in both experimental and clinical settings [56]. The clinical significance of these changes have yet to be determined, but these molecules can regulate gene expression and influence cell function in remote organs. Interestingly there were seven miRNAs that were increased in intestinal lymph during experimental acute pancreatitis and their log abundance correlated with acute pancreatitis severity [56]. Other groups have demonstrated changes in mesenteric lymph composition in acute pancreatitis. For example, it has been found that the tryptophan metabolites kynurenine and 3-hydroxykynurenine are elevated in rodent mesenteric lymph and plasma during acute pancreatitis and this elevation correlates with disease severity [57].

## Gut–Lymph Toxicity in Acute Pancreatitis

The pathophysiologic significance of the profound compositional changes in mesenteric lymph in acute pancreatitis is still to be elucidated. Some progress has been made by testing the toxicity of the altered mesenteric lymph. In our own studies we have tested toxicity on three levels: organelle (e.g., mitochondrial function [58]), cell (e.g., endothelial and cardiac cell cultures), and whole organ (e.g., isolated perfused heart and lung). Mesenteric lymph from experimental acute pancreatitis incubated with either endothelial cells or cardiac fibres was toxic. In the case of cardiac fibers there was lymph-induced toxicity that induced mitochondrial complex dysfunction [58]. Mesenteric lymph from a rodent model of ischemia–reperfusion injury was intravenously infused into other rats with acute pancreatitis [59], causing an increase in acute pancreatitis severity, augmented microcirculatory collapse, and evidence of lung injury [59]. Experimental acute pancreatitis is associated with a reduction in cardiac output, reduced contractility, and impaired relaxation, which can be replicated by infusion of mesenteric lymph collected from an experimental model of acute pancreatitis and then infused into an isolated and paced heart model. Significantly, this cardiac dysfunction can be prevented by thoracic duct ligation [27] (Fig. 16.3). Experimentally, thoracic duct ligation [21] and lymph diversion [60] have also been shown to ameliorate lung injury in acute pancreatitis. However, thoracic duct ligation might aggravate pancreatic and intestinal injury, possibly because the toxic factors were less able to drain from these tissues. This suggests that the preferred approach to intervention might be external drainage, rather than thoracic duct ligation, because there is no backpressure effect.

## Translating the Gut–Lymph Concept to Clinical Treatments for Acute Pancreatitis

There is a history of open surgical drainage of thoracic duct lymph in a number of clinical diseases, attested to by over 70 publications [61] in the literature, although none since 2004. The reasons for this abeyance is probably a combination of the invasive nature of the thoracic duct cannulation and the predominance of underpowered, nonrandomized, and uncontrolled study designs. Within this seemingly forgotten literature there were four studies [62–65] in which external lymph drainage was used for the treatment of acute pancreatitis. One uncontrolled study of 10 patients reported an improvement in abdominal pain, peritonism, and shock in a "dose-dependent" manner related to the volume of lymph drained [62]. Three of these studies investigated the effect of thoracic duct lymph drainage on pulmonary function in the setting of acute pancreatitis-associated acute respiratory distress syndrome. One study noted that arterial oxygenation improved immediately once drainage was instituted [63]. Another case series demonstrated elevated levels of pancreatic enzymes and cytokines in lymph and plasma but no clinical improvement [65].

The evidence that proteases contribute to lung injury in acute pancreatitis [66] and the evidence that thoracic

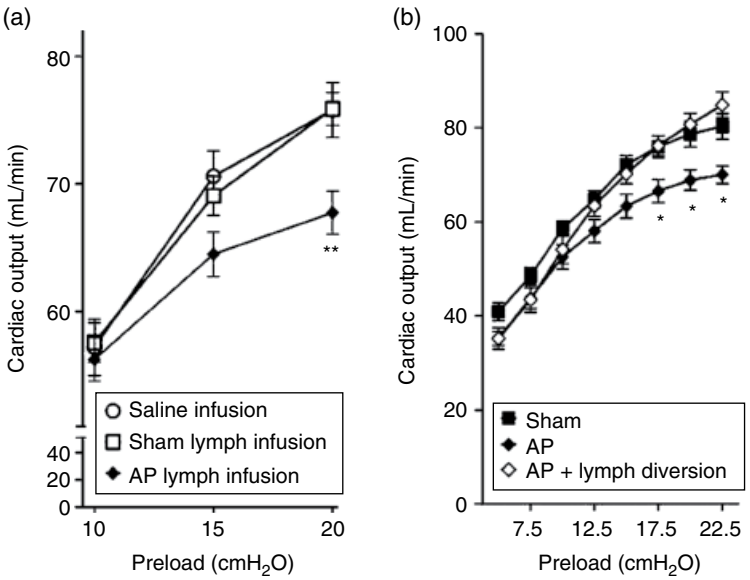

**Figure 16.3** (a) Cardiac output is reduced in *ex vivo* working hearts by acute pancreatitis (AP)-conditioned gut–lymph when compared to saline or sham lymph. (b) Cardiac output is maintained in rats with acute pancreatitis when compared to sham rats or rats with acute pancreatitis in which the thoracic duct is ligated. $^{*}P < 0.05$, $^{**}P < 0.02$.

duct lymph is flooded by pancreatic proteases in acute pancreatitis [53] suggests that external drainage is a treatment strategy that warrants more careful evaluation. A canine model of thoracic duct external drainage has shown that this is effective in reducing plasma amylase and lipase in acute pancreatitis [52].

Another potential treatment strategy, in addition to external drainage of lymph, might be to deliver treatments that target toxic factors in mesenteric lymph. In an experimental rodent model it was demonstrated that inhibition of tryptophan metabolites kynurenine and 3-hydroxykynurenine, which are elevated in mesenteric lymph of rats with acute pancreatitis, is protective against MODS [67]. In another experiment it was found that antiprotease treatment with naramostat significantly reduced endothelial cell death when combined with mesenteric lymph from experimental hemorrhagic shock and acute pancreatitis (Fig. 16.4). This raises the possibility of delivering antiprotease treatment to mesenteric lymph by supplementing enteral nutrition with lipophilic transporters.

The gut lymph concept has been largely derived from experimental studies. Translating this to new approaches to the treatment of severe acute pancreatitis will require a more complete understanding of the role of mesenteric lymph in the pathogenesis of the systemic inflammatory response and organ dysfunction. The major barrier has been the lack of a reliable, safe, and minimally invasive techniques for sampling, monitoring, and draining thoracic duct lymph in patients with severe acute pancreatitis.

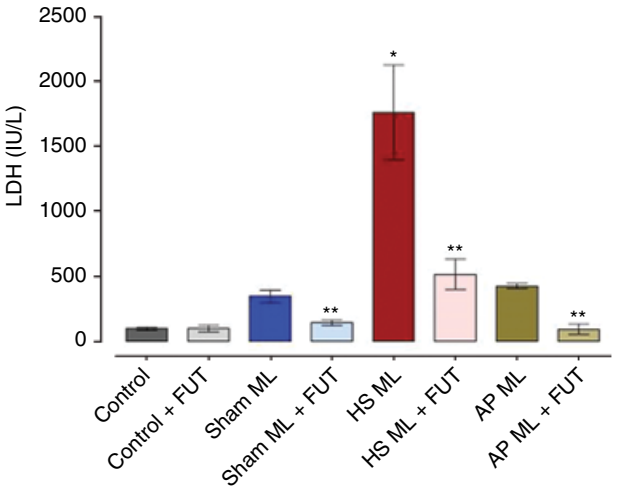

**Figure 16.4** Cell death (LDH level) of endothelial cells (HMEC) was increased on treatment with hemorrhagic shock (HS) or acute pancreatitis-conditioned gut–lymph (ML) when compared to control media or mesenteric lymph (ML) from sham-treated rats (*$P < 0.05$). Cotreatment with the antiprotease nafamostat (FUT) reduced cell death (**$P < 0.05$).

## Conclusion

There is emerging experimental evidence that altered mesenteric lymph contributes to the systemic inflammation and MODS that characterizes severe acute pancreatitis. The "gut–lymph" concept provides a new disease paradigm, a new field of research, and a long-awaited opportunity to develop new and specific treatments for severe acute pancreatitis.

# The Role of Neurogenic Inflammation in Pancreatitis

*Jami L. Saloman[1], Kathryn M. Albers[1,2], and Brian M. Davis[1,2]*

[1] *Department of Neurobiology, University of Pittsburgh, School of Medicine, Pittsburgh, PA, USA*
[2] *Department of Medicine/Gastroenterology, Hepatology, and Nutrition, University of Pittsburgh, School of Medicine, Pittsburgh, PA, USA*

Pancreatitis is a complex inflammatory disease with multiple etiologies that include both genetic and environmental (internal and external) components. Whereas the inciting factors that lead to pancreatic inflammation can be varied, the resulting pathology has a common histologic presentation, including edema, vasodilation, invasion of immune cells, and varying degrees of breakdown in the barriers between different tissue compartments within the pancreas. Recently, a major role has been recognized for the peripheral nervous system as a driver of inflammatory pancreatic responses, such that it is being investigated as a potential therapeutic target. Animal model studies indicate that manipulation of the peripheral nervous system can alter the course of the disease. Specifically, these manipulations have targeted sensory innervation of the pancreas based on studies that go back to the early twentieth century which found that activation of the primary sensory neurons produced vasodilation [1]. The studies by Bayliss [1] were the beginning of the recognition that sensory neurons have an "efferent" function through the peripheral release of small molecules such as substance P (SP), calcitonin gene-related peptide (CGRP), glutamate, cholecystokinin (CCK) and ATP. These molecules can act on blood vessels and immune cells to establish "neurogenic inflammation" [2–7]. Here we review the current state of our understanding of the role of neurogenic inflammation in pancreatitis and how this information might be translated into new treatments for human disease.

The pancreas is innervated by two types of sensory afferents: fibers that run in the vagus nerve and ones arising in spinal sensory ganglia that travel in splanchnic nerves (the greater splanchnic in human, both greater and lesser splanchnic in rodents), traverse the celiac ganglia and then enter the pancreas [8] (Fig. 17.1). The vagus nerve comprises both sensory (about 88% of the fibers in the hepatic branch innervating the rat pancreas) and parasympathetic preganglionic fibers [8]. The parasympathetic preganglionic fibers that travel to the pancreas synapse on parasympathetic postganglionic neurons located in small ganglia throughout the organ. Cell bodies of sensory axons that travel in the vagus nerve are located in the nodose ganglia. These cells transmit information to the nucleus tractus solitarii (NTS). The splanchnic nerves also contain sympathetic preganglionic neurons that form synapses on postganglionic sympathetic neurons within the celiac ganglia that in turn project to the pancreas where their targets include acinar and islet cells and vascular smooth muscle [9].

Sensory afferents that have been most closely identified with neurogenic inflammation are unmyelinated, peptidergic C-fibers that release one or more peptides, primarily SP and CGRP, although a review of the literature indicates that over 20 peptides and small molecules may be released from sensory endings [6]. Unmyelinated, peptidergic afferents that arise from cell bodies located in both nodose and spinal ganglia are the predominant type of fiber that innervates the pancreas [10–14]. Electrophysiological recordings from both nodose and spinal sensory neurons show similar responses to visceral stimulation (e.g., thresholds for firing, pattern of action potential discharge) [15–17]. However, activity in nodose afferents is correlated with affective sensations associated with visceral organ function, whereas the activity in visceral spinal afferents is associated with sensations more typically recognized as pain. A subset of both spinal and vagal afferents can release CGRP and/or

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

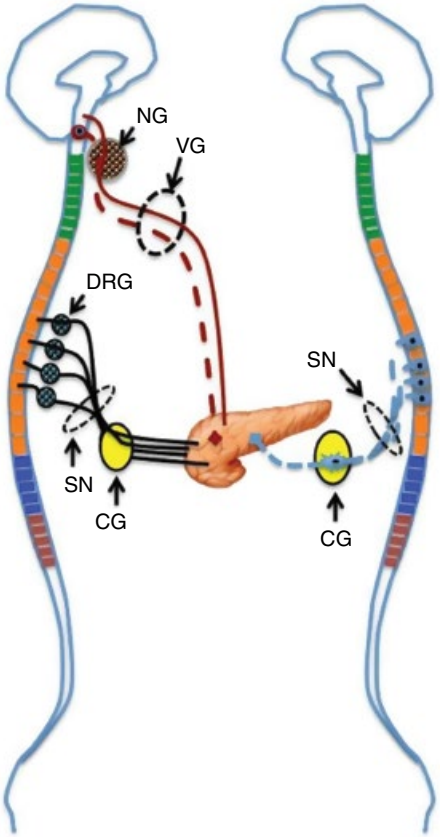

**Figure 17.1** Thoracic and abdominal organs (including the pancreas) receive sensory input from primary afferents whose cells bodies are located in the nodose ganglion (NG; solid red lines) and run in the vagus nerve (VN). Sensory innervation from dorsal root ganglia (DRG; also known as spinal ganglia) to the pancreas travel with sympathetic preganglionic axons (shown on right side of diagram) in the greater splanchnic nerve (SN) and pass through the celiac ganglion (CG). The VN also contains axons from parasympathetic preganglionic neurons (dashed red lines) whose cell bodies are located in the brainstem (in the dorsal motor nucleus of the vagus, not shown). These axons synapse on parasympathetic postganglionic neurons (not shown) that are in the organ wall. Sympathetic innervation arises from sympathetic preganglionic neurons (blue dashed lines on right side of diagram) whose cell bodies are located in the spinal cord intermediolateral cell column (not shown) at T5–9 vertebral levels. Axons from these neurons innervate sympathetic postganglionic neurons in paravertebral ganglia located along side the vertebral column (not shown) or prevertebral ganglia found near the organ. The prevertebral ganglia include the CG, whose neurons innervate pancreas. Anatomy shown for human, but rodents are organized in a similar fashion, varying only in the details.

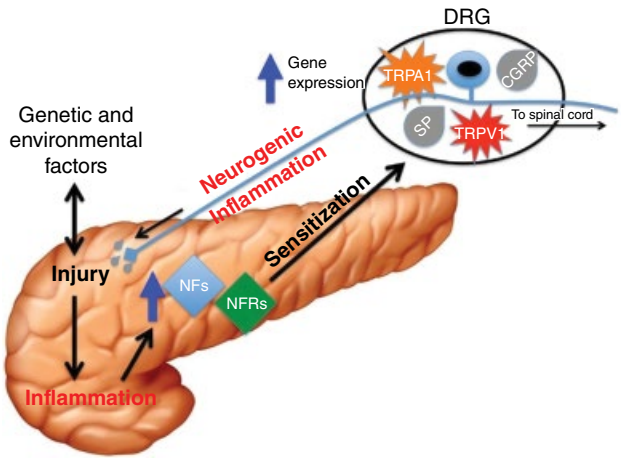

**Figure 17.2** Pancreatic injury, exacerbated or induced by environmental and genetic factors, leads to pancreatic injury and inflammation. This inflammation is accompanied by an increase in neurotrophic factors (NFs, e.g., nerve growth factor and artemin) as well as neurotrophic factor receptors (NFRs, e.g., TrkA). The NFs produce sensitization of sensory fibers innervating the pancreas and this leads to an increase in sensory neuron gene expression for receptors/channels that detect noxious stimuli (e.g., TRPA1 and TRPV1) as well increased production and release of small molecules that produce neurogenic inflammation in the pancreas (e.g., substance P [SP], calcitonin gene-related peptide [CGRP]). This feed-forward loop, if not blocked, can lead to fibrosis and permanent damage associated with chronic pancreatitis, as well as setting the stage for cancer development.

SP (as well as other small molecules) in the pancreas upon stimulation by chemical factors released by the pancreas as well as in response to mechanical stimulation produced by distension of ducts and blood vessels.

The idea that the sensory nervous system, via neurogenic inflammation (Fig. 17.2), plays a role in pancreatitis has led a number of investigators to test this hypothesis by inducing pancreatic inflammation and manipulating pancreatic sensory input, either surgically or chemically. Nathan et al. [3] hypothesized that sensory neurons were a "final common pathway" for neurogenic inflammation associated with pancreatitis. Using two experimental models of pancreatitis (repeated caerulein injections and common pancreaticobiliary duct ligation), they were able to show that sensory denervation (via neonatal capsaicin treatment) dramatically reduced multiple measures of pancreatic inflammation. Subsequent studies expanded on this concept by using pharmacologic approaches to block pancreatic afferent activity. Michalski and coworkers [18,19] demonstrated that cannabinoid receptors were expressed in the pancreas (on both nerves and other cell types) and then used cannabinoid agonists to decrease experimental pancreatitis pain and tissue damage. Schwartz et al. used a similar strategy in animal models of both acute [20] and chronic [21] pancreatitis. In these studies, antagonists for TRPV1 and TRPA1 (two excitatory ionotropic receptors expressed on pancreatic afferents; see later) were shown to be effective in blocking both pain and inflammatory markers, including upregulation of myeloperoxidase and neutrophil infiltration (acute pancreatitis), as well as fibrosis and nerve sprouting (chronic pancreatitis). The question then becomes what are the signals released by

the damaged pancreas that produce abnormal activation of pancreatic afferents?

The majority of pancreatic afferents express receptors on their pancreatic terminals that can induce activation and calcium influx into the presynaptic terminal, which can contribute to the release of inflammatory molecules (Fig. 17.2). The receptor in sensory endings that has received the most attention in recent years is the transient receptor potential cation channel subfamily vanilloid type 1 (TRPV1). This receptor is expressed in 80–90% of neurons that express CGRP and/or SP and is upregulated in pancreatic afferents during pancreatitis [10,22–24]. A significant percentage of these neurons also express a related family member, TRPA1 [20,21]. Both of these channels have been shown to be required for the development of inflammatory pain [25–27]. Moreover, both transient receptor potential channels are themselves upregulated by growth factors that are highly expressed in inflamed pancreata (e.g., nerve growth factor [NGF] and artemin [ARTN]) [28–31]. Whereas these receptors are best known for their response to plant-derived molecules (capsaicin; TRPV1, and mustard oil; TRPA1), endogenous molecules that can activate these receptors are present or increased following pancreatic injury including anandamide (an endogenous cannabinoid), protons, leukotriene B4, hydrogen peroxide, and products of lipid peroxidation such as 4-hydroxynonenal [32–35]. In addition, trypsin released from the injured acinar cells directly activates protease-activated receptor 2 (PAR2) expressed on sensory neurons and this has been shown to sensitize TRPV1 [32,36,37]. Assuming that pancreatic sensory terminals are similar to other visceral nerve endings, they will express a wide range of receptors that allow them to respond in an autocrine/paracrine fashion. These include multiple excitatory ionotropic and metabotropic receptors for nucleotides (e.g. ATP, ADP, adenosine), glutamate, 5-hydroxytryptamine, SP, acetylcholine, and prostaglandins [8,15,16,38,39]. These receptors could respond to molecules released by adjacent sensory fibers as well as to ATP and norepinephrine released from pancreatic sympathetic postganglionic neurons [40,41]. Many of these molecules may act locally on sensory endings to induce release in the absence of action potential generation. However, once an action potential is generated in a sensory fiber, this will trigger release of inflammatory molecules. Once this activity reaches the spinal cord it can rebound via a process known as a dorsal root reflex. This reflex produces a retrograde action potential that travels back out to the periphery and initiates release of inflammatory molecules [6,42–44]. The efficacy of this reflex is exaggerated by spinal cord inflammation, which has been shown to accompany pancreatitis [45,46].

Although nerve-targeted interventions effectively reduce pancreatitis symptoms in preclinical models, in most experimental paradigms these interventions are applied either simultaneously with the disease-inciting stimulus (e.g., caerulein) or early in the disease process. Thus, their relevance for treatment of patients is unclear, especially for acute pancreatitis where the primary symptom of pain is treated medically with nonsteroidal anti-inflammatory drugs and opioids. Clinicians are reluctant to use more aggressive procedures that include injections into splanchnic nerves or celiac ganglia due to occasional adverse affects that can be severe and difficult to justify for a disease that in many cases resolves relatively quickly. However, for chronic pancreatitis, nerve injections are an important option. There are three primary techniques that are utilized to manage intractable pancreatic pain: celiac plexus block (CPB), celiac plexus neurolysis (CPN), and thoracoscopic splanchnic denervation (TSD). Importantly, there is little or no evidence that these treatments affect nonpain disease features (which would be difficult to assess in the absence of large controlled trials). TSD can effectively reduce adrenomedullary function, pain scores, and opioid use in patients with chronic pancreatitis [47,48]. A meta-analysis of 16 studies reveals that TSD significantly reduces pain and improves quality of life. However, the pain returns in half of those initially achieving relief after just 1.5 years [49,50].

The efficacy of silencing sensory neurons for patients with pancreatitis will be worth revisiting in the future with the development of new drugs that have been developed for pain and that act by blocking either sensory nerve function or the inflammatory molecules released by sensory fibers. For examples, clinical trials are now under way for both anti-NGF and anti-CGRP antibodies and drugs [51–55]. These drugs may make it possible to conduct sufficiently powered clinical trails to determine if these types of therapies are both safe and effective for this difficult disease.

## Introduction

Acute pancreatitis is the most frequent cause for hospital admission among all nonmalignant gastrointestinal diseases [1]. It represents an inflammatory disorder of the exocrine pancreas caused, in most cases, by immoderate alcohol consumption or the passage of gallstones. Recent studies involving animal and isolated cell models have elucidated many of the pathophysiologic, cellular, and molecular processes involved in the disease onset. More than 100 years ago it was proposed that pancreatitis is essentially a disease in which the pancreas falls prey to its own, prematurely activated digestive enzymes. Why and how digestive zymogens undergo activation within the pancreas early in the disease process has been the topic of extensive research efforts and debate. Premature activation of pancreatic zymogens results in biochemical and later metabolic alterations, the mechanisms of which will be reviewed in this chapter.

Regardless of the underlying etiology, the natural course of pancreatitis, a primarily sterile inflammatory disorder, proceeds in three steps: (i) a local inflammatory reaction in conjunction with acinar tissue necrosis, (ii) a systemic inflammatory response, and (iii) eventually microbial superinfection of the pancreatic necrosis which frequently results in multiorgan failure and is closely associated with a rise in mortality. Mortality in severe acute pancreatitis peaks at two different time points: patients either pass away during the first 7 days after the onset of pain from an overwhelming inflammatory response syndrome resulting in multiorgan failure (approximately 30%) or they die late in the disease course facilitated by a compensatory anti-inflammatory response syndrome which permits translocation of gut bacteria into pancreatic necrosis, resulting in uncontrollable sepsis. Frequently, however, a mixed picture of a systemic inflammatory response and a compensatory anti-inflammatory reaction, called MARS (mixed anti-inflammatory response syndrome), is observed.

The pathogenesis of the inflammatory response in acute pancreatitis is indistinguishable from that of other traumatic or infectious immune reactions. Thirty per cent of all patients admitted to hospital suffering from acute pancreatitis have organ failure of two systems. Outside the pancreas the most frequently affected organs are the lungs, kidneys, and the gut [2].

## Molecular and Biochemical Abnormalities

### Pathophysiologic Significance of Digestive Protease Activation

Trypsinogen and other pancreatic proteases are synthesized by acinar cells as inactive proenzyme precursors and stored in membrane-confined zymogen granules. After activation in the small intestine, trypsin converts other pancreatic zymogens, such as chymotrypsinogen, pro-elastase, pro-carboxypeptidase, or pro-phospholipase A2, to their active forms [3]. Although small amounts of trypsinogen are probably activated within the pancreatic acinar cell under physiologic conditions, two protective mechanisms normally prevent cell damage from proteolytic activity: (i) Pancreatic secretory trypsin inhibitor (PSTI), the product of the *SPINK1* gene, is co-secreted with pancreatic zymogens. PSTI can inhibit up to 20% of potential trypsin activity in humans

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

[3], but this number may vary considerably among species. The fact that mutations in the *SPINK1* gene are associated with certain forms of human pancreatitis [4–7] indicates that this protective mechanism may play a role in pancreatic pathophysiology. The implications of *SPINK1* overexpression in a disease model of pancreatitis have recently been reported [8]. (ii) Cell biological experiments using living rodent acini provided evidence that trypsin limits its own activity by autodegradation under conditions that mimic pancreatitis [9] (see later). Furthermore, certain mutations associated with human hereditary pancreatitis stabilize cationic trypsin either against autolysis [10–12] or against degradation via chymotrypsin C [13], suggesting that proteolysis of trypsin might play a role in safeguarding the human pancreas against excess intrapancreatic trypsin activity. Although not demonstrated experimentally yet, it is probable that other pancreatic proteases in addition to chymotrypsin might participate in a similar protective mechanism. In humans, mesotrypsin has been labeled a candidate for this function [14,15]. This minor trypsin isoform constitutes less than 5% of total secreted trypsinogens. Interestingly, due to a Gly198 → Arg substitution (Gly193 → Arg in chymotrypsin numbering), this isoform is poorly inhibited by PSTI, which led to the suggestion that mesotrypsin might participate in degradation of other zymogens and proteases [16,17]. However, mesotrypsin is grossly defective not only in inhibitor binding, but also in cleaving protein substrates [18]. A pathophysiologic role of mesotrypsin in intracellular protease degradation and a protective function in pancreatitis is therefore somewhat unlikely.

The presence of another unknown enzyme activity effective in degrading protease zymogens was also observed in human pancreatic juice. This uncharacterized activity was named enzyme Y, and was proposed as one of the protective factors against pancreatitis [19]. It has recently been identified to be identical with chymotrypsin C and was found to play a major role in degrading activated trypsin [13].

Theoretically, premature activation of large amounts of trypsinogen could overwhelm these protective mechanisms, lead to damage of the zymogen-confining membranes and the release of activated proteases into the cytosol. Moreover, the release of large amounts of calcium from zymogen granules into the cytosol might activate calcium-dependent proteases such as calpains, which, in turn, could contribute to cell injury.

The suggestion that prematurely activated digestive enzymes play a central role in the pathogenesis of pancreatitis is based on the following observations: (i) The activities of both pancreatic trypsin and elastase increase early in the course of experimental pancreatitis [20,21]. (ii) The activation peptides of trypsinogen and carboxypeptidase A1 (CPA1), which are cleaved from the respective proenzyme during the process of activation, are released into either the pancreatic tissue or the serum early in the course of acute pancreatitis [2,17,22–25]. (iii) Pretreatment with gabexate mesilate, a serine protease inhibitor, reduces the incidence of endoscopic retrograde cholangiopancreatography (ERCP)-induced pancreatitis [26]. (iv) Serine protease inhibitors reduce injury in experimental pancreatitis [26]. (v) Hereditary pancreatitis is often associated with various mutations in the cationic trypsinogen gene that could either render trypsinogen more prone to premature activation or render active trypsin more resistant to degradation by other proteases [11,13]. (vi) Triplication of the trypsinogen locus in humans (i.e., an assumed gain in the trypsin activity) that is expressed in affected subjects leads to hereditary pancreatitis [27]. (vii) Mutations in the *SPINK1* gene, which might render PSTI less effective, are associated with certain forms of chronic pancreatitis [4–7].

On the cellular level, the initiating role of trypsin has come under debate by the observation that the deletion of trypsin 7, an isoform, largely prevents premature protease activation in a mouse model of pancreatitis but has little effect on the disease course and its severity [28]. Moreover, when cathepsin B-mediated trypsinogen activation is prevented, this appears to affect apoptosis, rather necrosis in the pancreas [29].

In clinical and experimental studies that investigated the time course of pancreatitis it was found that zymogen activation occurs very early in the disease course. One study that employed the caerulein model of acute pancreatitis reported a biphasic pattern of trypsin activity that reached an early peak after 1 hour and a later second peak after several hours [25]. This observation is interesting because it suggests that more than one mechanism may be involved in the activation of pancreatic zymogens and the second peak may require the infiltration of inflammatory cells into the pancreas [25,30,31]. Taken together, these observations represent compelling evidence that premature, intracellular zymogen activation plays a critical role in initiating acute pancreatitis.

## Clinical Evidence for Digestive Protease Activation

A number of recent studies involving patients have greatly contributed to our understanding of the role of zymogen activation in pancreatitis. In patients who underwent ERCP, an interventional medical procedure that requires cannulation of the pancreatic duct and is associated with a significant complication rate for pancreatitis, the prophylactic administration of a small molecular weight protease inhibitor reduced the

incidence of pancreatitis [32]. Although protease inhibitors have not been found to be effective when used therapeutically in patients with clinically established pancreatitis [33], the result of the prophylactic study supports the conclusion that activation of pancreatic proteases is an inherent feature of the disease onset. Moreover, since reasonably specific antibodies have become available that detect the trypsinogen activation peptide (TAP) but do not crossreact with either active trypsin or inactive trypsinogen [34], the presence of TAP in serum and urine of patients with acute pancreatitis provides direct evidence for an activation of trypsinogen during pancreatitis. The amount of TAP released also appears to correlate with the disease severity [35].

## Cathepsin B in Premature Digestive Protease Activation

Several lines of evidence have suggested a possible role for the lysosomal cysteine protease cathepsin B in the premature and intrapancreatic activation of digestive enzymes [35]. The largely circumstantial evidence for this "cathepsin B hypothesis" is based on the following observations: (i) Cathepsin B has been shown to activate trypsinogen *in vitro* [36]. (ii) During the initial phase of acute pancreatitis in several animal models a redistribution of cathepsin B into a zymogen granule-containing subcellular compartment was detected by density gradient centrifugation [37]. (iii) In the same pancreatitis models lysosomal enzymes were detected by immunogold electron microscopy in secretory organelles that also contained digestive enzymes (e.g., trypsinogen) [38]. Experimental approaches to show an essential role of cathepsin B in premature zymogen activation by inhibition of this lysosomal enzyme with synthetic inhibitors rendered contradictory results, either increasing [39] or decreasing premature zymogen activation [40], or failing to improve the course of experimental pancreatitis.

To test the cathepsin B hypothesis more directly and to overcome the shortcomings of lysosomal enzyme inhibitors, which have only limited specificity for cathepsin B, a cathepsin B-deficient mouse strain that was generated by targeted disruption of the *ctsb* gene was studied in experimental pancreatitis [41]. The results of these studies were unequivocal: 90% of intrapancreatic trypsinogen activation during pancreatitis depends on the presence of cathepsin B [41]. What remained puzzling was the observation that acinar cell injury did not decline to the same degree to which trypsinogen was reduced. The explanation for this discrepancy came from recent studies that investigated the cell death mechanisms involved in cathepsin B-mediated trypsinogen activation and found that neither induces necrosis, whereas both appear to be involved in apoptosis, a much less injurious kind of all death in terms of its systemic consequences [29,42]. The relevance for human disease, however, remained another matter.

First attempts to establish the relevance of the cathepsin B–pancreatitis hypothesis in humans focused on the capacity of the lysosomal enzyme to activate human trypsinogen, and specifically varieties of human trypsinogen, into which disease-relevant mutations had been introduced that were identified in the context of hereditary pancreatitis studies. Hereditary pancreatitis, as mentioned above, is a disease that follows an autosomal dominant inheritance pattern, is associated with an early onset of chronic pancreatitis (usually in children and young adults), and is associated with various germline mutations in the cationic trypsinogen gene (*PRSS1*) [43]. When recombinant trypsinogen with hereditary pancreatitis mutations was subjected to activation by cathepsin B *in vitro* it was indeed found that some trypsins behaved differently from their wild-type counterparts [13,44], an observation that clearly supported the cathepsin B hypothesis of pancreatitis. On the other hand, the most common *PRSS1* mutations, such as R122H and N29I, did not convincingly vary from wild-type trypsin in their activation kinetics by cathepsin B [45]. The same study demonstrated further that cathepsin B is abundantly secreted from the human exocrine pancreas, plentiful in pancreatic secretory zymogen granules (rather than in lysosomes), and active within the secretory pathway [45]. Thus, all cellular conditions for the cathepsin B–pancreatitis hypothesis to be operative in humans were met. Moreover, the proposed requirement for a subcellular redistribution of cathepsin B into the secretory compartment [37] could finally be put to rest because most cathepsin B in the pancreas was found to already reside in the secretory compartment under physiologic conditions [45,46], rather than having to be redistributed there from lysosomes. Nevertheless, no direct evidence for an active involvement of cathepsin B in the onset of human pancreatitis—at least not in hereditary pancreatitis caused by the most common trypsin mutations—could be produced from these studies.

This has finally been achieved in a recent study in which a group from India has sequenced the entire coding region of the *ctsb* gene in 140 Indian patients with pancreatitis and 155 controls and reported that *ctsb* germline changes may explain the disease onset [47]. Unfortunately these data could not be confirmed in a Western population with idiopathic pancreatitis [48].

So far it must be remain open whether cathepsin B-induced activation of trypsinogen plays a role in human as much as in experimental pancreatitis. Moreover, whether this mechanism determines disease onset and

severity is also unclear [29,42]. Finally, whether or not other lysosomal cathepsins that can clearly counteract the effects of cathepsin B, such as cathepsin L [49] predominate the events in early human and animal pancreatitis remains the object of ongoing studies.

### Conclusions

Recent advances in cell biological and molecular techniques have permitted investigators to address the intracellular pathophysiology in a much more direct manner than was previously considered possible. Initial studies that have employed these techniques have delivered a number of surprising results that appear to be incompatible with long-standing dogmas and paradigms of pancreatic research. Some of these insights will lead to new and testable hypotheses that will bring us closer to understanding the pathogenesis of pancreatitis. Only progress in elucidating the intracellular and molecular mechanisms involved in the disease onset will permit the development of effective strategies for the prevention and cure of this debilitating and still somewhat enigmatic disease.

## Metabolic and Systemic Abnormalities

In the past, patients with acute pancreatitis have been categorized according to the presence or absence of complications and the definitions of severe disease, and the recently revised Atlanta classification [50] has codified this concept. Complications include systemic organ failures as well as local disease manifestations. Recently, it has been shown that organ failure during the first week of admission is invariably associated with a high mortality rate of >50% [51]. An investigation of 290 patients with predicted severe acute pancreatitis showed that early organ failure was present in 60% of patients. When organ failure was only transient, clinical outcome was good (mortality below 1%), whereas persistent organ failure resulted in a mortality rate of 35% [2]. A better understanding of the pathogenesis of early multiorgan failure might therefore be essential for the development of new strategies for the prevention or treatment of acute pancreatitis.

### Pathogenesis of Pulmonary Failure

Acute respiratory distress syndrome (ARDS), later termed acute lung injury (ALI) is a frequent manifestation of organ dysfunction in an intensive care setting and can be the cause of death in critically ill patients. The exact incidence remains unknown but may be as high as 75 per 100 000 population in the United States [52]. Overall, acute pancreatitis is a condition in which patients rarely develop ARDS (8% of total), but severe attacks are frequently associated with ALI and ARDS [53]. The definition set in 1994 for ALI is a syndrome of inflammation and increased permeability that is associated with a constellation of clinical, radiologic, physiologic abnormalities that cannot be explained by, but may coexist with, left atrial or pulmonary capillary hypertension [54,55]. The distinction between ALI and ARDS is the degree of hypoxemia. The incidence of pulmonary complications in acute pancreatitis varies between 15% and 55% and their severity ranges from mild hypoxemia without clinical or radiologic signs to severe ARDS. The major cause of hypoxemia is ventilation/perfusion mismatch which results in right to left pulmonary shunting. In ARDS the injured lung is believed to go through three phases: exudative, proliferative, and fibrotic, but the course of each phase and the overall disease progression are variable. The pathophysiologic features of the lung in ARDS arise from severe injury to the alveolocapillary unit. The histologic features are dense eosinophilic hyaline membranes and alveolar collapse. The endothelial cells swell, the intercellular junctions widen, and pinocytic vesicles increase, causing capillary leak and edema formation. Approximately 10% of patients with acute pancreatitis show alveolar edema on chest radiographs and a third of patients develop progressive hypoxemia during the first week of hospitalization [56]. The cause for the development of alveolar edema is an increase in microvascular permeability in the context of systemic inflammatory response syndrome (SIRS) [57,58]. This was shown by applying labeled transferrin as an indicator for lung vascular permeability within 48 hours after hospital admission. This was found to be significantly increased in the lung tissue of patients who had later died in the disease process [59]. A similar observation was reported more recently in which an increase in the gallium–transferrin pulmonary leak index strongly correlated with the mortality rate [60].

Lankisch and coworkers determined the incidence of pulmonary infiltrates in 140 consecutive patients with acute pancreatitis with 26% within 24 hours after admission to hospital [61] (Fig. 18.1). The mortality rate of acute pancreatitis significantly correlated with the presence of pulmonary infiltrates and effusions. Logistic regression analysis showed that radiologic abnormalities were associated with a 15-fold increase in mortality rate [62]. A reduced $PaO_2$ on hospital admission has long been regarded as a prognostic factor for the severity of pancreatitis and is part of the Ranson Score, the Imrie Score, and the International Guidelines which recommend to hold peripheral oxygen saturation above 95% to prevent organ failure as a treatment goal [63].

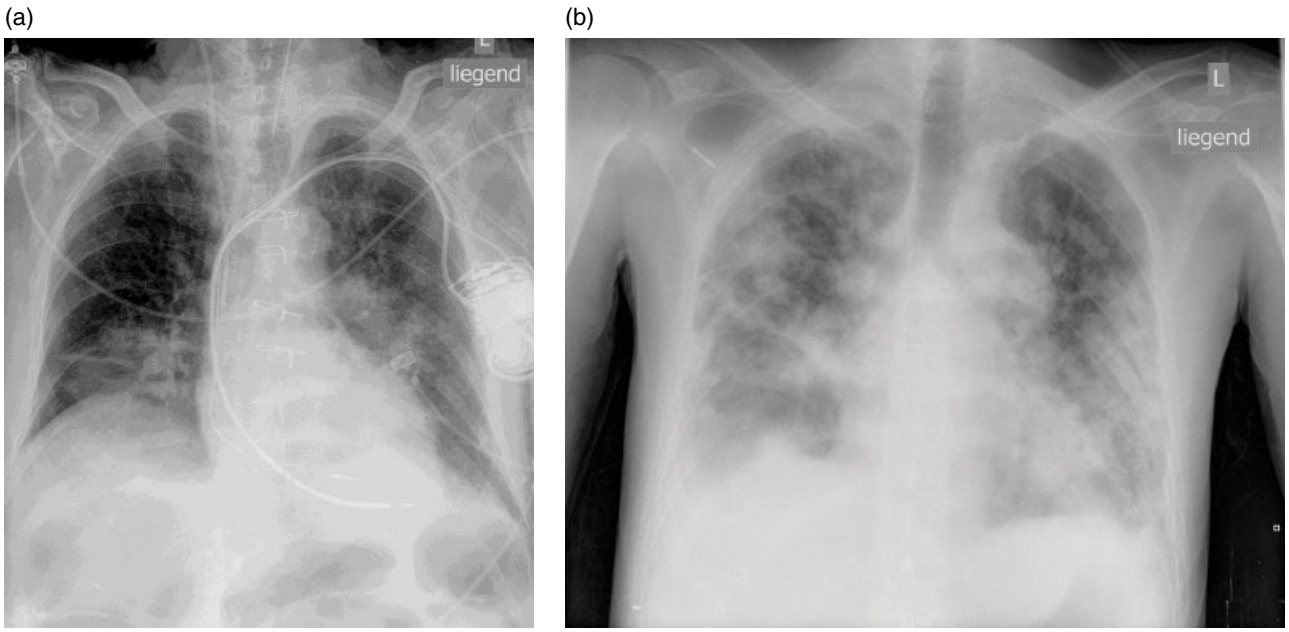

**Figure 18.1** Pulmonary infiltrates in severe acute pancreatitis.

With respect to the pathophysiology of ARDS in acute pancreatitis, two case series showed that massive cytokine release may have a contributing role in SIRS. Interleukin 8 (IL-8) was reported to be significantly higher at admission in patients who later developed acute severe lung injury [64]. In pleural effusions tumor necrosis factor α (TNF-α), IL-1, IL-6, and polymorphnuclear cell elastase (PMN-elastase) were significantly higher in serum in patients with ARDS, which may point to a direct impact of these cytokines on the development of ARDS but could also occur because of a diminished excretion of cytokines into pleural effusions [65]. Futhermore, in patients who later developed ARDS, elevated serum levels of thromboxane and prostacyclin were reported [66].

Phospholipase A2 (PLA-2) has long been regarded as a major cause of ALI in acute pancreatitis. Studying PLA-2 one needs to consider that there are numerous subtypes, of which two—PLA-2 type I and PLA-2 type II—could have a role in the pathogenesis of pancreatitis. Older studies suggested that PLA-2 type II (leukocyte-derived PLA-2) is responsible for the cell necrosis in acute pancreatitis by converting its endogenous substrate lecithin (part of the lipid bilayer of cell membranes) into the more toxic compound lysolecithin [67,68]. Thus PLA-2 could break down pulmonary surfactant, which consists of phospholipids, and could therefore impair oxygenation and increase vascular permeability. This notion was confirmed as elevated circulating plasma levels of PLA-2 correlated with more severe pulmonary changes in patients with gram-negative septic shock [69]. Furthermore, intratracheal application of nonpancreatic PLA-2 induced lung injury with interstitial edema and accumulation of inflammatory cells, but the concept that release of pancreatic PLA-2 from necrotic acinar cells mediates lung injury had to be abandoned [69–71]. In addition to the hypthesis of a direct impact of PLA-2, other pancreatic zymogens and nitric oxide released from pulmonary macrophages have been implicated in contributing to pulmonary complications in acute pancreatitis [72]. An experimental study testing this concept showed that intravenous application of elastase or trypsin resulted not only in pulmonary damage through NFκB activation and TNF-α release with subsequent transmigration of neutrophils, but also in an increase in lung vascular permeability [73–78].

Neutrophils have been implicated in mediating lung injury in acute pancreatitis and inhibition of neutrophil-derived serine proteases such as PMN-elastase seem to be promising treatment targets [30,31]. In an attempt to remove activated pancreatic zymogens to prevent systemic injury, two rather small studies (recruiting 12 and 6 patients) performed thoracic duct drainage. One of the two studies found an improved pulmonary gas exchange and a reduction in time on mechanical ventilation [65], whereas the second study failed to confirm these data [79] and the benefit of this approach is still doubtful.

In conclusion, severe attacks of acute pancreatitis are frequently associated with ALI. Arterial hypoxemia, pulmonary infiltrates, pleural effusions, and ARDS may

develop as complications of the disease. Within the first few days following the onset of severe acute pancreatitis, lung injury develops as a consequence of acute pancreatitis. Sepsis is the predominant cause of lung injury in the later phase of the disease. Besides best supportive care, protective mechanical ventilation, hemodynamic monitoring, as well as enteral nutrition and renal replacement therapy have been considered to be of potential benefit to treat pulmonary complications and have therefore been extensively studied [80–86]. Unfortunately, even if the results from animal experiments were very promising, the results obtained from clinical trials were rather disappointing [87–91]. The pathogenesis of pulmonary injury still remains incompletely understood.

## Pathogenesis of Renal Failure

Acute renal failure (ARF) occurs in 19% of patients with moderate sepsis, 23% with severe sepsis, and 51% with septic shock when blood cultures are positive [92,93]. The cytokine-mediated induction of nitric oxide synthesis that occurs in SIRS and sepsis decreases systemic vascular resistance. This arterial vasodilatation predisposes patients with SIRS to ARF [94]. Patients who develop ARF in the setting of critical illness are more likely to die than dialysis-dependent patients admitted to intensive care, suggesting that the bad outcome associated with the recent development of renal failure is due to SIRS, rather than merely due to renal dysfunction [95]. The clinical syndrome of ARF in the setting of critical illness, manifested by rising serum creatinine and decreasing urine output, results from injury to the tubular epithelial cells or acute tubular necrosis. In necrotizing pancreatitis, renal insufficiency occurs in 21% of patients after a median time period of 8.3 days after the onset of pancreatitis. The extent of pancreatic necrosis correlates with the development of ARF but infection of the pancreatic necrosis is not associated with a higher rate of ARF [96]. ARF has never been studied systematically either in the clinical setting of pancreatitis or in pancreatitic animal studies.

In analogy to the pathogenesis of ARF in critically ill patients with SIRS, a combined pathomechanism of prerenal failure due to extensive fluid loss into the third space, together with a prolonged cytokine-mediated organ failure even after fluid resuscitation can be assumed to be operative. Simmons and coworkers showed that increased plasma proinflammatory cytokine levels (TNF-α, IL-1b, IL-6) predict the mortality in patients with ARF [97] and an anti-TNF-α-directed therapy was found to improve several early events during experimental pancreatitis, including protease activation [98]. This finding is supported by the fact that in animal models infusion of high concentrations of proinflammatory cytokines can lead directly to the development of multiorgan system failure [99,100]. Furthermore, patients with SIRS and associated ARF show signs of intense endothelial damage and hypercoagulability as indicated by increased von Willebrand factor, thrombomodulin, tissue plasminogen activator, plasminogen activator inhibitor-1, and D-dimer activity [101]. Vasoactive mediators appear to be a contributing factor of some importance [102].

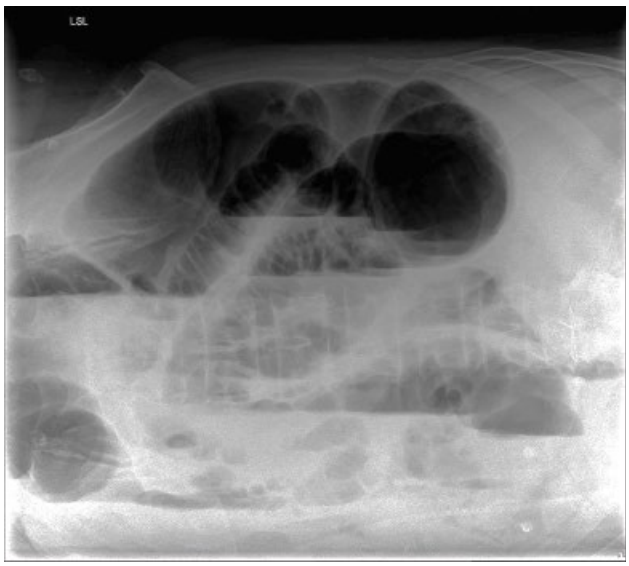
In conclusion, ARF is a frequent extrapancreatic complication of acute pancreatitis, but further studies on the pathogenesis of ARF are urgently needed to treat this potentially fatal complication.

## Pathogenesis of Paralytic Ileus and Gut Permeability

Patients with acute pancreatitis often suffer from severe intestinal motility disturbances which render them prone to bacterial translocation into the pancreatic necrosis due to bacterial overgrowth and increased gut permeability, which is then burdened with an increase in mortality (Fig. 18.2). The mechanisms of impaired intestinal motility are largely unknown [103]. Studies on mice fed a CDE (choline-deficient, ethionine-supplemented) diet revealed that acute necrotizing pancreatitis inhibits gastric emptying and intestinal transit *in vivo*. The global reduction in jejunal contractility is explained by the disruption of the intestinal motor function at the postreceptor level, which plays an important role in the development of an intestinal ileus during acute pancreatitis [104–107]. This notion suggests why conventional pharmacologic gut stimulation (e.g., by parasympathomimetics) in daily clinical routine has a rather disappointing effect. However, clinical trials systematically investigating the impact of parasympathomimetics in acute pancreatitis are currently not available.

Clinical as well as experimental studies have shown that the intestinal tract becomes more permeable for macromolecules during the course of acute pancreatitis and this permeability increase correlates with greater bacterial translocation, greater severity, and an increased rate of infected necrosis [106,107]. The early changes in intestinal permeability have been associated with corresponding levels of systemic endotoxin exposure [107]. The pathogenesis of gut barrier failure can be attributed to local (instestinal) factors, namely mucosal ischemia, disruption of mucosal epithelial integrity, reperfusion injury, disruption of intestinal bacterial ecology, and impaired mucosal immunity. On the cellular level, human and animal studies have attributed these changes to alterations in epithelial tight and adherent junctions,

(a)



(b)

**Figure 18.2** Paralytic ileus in severe acute pancreatitis.

including protein classes such as claudins [108,109], occludins [110], and myosins [111,112], all of which can represent susceptibility factors for pancreatitis per se, as well as for bacterial translocation during pancreatitis. Furthermore, systemic factors, such as impaired systemic immunity, endotoxemia, cytokines and chemokines, malnutrition, and/or parenteral nutrition, have been implicated in impaired gut permeability. Some of the factors affecting gut barrier failure mentioned earlier can be effectively treated with early enteral nutrition or by immune-enhancing nutritional regimens [113,114]. Thoracic epidural analgesia for pain also augments ileal mucosal capillary perfusion and improves survival in severe acute pancreatitis [115].

## Pathogenesis of Coagulopathies

The systemic inflammatory reaction and the development of organ failure in acute pancreatitis share similarities with a complicated course of sepsis, major trauma, or burns [116,117]. As early as 1977 Ranson and coworkers noted abnormalities in coagulation factors during severe acute pancreatitis. They concluded from a prospective analysis of 35 patients in which they correlated amylase levels with respiratory, renal, and hepatic dysfunction that enzyme-related intravascular coagulation is involved in the pathogenesis of these coagulation complications during acute pancreatitis [118]. In systemic inflammation a rapid activation of coagulation may turn into a global or selective exhaustion of physiologic anticoagulant systems.

The interactions between coagulation and inflammatory pathways are essential for the pathogenesis of disseminated intravascular coagulation. For example, the proinflammatory cytokines TNF-α, IL-1, and IL-6 upregulate thrombin formation and downregulate physiologic antithrombotic defense mechanisms, especially the protein C pathway [119]. The protein C pathway is both a major physiologic anticoagulant system and a central link between inflammation and coagulation. The zymogen protein C is converted to activated protein C (APC) by thrombin bound to thrombomodulin on the endothelial surface [120]. This effect is enhanced by the endothelial PC receptor [121]. APC conveys its anticoagulant function mainly by proteolytic inactivation of coagulation-activated factor V and activated factor VIII. APC also exhibits distinct anti-inflammatory and antiapoptotic properties [122]. Although the underlying mechanism is incompletely understood, recombinant APC decreased the levels of IL-6 and D-dimer and reduced mortality in severe sepsis patients. Investigating levels of APC, protein C, and D-dimer in 31 patients with severe acute pancreatitis showed that protein C deficiency and decreased APC generation contributed to a compromised anticoagulant and anti-inflammatory defense, which subsequently aggravated multiorgan failure [123]. Clinical trials evaluating treatment with protein C are warranted in severe acute pancreatitis.

In addition to the therapeutic impact of restoring coagulation in severe acute pancreatitis a recent clinical study has shown that signs of disseminated intravascular coagulation are also of high prognostic value. The aggravated

coagulation parameters predict a fatal outcome in patients with acute pancreatitis. An antithrombin III level <69% was the most accurate marker for poor outcome of acute pancreatitis at admission [124,125]. Experimentally, the substitution of antithrombin III has long been shown to have a beneficial effect on pancreatitis severity [126].

## Electrocardiographic Abnormalities in Acute Pancreatitis

Acute pancreatitis has been reported to be associated with electrocardiographic abnormalities including arrhythmias, bradycardia, T-wave changes, intraventicular conduction disturbances, and ST-segment elevation termed "pseudoinfarction" (Fig. 18.3). The clinical relevance and causes of such electric abnormalities are poorly understood. However, experimental studies performed on a murine model of acute pancreatitis have reported ultrastructural disturbances including interstitial edema and cardiomyocyte hypoxia, myofiber overcontractility, intracellular edema between cardiomyocytes, and cardiomyocyte hypertrophy with collagenization of myocardial stroma [127]. Albrecht and Laws [128] proposed a direct cardiotoxic effect of proteolytic pancreatic enzymes as a cause of ST-segment elevation and myocardium-specific enzyme increase (particularly phosphokinase MB fraction).

Other mechanisms that have been proposed to explain electrocardiographic abnormalities appearing during acute pancreatitis are those associated with metabolic disturbances, hemodynamic instability, vasopressor drug use, pericarditis, myocarditis, exacerbation of underlying cardiac disease, coagulopathy, and coronary artery spasm [128–130].

Patients with acute pancreatitis have a high risk of developing metabolic abnormalities. The consequences of low or high serum electrolyte levels on cardiac electric activity include changes in the T-wave morphology, bundle branch blocks, arrhythmias, QT-internal shortening or prolongation, asystoly, prominent U-wave, ST-segment depression or elevation, and ventricular fibrillation [131–134]. Recently two prospective studies have reported abnormalities on electrocardiogram (ECG) and correlated these changes to the severity of acute pancreatitis. The study by Rubio-Tapia concluded that 55% (28 patients) of patients displayed abnormalities on ECG but most changes are transient and are related to electrolyte

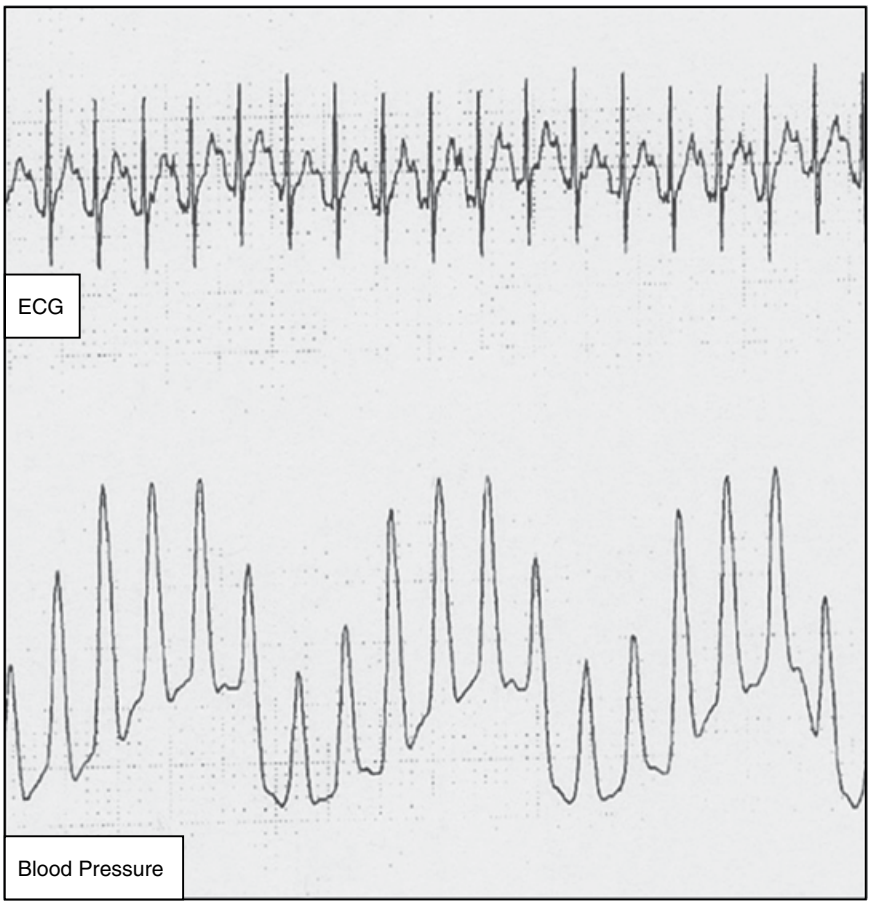


**Figure 18.3** ECG changes in severe hypovolemia and hypokalemia.

alterations [135]. In contrast, the study by Stimac and coworkers investigating 303 patients observed significantly different results for heart rate, PQ interval, and ST elevation when mild pancreatitis was compared to severe pancreatitis. They explained an increase in heart rate and shortened PQ interval as a result of increased sympathetic activity [136].

## The Role of Hypocalcemia and Hypomagnesemia

Hypocalcemia is a frequent finding in patients with severe acute pancreatitis and has been implicated to be of prognostic value by Ranson and Imrie, who included it in their respective severity scores of acute pancreatitis [137–139]. Calcium levels below 2 mmol/L are considered to be a poor prognostic sign. Several pathogenetic mechanisms contribute to the development of hypocalcemia and need to be considered in evaluating hypocalcemia: (i) Serum calcium levels reflect only part of the physiologically active ionized calcium. More than half of the circulating calcium is bound to albumin and serum calcium levels need to be corrected for serum albumin levels. During acute pancreatitis, albumin is lost in the third space and therefore serum calcium levels decrease. When calcium levels are corrected for albumin, the majority of patients display normocalcemia, which explains the absent symptoms of hypocalcemia, such as arrhythmias and tetany [140–142].

(ii) In response to decreased serum calcium levels circulating parathyroid hormone levels (PTH) are increased. This subsequently leads to calcium mobilization from bone, and calcium reabsorption in the kidneys is increased. In a prospective study by McKay PTH levels were determined to be invariably elevated in response to hypocalcemia in acute pancreatitis but significantly increased concentrations were found in patients with a complicated course of the disease [143]. Inadequate mobilization of calcium from bone indicating end-organ failure could offer an alternative explanation for hypocalcemia. This hypothesis was refuted, however, by Robertson et al. [144]. Patients suffering from acute pancreatitis were shown to react with an adequate rise in serum calcium levels and urinary cyclic adenosine monophosphate upon infusion of exogenous PTH. These findings had been previously substantiated by data from animal experiments [144].

Hypomagnesemia, together with hypocalcemia, can inhibit PTH secretion as well as peripheral actions of PTH. Ryzen and Rude determined intracellular magnesium levels in patients with acute pancreatitis. They concluded that patients with acute pancreatitis and hypocalcemia commonly also show intracellular magnesium deficiency despite normal serum magnesium concentrations. Magnesium deficiency could therefore play a significant role in the pathogenesis of hypocalcemia in acute pancreatitis [145]. Magnesium is known to be a cofactor for multiple enzymatic reactions, including zymogen activation *in vitro*. The bivalent cation $Mg^{2+}$ counteracts intracellular calcium signaling and thereby antagonizes the deleterious effects of high and sustained intracellular $Ca^{2+}$ levels on premature zymogen activation [146,147]. In experimental pancreatitis models oral $Mg^{2+}$ given as a food supplement had significant beneficial effects on the course of the disease [148]. Currently two multicenter, multinational, randomized, placebo controlled phase II trials investigating the efficacy of magnesium for either recurrent idiopathic pancreatitis or the prevention of ERCP-induced pancreatitis are being conducted [149].

(iii) The role of increased free fatty acids (FFAs) in the pathogenesis of hypocalcemia in acute pancreatitis has not been clearly elucidated and different pathophysiologic mechanisms have been proposed. Circulating lipase and phospholipase released from necrotic pancreatic acinar cells may cleave triglycerides and thereby lead to elevated serum FFAs. Warshaw et al. determined the effect of FFAs on serum calcium levels in an animal model. Their findings suggested that (i) changes in the concentration of FFA occur spontaneously but may have an impact on calcium levels, (ii) the observed depression of calcium may be due to intravascular sequestration of calcium by FFA-albumin, but increased flux of circulating calcium–FFA complexes into extravascular and intravascular sites may also be important, (iii) the markedly increased FFA concentration in some patients with acute pancreatitis may contribute significantly to hypocalcemia and calcium flux in these patients [150].

Recent experimental work has demonstrated that fatty acid ethyl esters (FAEEs), although less damaging than their parent fatty acids [151], are directly involved in intracellular calcium toxicity via the inositol trisphosphate ($IP_3$) receptors and ATP depletion [152]. As shown for a direct interference with pathologic calcium signaling via magnesium substitution [148,149] this $IP_3$-dependent mechanism offers itself to therapeutic intervention—or at least prevention—by caffeine [153]. This may be the reason why coffee consumption has recently been identified as a protective epidemiologic factor for pancreatitis [154].

To what extent fat necrosis outside the pancreas and the lipolytic generation of unsaturated fatty acids contribute to the onset and severity of pancreatitis is still incompletely understood and a very active research field [155].

In conclusion, hypocalcemia is a frequent finding in severe acute pancreatitis. Hypocalcemias in acute pancreatitis frequently turn out to be normocalcemias if corrected for serum albumin. Experimental studies have proven an important effect of high intracellular calcium concentrations and, more importantly, a beneficial effect of antagonizing calcium with magnesium on premature zymogen activation and the severity of pancreatitis. The clinical benefit of a magnesium substitution still needs to be shown in clinical trials.

# Histopathology of Acute Pancreatitis

*Günter Klöppel*

*Department of Pathology, Consultation Center for Pancreatic and Endocrine Tumors, Technical University Munich, Munich, Germany*

## Introduction

In this chapter, the histopathology of acute pancreatitis is reviewed and the various patterns of tissue damage that have been described so far are related to the known etiologic factors and the discussed pathogenetic mechanisms. Finally, an attempt is made to correlate the histopathologic findings with the clinical and radiologic criteria of the 2012 Atlanta Classification of Acute Pancreatitis [1] that revised the 1992 Atlanta classification [2].

## Definition

Acute pancreatitis is histologically a necroinflammatory tissue reaction to functional and/or structural acinar cell damage and rarely duct cell necrosis, usually caused by noninfectious factors and only rarely by infectious agents [3]. It can be separated into a mild form called acute interstitial edematous pancreatitis affecting 90–95% of patients, and a severe form called acute necrotizing pancreatitis affecting only 5–10% of patients. The mild form of acute pancreatitis is often associated with gallstone disease, whereas the severe form is usually linked to alcoholism.

## Histopathologic Patterns of Tissue Necrosis

Central to the development of acute pancreatitis is the initial damage to exocrine cells of the pancreas. Histologically this damage is recognized as tissue necrosis, which is followed by an inflammatory reaction. The observed patterns of necrosis can be classified into three types (Fig. 19.1). Type 1 shows a necrotic process that initially affects the fatty tissue in the interstitial spaces within the pancreas and in the peripancreatic area; in the second type, necrosis affects the duct epithelium; and in the third type it is the acinar cell that shows necrosis. Whereas the first type is frequent, the second and third types are rare [4].

## Acute Pancreatitis with Type 1 Necrosis Pattern

This necrosis pattern characterizes the type of acute pancreatitis that is most common. The severity of its changes can be correlated to either interstitial acute pancreatitis or necrotizing acute pancreatitis [1] (Table 19.1).

### Initial Phase

In interstitial acute pancreatitis the pancreas shows an edematous swelling, but may also look normal. In addition it displays tiny white disseminated spots of fatty tissue necrosis on its surface and also in the interlobular fatty tissue [5] (Fig. 19.2).

In necrotizing acute pancreatitis there are numerous large and confluent white areas of fat necrosis in the peripancreatic tissue (Fig. 19.3). In addition, the pancreas shows parenchymal necrosis, although it is usually less extensive than the peripancreatic necrosis and seems to depend in its extent on the amount of interlobular fatty tissue present in the individual pancreas. This means that in the pancreas of obese subjects necrosis may be more severe than that seen in normal weight individuals. Where fat necrosis involves blood vessels, especially

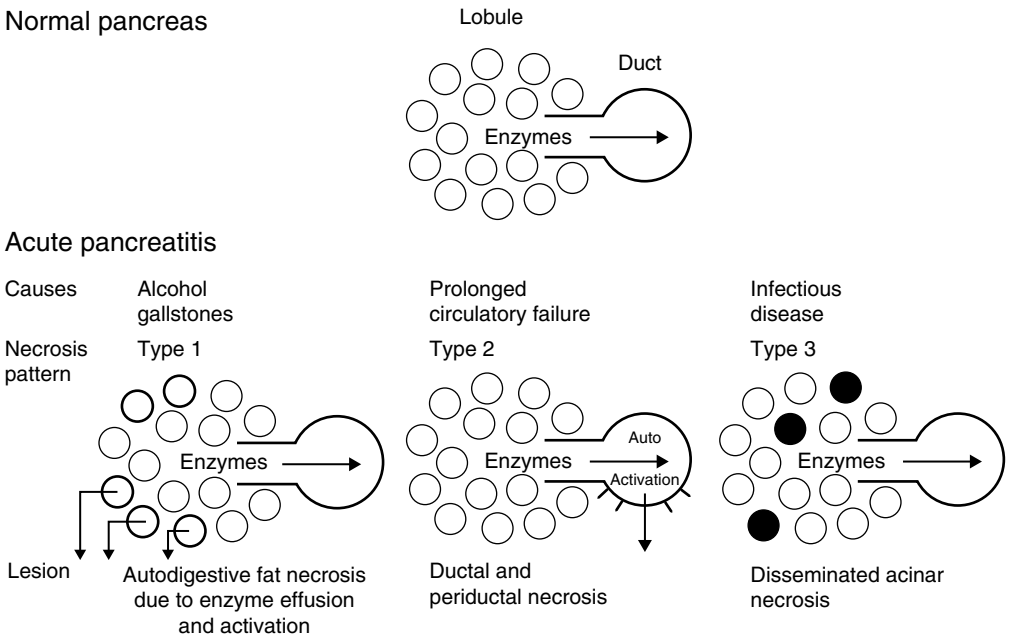

**Figure 19.1** Schematic presentation of three types of necrosis in the human pancreas related to their causative factors.

**Table 19.1** Correlation of the most important criteria of the Atlanta classification 2012 with the main histopathologic features of conventional acute pancreatitis.

| Type and severity | Complications | Histopathologic features |
|---|---|---|
| **Interstitial edematous pancreatitis** | | |
| Mild | No | Parenchymal edema with tiny fat necroses |
| Moderately severe | Transient organ failure and/or acute peripancreatic fluid collection (APFC) | Peripancreatic fat necrosis |
| | Pseudocyst (derived from unresolved APFC) | Pseudocyst (without debris) |
| **Necrotizing pancreatitis** | | |
| Severe | Persistent organ failure, systemic complications, acute necrotic collection (ANC) | Pancreatic and peripancreatic parenchymal and/or fat necrosis with or without hemorrhage |
| | Walled-off necrosis (derived from ANC) | Pancreatic and peripancreatic necrosis, well demarcated by granulation tissue and fibrosis, corresponding to pseudocyst with associated necrosis |

veins, the necrosis becomes hemorrhagic, because of vessel wall damage with subsequent thrombosis or rupture. Arteries, because of their thick walls, are more resistant to necrosis, but if damaged they may develop thromboses, which can result in panlobular ischemic necrosis. Another important result of expanding fat necrosis is the destruction and rupture of a duct, leading to duct leakage and effusion of secretions into the adjacent necrotic area. Non-necrotic acinar cells at the margin of fat necrosis appear well preserved despite their proximity to necrosis. As the only change they may show widened lumina, so-called tubular complexes, which may be filled with PAS-positive secretions. Islets are affected only in lobules that are largely or entirely necrotic. In the course of the disease, the necrotic areas are demarcated by a collar of foamy macrophages intermingled with granulocytes. These granulocytes later disappear, leaving macrophages and myofibroblasts to build up a wall of granulation tissue separating the necrosis from intact tissue.

## Outcome

In interstitial acute pancreatitis, the edema, which is probably rich in pancreatic enzymes, is usually resolved by macrophages within a few days and does not result in

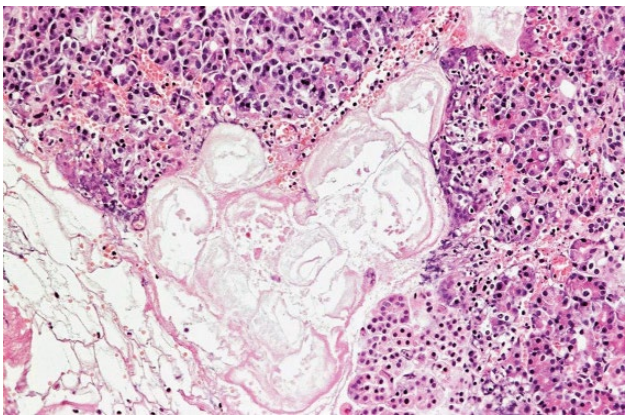

**Figure 19.2** Interstitial type of acute pancreatitis. Tiny necrosis of peripancreatic fatty tissue. Note the preservation of the adjacent acinar cells.

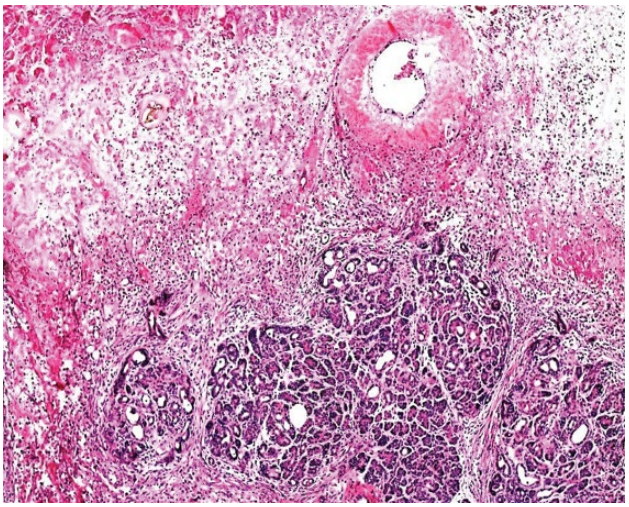

**Figure 19.3** Necrotizing type of acute pancreatitis. Advanced confluent peripancreatic fat necrosis (top) extending into the pancreas and involving a duct (top).

secondary changes. The same happens to the tiny foci of fat necrosis. The diameters of these usually do not exceed 10 mm, so they are barely detectable by imaging. Larger liquefied foci of peripancreatic fat necrosis, which probably correspond to the radiologic lesion called "acute peripancreatic fluid collection," are rare. If such a rare lesion does not resolve and gets encapsulated by granulation tissue (see later), it may become a pseudocyst.

In necrotizing hemorrhagic pancreatitis, the large fat necroses liquefy and, if not exceeding 2–5 cm in diameter, are slowly reabsorbed by macrophages. Larger necrotic areas (usually >5 cm), particularly when encompassing pancreatic parenchyma, may not resolve spontaneously and their liquefied and solid content is then lined by macrophages, which, together with some granulocytes and lymphocytes, form a thin layer of

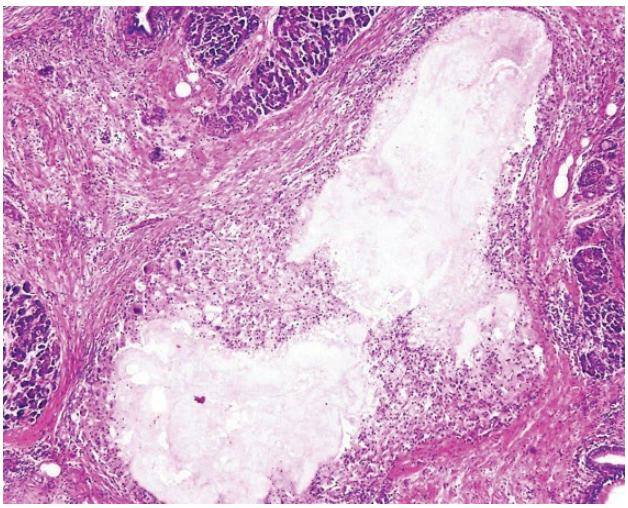

**Figure 19.4** Necrotizing type of acute pancreatitis 6 weeks after onset. Development of cell-rich interlobular fibrosis induced by the resorption of a fat necrosis (center). H&E, ×125.

granulation tissue within 10–20 days of the onset of the disease. This change may correspond with an "acute necrotic collection" as described by the radiologist [6]. Often the macrophages in the granulation tissue contain hemosiderin, since the content of these necrotic areas may be hemorrhagic. After 20–30 days, the granulation tissue starts to be replaced by fibrosis containing collagen types 1 and 3 and a well-defined wall is built up. If the demarcation is fully developed the change is radiologically called "walled-off necrosis," which corresponds to the older term "pseudocyst associated with necrosis" (Table 19.1). Most of these advanced lesions are found outside the pancreas, particularly around the head of the pancreas [7,8]. The fact that walled-off necrosis/pseudocysts contain amylase suggests communications with the pancreatic duct system. This may be particularly the case in those pseudocysts which, in time, increase in size and by growing compress or erode such structures as the bile duct, duodenum, stomach, vessels, or peritoneum. The involvement of vessels may lead to sudden hemorrhage.

Fat and/or parenchymal necrosis may become infected with (mostly gut-derived) bacteria or fungi. This usually takes place during the period (days 4–20) when the demarcation of the liquefied necrotic area still consists of only a small rim of granulation tissue.

The resolution of necrotic tissue within the pancreas is usually followed by the development of interlobular fibrosis replacing the necrotic tissue (Fig. 19.4) [9,10]. If this necrosis–fibrosis sequence [11] takes place repeatedly because of recurrent attacks of necrotizing acute pancreatitis and also involves the large interlobular ducts and the main duct, relapsing acute pancreatitis may evolve into chronic pancreatitis [12,13].

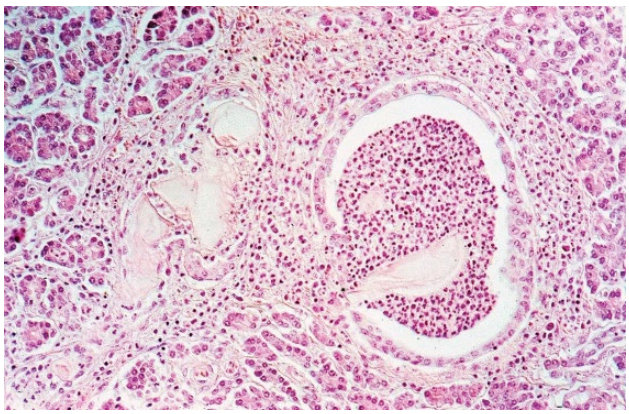

Figure 19.5 Acute pancreatitis with type 2 necrosis pattern. Interlobular duct containg secretions and granulocytes. Rupture of the duct epithelium with granulocytes infiltrating the interstitial space. H&E, ×120.

## Acute Pancreatitis with Type 2 Necrosis Pattern

### Initial Phase

Disseminated ductal necrosis of small to medium-sized interlobular ducts, which contain granulocytes mixed with precipitations of eosinophilic secretions, is the key lesion of type 2 necrosis. It results in duct rupture and extension of the necrosis into the periductal area (Fig. 19.5). This may be a sollitary change, but is also observed in association with foci of fat necrosis [14–16]. The ensuing acute pancreatitis seems to be usually mild.

### Outcome

In acute pancreatitis with type 2 necrosis the outcome is largely unknown because the patients in whom this necrosis pattern has been observed and described all died from prolonged circulatory failure that was usually not caused by acute pancreatitis, but by various extrapancreatic diseases such as hepatic failure. Our only observation of type 2 necrosis so far, made in a pancreatic resection specimen from a patient with hereditary pancreatitis [16], could suggest that in this setting the initial necrosis of the duct-lining cells, followed by an inflammatory involvement of the surrounding interstitial tissue, may result in structural changes such as irregular dilatations and periductal scarring of the affected pancreatic ducts.

## Acute Pancreatitis with Type 3 Necrosis Pattern

### Initial Phase

Scattered intralobular foci of acinar cell necrosis are the key lesions of type 3 necrosis (Fig. 19.6). It is accompanied by an inflammatory infiltrate consisting of neutrophil granulocytes and single macrophages. Fat or ductal necrosis is notably absent. It appears that these changes are indicative of a pancreatitis caused by an infection.

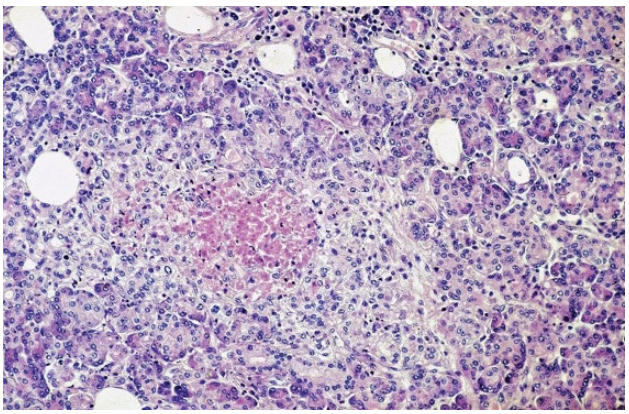

Figure 19.6 Acute pancreatitis with type 3 necrosis pattern. Focus of acinar cell necrosis within a lobule.

### Outcome

In acute pancreatitis with type 3 necrosis the outcome seems to be favorable in most cases. It is noteworthy that in the cases reported so far there was usually only mild pancreatitis [17].

## Histopathology Related to Etiologic Factors and Pathophysiologic Mechanisms

Acute pancreatitis with type 1 necrosis pattern is most frequently associated with alcohol abuse and gallstone disease. The only difference between the two etiologic factors regarding the resulting morphologic changes seems to be the disease severity, since biliary pancreatitis usually follows a mild course as compatible with interstitial pancreatitis, whereas alcoholic pancreatitis is a severe necrotizing disease. Rare causative factors are metabolic or drug-associated processes, and familial hereditary or acute hypoxia-related conditions.

Via as yet unidentified or hypothetical mechanisms these factors cause a limited or extensive sudden release of digestive enzymes from the acinar cells into the interstitial tissue, a release that is combined with their intrapancreatic activation [2]. The pathophysiology of this mechanism concentrates on assumed functional acinar cell damage, meaning a complex disturbance of acinar cell function, culminating in deranged intracellular compartmentalization and uncontrolled liberation of enzymes. These alterations could lead to intracellular enzyme activation by lysosomal hydrolases [18] and/or an abrupt effusion of enzymes into the interstitial space [19], resulting in fat necrosis as the first visible histologic

tissue damage. This necrosis is probably caused by lipase (one of the few pancreatic enzymes that do not require activation) [20,21]. Whether fat necrosis depends on the action of lipase alone or the combined action of lipase plus other enzymes, such as phospholipase A2 and trypsin, is not known, but it seems that proenzymes become activated during this process and may help to destroy interstitial tissues and finally also acini and ducts. Since these changes appear to occur predominantly in the lobule periphery where the cells are most remote from the arteries supplying the lobules, it is possible that the effects of the different etiologic factors might be mediated by microcirculatory changes.

Another pathophysiologic theory related to type 1 necrosis, which rests on the frequent association of gallstone disease with pancreatitis, is the duct obstruction–bile reflux theory (based on Opie's common channel theory) [22]. It postulates that temporary obstruction of the common bile duct and the main pancreatic duct by a gallstone (or tumor tissue or inspissated secretions as in cystic fibrosis) [23] causes increased intraductal pressure and/or ampullary incontinence, with duodenopancreatic and bile reflux. This in turn activates pancreatic proenzymes, which leak from small ducts into the interstitial space. However, despite the obvious clinical association between gallstone migration and pancreatitis, definite functional and histologic proof of the duct-obstruction pathogenesis is, thus far, lacking in human acute pancreatitis.

Acute pancreatitis showing type 2 necrosis, which focuses initially on the pancreatic duct epithelium, is associated with prolonged circulatory failure. In this case the tissue hypoxia in the pancreas seems to injure especially the medium-sized interlobular ducts and cause its necrosis. In addition, there could be an autoactivation of trypsinogen within the duct lumen, as the ducts in type 2 necrosis are filled with dense pancreatic secretions and neutrophil granulocytes [14]. This could be due to a stasis of pancreatic juice, which became viscous and sluggish because of a general slowdown of secretory processes in the exocrine pancreas as a result of a severe circulatory failure. Since we saw a comparable picture in a case of familial pancreatitis, it may be that similar duct damage as in prolonged circulatory failure occurs due to mutational changes to the trypsinogen molecule, allowing its uncontrolled activation.

In acute pancreatitis with type 3 necrosis, which focuses on acinar cell destruction without any significant autodigestive interstitial necrosis, there seems to be a direct cytotoxic damage to the acinar cells by microorganism such as mumps virus or bacterial agents.

## Unsolved Questions

There are a number of unsolved questions in acute pancreatitis. The most important one concerns its pathogenesis and pathophysiology. The concepts currently discussed usually refer entirely or to some extent to experimental pancreatitis models [24]. Although these models have markedly improved our knowledge of pathogenetic mechanisms in acute pancreatitis, it has to be emphasized that none of them are fully comparable to what is seen in humans.

Another question that remains to be solved relates to the severity of acute pancreatitis. It is not yet known which factors govern the mechanisms that determine a mild or severe course of the disease.

A third question is how the criteria that define the Atlanta 2012 classification [1] and are solely based on radiologic [6] and clinical features relate to the macroscopic and especially microscopic findings in acute pancreatitis. Table 19.1 attempts to summarize and correlate the most important criteria of the Atlanta 2012 classification with the histopathologic changes that can be observed in conventional acute pancreatitis.

# Clinical Classification Systems of Acute Pancreatitis

*John A. Windsor and Max S. Petrov*

*Department of Surgery, University of Auckland, Auckland, New Zealand*

## Introduction

The accurate classification of acute pancreatitis severity is important for clinical and research reasons because it will "improve communication and advance our understanding of the disease and its management" [1]. When specific treatments become available for clinical trial in acute pancreatitis "an inclusive clinical classification system will assume increasing importance" [2]. Systems for classifying severity will continue to evolve with new scientific knowledge and for this reason they are best considered "working" classifications. The aim of this chapter is to outline the reasons for classifying severity, review the two new systems and studies that compare them, and identify areas for further improvements.

## Reasons for Classifying the Severity of Acute Pancreatitis

Classification systems are required in both clinical and research settings, and there are different reasons within each setting (Table 20.1). Many of these reasons are best met by prediction, rather than by classification, and it is common for these to be confused [3–5]. When the ultimate disease severity needs to be anticipated, prediction of severity is required. When the severity is needed at a particular time point, classification of severity is required. In this way prediction is about the future and classification is about the present and the past. Prediction is usually required early in the disease course, whereas classification is required at any time during the disease course.

## New Classification Systems

The first classification system for acute pancreatitis was published in 1983 [6], and with the later clinically based classification system from the Atlanta symposium [7], embedded the binary concept of mild and severe disease. There has never been difficulty in identifying patients with uncomplicated course of disease but the severe category encompasses subgroups with distinct outcomes, and this category is not sufficiently granular for clinical and research purposes.

Two new systems for classifying the severity of acute pancreatitis have recently been published (Table 20.2): the "determinant-based classification" (DBC) in 2012 with four categories of severity [8] and the "revised Atlanta classification" (RAC) in 2013 with three grades of severity [9].

There are a number of differences between the two classifications (Table 20.3). Having different classification systems has raised questions about which is more valid, which has higher utility, and which should be used. These differences should not raise concern as they are to be expected when the systems were derived by quite different methodologies [10]. And although the two classifications have been considered to have "few differences" [11] there are some worth noting.

The RAC definition of the "moderately severe" grade was added at the end of the 7-year process, in the second half of 2012. Prior to that, at least five "provisional" versions were published in peer-reviewed literature and all them contained only two grades of severity. The definition of the moderately severe grade includes "exacerbations of comorbid disease" and this is not considered to be a determinant of severity and is not included in the DBC. Patients with infected local complications (and

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

**Table 20.1** The reasons for classification systems in acute pancreatitis.

| | |
|---|---|
| Reasons related to clinical decision making | Triage of patients regarding initial treatment intensity[a] |
| | Transfer of patients to specialist unit or intensive care[a] |
| | Trajectory of patients clinical course |
| | Treatment early in disease course (e.g., enteral nutrition)[a] |
| Reasons related to research decision making | Audit of outcome |
| | Allocation of patients to trial arm[a] |
| | Analysis of interventions |

[a] Denotes reason that are more appropriate for prediction than classification systems.

**Table 20.2** New classifications for the severity of acute pancreatitis.

| | |
|---|---|
| **Determinant-based classification [8]** | |
| Mild | No (peri)pancreatic necrosis |
| | No organ failure |
| Moderate | Sterile (peri)pancreatic necrosis and/or transient organ failure |
| Severe | Infected (peri)pancreatic necrosis or persistent organ failure |
| Critical | Infected (peri)pancreatic necrosis and persistent organ failure |
| **Revised Atlanta classification [9]** | |
| Mild | No organ failure and no local or systemic complications |
| Moderately | Severe transient organ failure and/or local or systemic complications or exacerbations of preexisting comorbidities |
| Severe | Persistent organ failure (single or multiple) |

without persistent organ failure) are also defined as having "moderately severe" grade in the RAC. The explanation given for this was that "infected necrosis without persistent organ failure […] has a lesser mortality rate than infected necrosis with persistent organ failure." These patients have been shown to have a similar outcome to those with "severe" grade acute pancreatitis [12] which is consistent with the meta-analysis of 14 studies which demonstrated that infected (peri)pancreatic necrosis and persistent organ failure are independent and virtually equivalent determinants of mortality [13]. On this basis the DBC includes infected (peri)pancreatic complications in the "severe" category and the "critical" category is defined when it is present with persistent organ. The utility of the critical category has been questioned because of its relatively infrequency in some series [4], but in other series it has a significantly higher mortality and is endorsed [14–16].

**Table 20.3** Key differences between the two classification systems.

| | Severity classification systems | |
|---|---|---|
| **Criteria** | **DBC category** | **RAC grade** |
| Exacerbation of comorbid disease | Not included | Moderately severe |
| Infected (peri)pancreatic necrosis without persistent organ failure | Severe | Moderately severe |
| Infected (peri)pancreatic necrosis with persistent organ failure | Critical | Severe |

DBC, determinant-based classification; RAC, revised Atlanta classification.

## Validation and Comparison of Classification Systems

A number of studies have compared the validity of the two new classification systems (Table 20.4). Most of the studies have been from single tertiary centers and subject to selection bias. Only two of the 10 comparative studies were prospective. A review of the key findings indicate that there is little difference between the two classification systems, being considered "equivalent" or "comparable and complementary" [3,4]. All the 10 studies used an unsophisticated approach to the comparison of the two classifications and none employed the "gold standard" approach to determining the comparative usefulness of two or more classification systems, which is a calculation of the net reclassification improvement [17]. At present, the decision about which classification system to use has to be based on a combination of factors including the evidential base, method of development, the setting, validity, and ease of use. If a unified classification system is to be developed then it needs to be recognized that both classification systems have limitations and there is room for improvement.

## Future of Classification Systems

The differences in classification systems represent an opportunity for further improvement, and some research priorities have been recently published [18,19]. There is the need to determine whether classification systems should be matched to the setting. In a district or secondary center, the incidence of severe and critical acute pancreatitis is low and the fundamental clinical decision is whether the patient needs to be transferred to a tertiary center or not. In this setting a binary classification system might well suffice; that is, severe patients are transferred.

**Table 20.4** Studies that have compared the determinant-based classification (DBC) and revised Atlanta classification (RAC) systems from the same dataset.

| First author (year) | Ref | Setting | Study design | Key findings |
|---|---|---|---|---|
| Nawaz (2013) | 3 | Tertiary (SC) Pittsburgh | Retrospective (prospective database) | DBC and RAC comparable for predicting ICU admission, ICU length of stay, and mortality. The RAC was better at predicting hospital stay and DBC better for predicting the need for intervention |
| Acevedo-Piedra (2014) | 12 | Tertiary (SC) Spain | Retrospective (prospective database) | No significant differences in the distribution and outcomes between the two classifications, but very low incidence of severe and critical categories |
| Chen (2015) | 20 | Tertiary (SC) Nanjing | Retrospective (prospective database) | RAC and DBC comparable in relation to long-term clinical prognosis, major complications, and clinical interventions. Critical category very high risk and distinct from severe category in DBC |
| Mircea (2015) | 21 | Tertiary (SC) Bucharest | Retrospective | Similar for clinical outcomes, although RAC has slight advantage for hospital length of stay and DBC for ICU admission and length of stay. DBC easier to use |
| Xu (2015) | 22 | Tertiary (SC) Lanzhou | Retrospective | Similar distribution and outcomes. Recommended combining RAC and DBC |
| Guo (2105) | 23 | Tertiary (SC) Chengdu | Prospective | No significant difference between RAC and DBC. Mortality similar and distribution of severity marginally different |
| Kadiyala (2016) | 4 | Tertiary (SC) Boston | Retrospective (prospective database) | The RAC and DBC were essentially equivalent in predicting mortality, need for admission to the ICU, ICU length of stay, and hospital length of stay. Paucity of critical category, limited utility. Neither classification accounts for multisystem persistent organ failure, the strongest predictor of mortality |
| Bansal (2016) | 24 | Tertiary (SC) Birmingham | Retrospective (prospective database) | The RAC and DBC perform equally well. DBC critical category associated with doubled mortality risk, ICU stay and need for drainage or surgery greater than RAC, with definite implications for prognosis |
| Fernandes (2016) | 25 | Tertiary (SC) Portugal | Retrospective | RAC and DBC were similar for outcomes |
| Zubia-Olaskaoaga (2016) | 16 | Tertiary (MC) Spain etc. | Prospective observational | Proposed a modified DBC for only ICU patients. Superior to DBC and RAC for mortality. Similar to DBC for morbidity and superior to RAC. Severe DBC category separated into two groups: transient organ failure with infected local complications and persistent organ failure and no infected local complications |

ICU, intensive care unit.

In a tertiary center the requirements are different and there is a need for more than two categories of severity. With several options for intervention and intensive care, the need to accurately allocate patients to research arms and the intention to tailor treatments to individual patients, it is desirable to have distinct and homogeneous patient subgroups to study and treat. For instance, if there were a new treatment for organ failure to be tested it would confound interpretation of outcomes if all patients were included with organ failure, even if this contained those who would respond promptly (e.g., transient organ failure), those who might not respond (e.g., persistent organ failure), and those who cannot respond (e.g., no organ failure). Further, if the purpose of a treatment were to reverse established organ failure it would be necessary to exclude patients with transient organ failure. If the purpose were to prevent the development of persistent organ failure it would be necessary to include patients with transient organ failure. These examples indicate that the binary classification is probably sufficient for those in primary and secondary care settings, whereas more categories are required in the tertiary setting. Tailoring the severity classification needs to be tested, particularly in the secondary setting.

**Table 20.5** Modified determinant-based classification (DBC) system for patients admitted to intensive care with organ failure [16].

| | Parameters | | | | |
|---|---|---|---|---|---|
| Group | Organ failure | Infected necrosis | Mortality | Intensive care LOS | Intervention |
| 1 | TOF | No | 2% | Short | – |
| 2 | TOF | Yes | 6.6% | Long | + |
| 3 | POF | No | 41% | Short | – |
| 4 | POF | Yes | 59% | Long | + |

TOF, transient organ failure; POF, persistent organ failure; LOS, length of stay.

The exclusion of any local complications from the RAC "severe" grade requires rethinking (Table 20.2). Clinicians know that the development of infection is associated with increasing severity and the likely need for intervention. It has been shown that patients with infected necrosis, in the absence of persistent organ failure, can behave like severe disease [12,14,26]. Although considered to limit the utility of the DBC system, infection of local complications can be diagnosed in the vast majority of patients on the basis of a deteriorating patient clinical trajectory, a rise in C-reactive protein, and further cross-sectional imaging [27].

A modified DBC has been proposed for patients with organ failure admitted to intensive care [16]. In the only multicenter prospective study we find endorsement for the DBC and the critical category and the finding that the "severe" category contains two further subgroups with distinct outcomes. With mild patients excluded, four groups were defined (Table 20.5). The DBC severe category does not distinguish groups 2 and 3 and yet the mortality, need for intervention and length of intensive care stay is very different in this study. They also suggested including other local complications that impacted outcome, including abdominal hemorrhage and intestinal perforation. Other groups have also recognized subgroups within the DBC "severity" category [23].

Neither classification system formally accounts for patients with multiple organ failure in the first week of presentation [4,12,26,27] though it is noted that these patients almost certainly have persistent organ failure as well. This is one of the most challenging subgroups of patients with a high mortality risk [28–30] and this suggests that the timing of organ failure onset might need to be included in a new classification system [31]. Understanding the importance of different aspects of organ dysfunction is also required [32], including the duration, number, combination, and sequence of the organs affected. Data on these dimensions may allow more accurate classification of patients with severe and critical acute pancreatitis.

## Conclusions

The classification of severity of acute pancreatitis is important for the clinical care of patients and for research purposes. Classification is not prediction and has a more limited role. Advances in the care of patients with acute pancreatitis will require improvements on current methods for classifying severity, although the two new classifications are an important step forward. There are several reasons for classifying severity and these differ between secondary or tertiary settings. Ultimately, improvements in classifying severity will come from the discovery of early biomarkers of severity that accurately reflect the key changes in the pancreas, peripancreatic tissues, and distant organs. For now we are reliant on clinical indicators related to the presence of organ failure and infected local complications. The two new classifications of severity both rely on these factors, but there are important differences, as discussed, which highlight areas where further research is needed in the search for improvements in severity classification.

## Introduction

Among the inflammatory digestive disorders, acute pancreatitis continues to challenge physicians as it is one of the most difficult to predict in terms of clinical course and outcome. Ever since the first classification system of acute pancreatitis was established in Marseille in 1965 [1] the definition of "severe" disease has been linked to the occurrence of disease-specific complications with an increased risk of mortality [2,3]. Stratification of severity is required to target individual patients (i) for interventions against evolving complications or for referral to specialist centers and (ii) for comparing patients for scientific purposes or recruitment into clinical trials. The type and clinical relevance of a complication that render the course of acute pancreatitis as "severe" has been subject of continuous development and changes. New insights into the pathomechanism and natural course of acute pancreatitis, the development of laboratory variables, diagnostic imaging procedures, and new therapeutic approaches have strongly influenced definitions and classification systems over the past decades.

## Historical Perspectives: Approaches to Severity Assessment

Attempts to stratify severity and prognosis date back to the second half of the last century and have been substantially driven by major advances in new imaging procedures and laboratory tests. The development of serum amylase measurement in 1929 [4] was instrumental in providing a noninvasive diagnosis of acute pancreatitis and it soon became evident that in the majority of patients a mild course with uneventful recovery was the rule rather than the exception. Supported by the availability of intensive care treatment and more restrictive indications for surgical interventions in patients with clinically severe disease, interest in prognostic assessment gained considerable headway in the 1960s. Attempts to define objective criteria for assessing disease severity and prognosis were pioneered by John Ranson in New York [5] and Clement Imrie in Glasgow [6] in the 1970s and these found widespread application in the pancreatic community.

During the early 1980s intraoperative findings revealed local morphological features, such as presence and extent of necrosis [7,8] and infection of necrosis [9], that showed an excellent correlation with systemic severity and outcome. With the introduction of contrast-enhanced computed tomography (CE-CT) and percutaneous guided fine-needle-aspiration (FNA), nonoperative assessment of these complications became possible, which further substantiated the predominance of morphology-based severity stratification. Hence, imaging has become indispensable for assessment of severity in acute pancreatitis and an integral part of new classification systems [2,3] and treatment algorithms [10–12] alike.

After almost two decades of mainly morphology-based severity stratification, the role of systemic aspects in terms of onset, severity, and persistence of pancreatitis-related organ failure was recognized as central determinant of severity [13–21]. Currently, early and persisting multiorgan dysfunction syndrome (MODS) has been found to outweigh morphological factors such as necrosis and even infection of necrosis as far as nonsurvival is concerned [16].

## Dynamics of Organ Failure

The prognostic role of early pancreatitis-associated organ failure was first recognized during the early 1970s. Objective measurement of pulmonary failure by arterial oxygen pressure or renal failure by serum creatinine had become available and had been integrated into prognostic multiparameter scoring systems according to Ranson [5] and Imrie [6]. However, it took another three decades before pancreatologists realized that the occurrence of a temporary single organ failure does not necessarily indicate a life-threatening disease. Specific aspects such as onset, severity, and persistence of organ failure have gained special attention only recently.

### Early Organ Failure

The role of "early" organ failure, defined as failure of one or more organ systems within the first 3 days after onset of acute pancreatitis/hospital admission, was first described by Isenmann et al. in 2001 [13]. The presence of "early" single or multiple organ failure leads to a significant increase of mortality up to 56%, irrespective whether necrosis is sterile or infected [13–15,17,18]. Early multiple organ failure represents the most important risk factor of death and even seems to outweigh local morphological complications such as extent or infection of necrosis [16].

### Persistent Organ Failure

The dynamics of organ failure in terms of response/resolution or nonresponse/persistence despite intensive care treatment has been identified as another major determinant of complications and death. In several prospective and retrospective studies in patients with severe acute pancreatitis, resolution of organ failure within the first week of the disease resulted in mortality rates close to zero, whereas mortality rates rose to 55% if organ failure persisted beyond the first week [18–21]. Moreover, organ failure nonresponsive to intensive care treatment closely correlates with the development of pancreatic infections and death [22,23].

Currently, there is little doubt that organ failure is one of the most important determinants of prognosis and mortality in acute pancreatitis. The revised Atlanta classification of 2012 [3] defined organ failure as a central criterion in differentiating three severity groups of acute pancreatitis (Table 21.1).

**Table 21.1** Definition of three grades of severity in acute pancreatitis according to the revised Atlanta classification 2012 [3].

| | |
|---|---|
| Mild acute pancreatitis | No organ failure |
| | No local or systemic complications |
| Moderately severe acute pancreatitis | Organ failure that resolves within 48 h (transient organ failure) and/or |
| | Local or systemic complications without persistent organ failure |
| Severe acute pancreatitis | Persistent organ failure >48 h |
| | Single organ failure |
| | Multiple organ failure |

### Abdominal Compartment Syndrome

Abdominal compartment syndrome (ACS), defined as intra-abdominal pressure >20 mmHg and newly developed organ failure [24], has been recognized as a determinant of prognosis within recent years. Abdominal hypertension (intra-abdominal pressure >15 mmHg) is observed in up to 75% of patients with severe acute pancreatitis [25,26] and ACS in about 25% [27]. Several studies revealed a strong association between intra-abdominal hypertension and the development of multiple organ dysfunction which occurred in more than 90% of patients [14,25]. Multiple organ dysfunction in turn carries excessively high mortality rates. Clinical evidence suggests that "early" multiple organ failure may be the result of undiagnosed ACS arising from the extensive inflammatory process in the retroperitoneum and an aggressive fluid resuscitation.

Beyond its prognostic role, the diagnosis of ACS has therapeutic implications that have been impressively shown in some studies [28,29].

## Multiparameter Scoring Systems

Analysis of the numerous objective clinical and biochemical variables thought to contribute to complications and death led to the development of the very first multiple parameter scores by John Ranson [5] and Clement Imrie [6]. Both systems still offer a track record and a good level of accuracy, but have the disadvantage that valid calculation is restricted to primary admissions within the first 48 hours of treatment, and recalculation beyond 48 hours is impossible. Since their original description, the requirements of researchers and clinicians have changed and are driven more than ever by the need for speed and simplicity. Supported by the recognition of organ failure as a major determinant of outcome, new scoring systems such as the Marshall score [30] and sequential organ failure assessment (SOFA) [31] score, which have all been developed and validated in the intensive care setting, have led to more flexible and practicable assessments of severity and prognosis in acute pancreatitis.

## The APACHE II Score

Dissatisfaction with the temporal applicability of the Ranson and Imrie systems led pancreatologists to search for more flexible scoring systems. One of the first multiple parameter scores applied in acute pancreatitis was the acute physiology and chronic health evaluation (APACHE) score in the early 1980s. A modification of the initial system by the Intensive Care Research Group from Washington, DC, USA [32] reduced the number of physiological variables from 35 to 11 and was termed APACHE II score [33]. Despite further modifications, this remains the most commonly used version. Larvin et al. from Leeds, UK published the first evaluation in 290 attacks of acute pancreatitis [34]. Initial APACHE II scores of 10 or more revealed a sensitivity of 63% and a specificity of 81% (positive predictive value [PPV] 46%, negative predictive value [NPV] 90%) in predicting "severe" disease. By 24 hours APACHE II scores >10 provided a sensitivity of 71% and a specificity of 91% (PPV 67%, NPV 93%), which further rose to a sensitivity of 75% and a specificity of 92% (PPV 71%, NPV 93%) at values >9 after 48 hours.

The APACHE II scores at 24 hours outperformed both the Ranson scores and Imrie scores at 48 hours. The results of the Leeds study have been confirmed exhaustively in the years since it was published [35–38]. The original Atlanta classification incorporates an APACHE II score of 8 or more as denoting a severe attack [2].

The advantage of the APACHE II system is clearly its flexibility and greater speed, and the possibility of recalculation at any time throughout the course of the disease for monitoring purposes. On the other hand, calculation of this score is complex and time consuming and carries the risk of miscalculations.

## Organ Failure-Related Scoring Systems

Organ failure-related intensive care scores, such as the Marshall score [30] and the SOFA score [31], have been applied in acute pancreatitis by a number of studies to assess organ failure or outcome [19,22,23,38–44]. These two scores belong to the newer generation of organ failure-related systems, which can describe the evolution of individual and multiple organ dysfunction over time. Both scoring systems rely on six major organ systems: pulmonary, cardiocirculatory, renal, hepatic, and neurologic function, as well as coagulation. Failure of each organ system is scored as absent or up to 4 points with escalating severity. The SOFA score is basically a further development of the Marshall score, with the inclusion of treatments such as ventilation and vasopressors, thus reflecting clinically relevant severity of organ failure [31].

### Marshall Score

The first detailed validation study of the Marshall score was published by Halonen et al. in a large series of Finnish patients with severe acute pancreatitis. This scoring system provided a sensitivity of 59% and a specificity of 91% in predicting mortality within 72 hours of hospital admission. Comparable results were obtained using the APACHE II system (sensitivity 65%, specificity 91%) [42]. In another retrospective study of the same group in 113 patients with severe acute pancreatitis admitted to the intensive care unit, both admission and peak Marshall scores were as accurate as SOFA scores in assessing the risk of hospital mortality. Unfortunately, no information about optimum cut-off levels, sensitivity, and specificity was provided [41]. A modification of the Marshall score, excluding hepatic and neurologic function, has been applied in two prospective studies [19,20] and the original score in a retrospective study [21] from the United Kingdom to quantify organ failure. The components for pulmonary, cardiocirculatory, and renal function match well with the definitions of the original Atlanta classification, but hepatic (bilirubin), neurologic (Glasgow Coma Scale), and coagulation parameters (platelet function) may further increase total scores, even if true organ failure is absent. The revised Atlanta classification of 2012 has adopted the Marshall components for pulmonary, cardiocirculatory, and renal function to define and quantify early pancreatitis-associated organ failure [3].

### SOFA Score

Two detailed evaluation studies in acute pancreatitis are available for the SOFA score. In a prospective international multicenter study, SOFA scores >4 were predictive of death with a sensitivity of 86% and a specificity of 79% (PPV 27%, NPV 98%) 48 hours after onset of symptoms [43]. Corresponding results have been reported by a Finnish study for admission scores in an intensive care unit (ICU) population-based cohort at a cut-off level >8 [41]. Interestingly, a separate analysis of the six different components revealed, that not all "organ failures" affect mortality to the same degree: only cardiocirculatory, renal, and hepatic failure were independently associated with hospital mortality [40,44]. Among the critical care systems discussed, the SOFA system offers obvious advantages since it is easy to calculate and includes therapeutic requirements such as mechanical ventilation and inotropic substances.

The advantage of organ failure scores clearly lies in their widespread implementation in intensive care medicine, which allows good comparison with other critically ill patients (e.g., patients with sepsis). The introduction of the modified Marshall score in the revised Atlanta classification has overcome the problem of erronenously high scoring points by omitting the hepatic and

neurologic components. The latter are truly problematic in acute pancreatitis, because high bilirubin values or delirium tremens are frequent features of biliary or alcoholic pancreatitis, albeit not representing organ failure.

## Laboratory Variables

In the mid 1960s, the first evidence arose that the severity of acute pancreatitis is reflected by abnormalities of many serum/plasma variables [45]. Hence, a number of laboratory markers have been identified which allow early stratification of patients at risk of developing complications, such as necrosis, infection of necrosis, septic complications, organ failure, and death. As well as having the potential to predict disease severity, many of these parameters were found to be determinants of disease progression and subsequent complications in the pathomechanism of acute pancreatitis, such as proteases, cytokines, chemokines, adhesion molecules, and acute-phase proteins [46].

An ideal laboratory test to assess severity of acute pancreatitis should be simple to perform, readily available under routine and emergency conditions, accurate, and cost effective. However, despite a large array of potentially useful parameters being developed, their large-scale clinical use is limited by time-consuming and expensive assay procedures. As a consequence, only few tests have passed the threshold into routine clinical application.

### Routine Laboratory Variables

Since the introduction of the Ranson and Imrie scoring systems, the abilities of single routine laboratory components, such as hematocrit, creatinine or blood urea nitrogen (BUN), and blood glucose, to predict complications and thus "severe" disease have been extensively investigated, either alone or in combination.

#### Hematocrit

Admission hematocrit and its subsequent changes during fluid resuscitation still represents a simple and good prognostic estimate. An admission hematocrit >44% has been found to be closely associated with complications in terms of necrosis and organ failure [47] or pancreatic infection [48]. An overall high negative predictive value of around 90% excluding "severe" acute pancreatitis at admission hematocrit <44% [47] and <40% [49] was reported by some sauthors. However, admission hematocrit of >41% to >44% failed to predict severity, organ failure, or death in other large studies [35,49]. In a recent international multicenter analysis in 1612 patients with acute pancreatitis, admission hematocrit ≥44% and increasing BUN levels at 24 hours were able to predict persistent organ failure and pancreatic necrosis in 54% and 60% of patients, respectively [50]. Taken together, hematocrit serves as a widely available and simple rough estimate to exclude severe attacks, but is no reliable means to predict severity or any other specific complication accurately.

#### Serum Creatinine and Blood Urea Nitrogen

Creatinine and BUN are surrogate laboratory tests that indicate and define renal failure. Renal failure, defined as creatinine >2 mg/dL (177 μmol/L) by the Atlanta classification, is one of the most serious organ complications in acute pancreatitis and has been shown to be an independent risk factor for fatal outcome [41,42,51]. However, the widely used cut-off level >2.0 mg/dL is frequently not reached at the day of hospital admission, which limits the use of this variable for "early" risk estimation. As far as disease severity in terms of local or systemic complications is concerned, admission BUN achieved no satisfactory test performance [52,53], reaching a maximum sensitivity of 79% and a specificity of 67% (PPV 43%, NPV 91%) only [52]. In the largest patient cohort ever published, rising BUN within 24 hours after admission achieved a sensitivity of <60% in predicting persistent organ failure or pancreatic necrosis [50], but revealed increasing diagnostic accuracy rates beyond 48 hours after admission [54].

### Acute-phase Proteins

Acute-phase proteins constitute a family of inflammatory proteins that are mainly synthesized in the liver in response to infectious and noninfectious stimuli. The best-known member is C-reactive protein (CRP). Serum amyloid A protein (SAA) was also thought to be useful in the spectrum of acute-phase reactants for biochemical severity stratification of acute pancreatitis. Both parameters share an essential feature for a large-scale routine application—they are available as fully automated immunoassays.

#### C-Reactive Protein

Severity stratification of acute pancreatitis by CRP has a long tradition and still represents the "gold standard" for both early severity stratification and monitoring the course of the disease [53,55–59]. CRP is the laboratory variable of choice to differentiate necrotizing from interstitial edematous acute pancreatitis. However, the majority of studies have focused on the discrimination between mild and severe acute pancreatitis, according to the original Atlanta classification of 1993. Herein, CRP achieves

diagnostic accuracy rates between 70% and 80% at a cut-off level >150 mg/L within 48 hours after disease onset [56,60]. As is well documented for all acute-phase proteins, CRP is not useful for prediction of infected necrosis, organ failure, or death within the first week after disease onset [53,61]. Another shortcoming of CRP is the relatively long delay in its induction, with systemic peak values at 72–96 hours after disease onset, thus making very early severity assessment impossible.

#### Serum Amyloid A

Despite its earlier release and wider dynamic range, SAA failed to show any relevant benefit over CRP in estimating severity or prognosis of acute pancreatitis [55,57]. Therefore, this alternative acute-phase reactant has never achieved meaningful clinical application.

## Cytokines and Chemokines

A wealth of experimental and clinical studies during the 1990s convincingly demonstrated that cytokines and chemokines play a key role in the pathophysiology of acute pancreatitis by promoting local tissue destruction and mediating distant organ complications [62,63]. As a consequence, cyto- and chemokine measurement was thought to offer an excellent approach to biochemical severity assessment. Despite the development of fast and fully automated assay techniques, however, the vast majority of cytokine and chemokine family members play no role as biochemical markers for acute pancreatitis in the clinical setting. So far, only the cytokine interleukin 6 (IL-6) and the chemokine interleukin 8 (IL-8) have passed from pathophysiologic importance to clinical application.

#### Interleukin 6

Systemic concentrations of IL-6 have been found to be early and excellent predictors of severity. A large number of clinical studies have uniformly shown that IL-6 is dramatically increased in complicated attacks [53,59,64–66]. IL-6 concentrations generally rise 24–36 hours earlier than CRP levels and remain significantly elevated as long as complications persist. One of the first series in 24 patients from Glasgow found a sensitivity of 100% and a specificity of 71% (PPV 71%, NPV 100%) at a cut-off level >130 IU/mL for IL-6 in predicting a severe attack within 36 hours of symptom onset [64]. Beyond discriminating mild from severe attacks, IL-6 closely correlates with evolving organ failure [53,59,65]. IL-6 has been introduced as a routine parameter in some laboratories and represents an easy and rapid means to select patients at risk of developing severe disease. However, a large-scale application of IL-6 measurements in acute pancreatitis has never been carried out.

#### Interleukin 8

IL-8 was initially described as an early marker of disease severity within the first day after onset of symptoms, with a rapid decrease after 3–5 days [66,67]. However, beyond simple discrimination of mild from severe attacks an even more interesting aspect of IL-8 assessment was described by our group in 1997. In patients with necrotizing pancreatitis who developed septic multiple organ failure or died during the later stages of the disease, IL-8 has proven to be an excellent marker for monitoring these life-threatening complications [61]. As for IL-6, a fully automated assay is available for IL-8 and the use of this chemokine for disease monitoring has become possible on a routine basis in large hospitals, but is still not widely used as a marker in acute pancreatitis.

## Procalcitonin

Ever since its first description in 1993 [68], procalcitonin (PCT) has been an established marker for predicting bacterial/fungal infections, sepsis, and septic shock in the intensive care setting [69,70]. A close correlation between elevated PCT concentrations and the development of infected necrosis was first described in a cohort study comprising 51 patients with acute pancreatitis by our group in 1997. At a cut-off level of >1.8 ng/mL, PCT was able to predict this complication with a sensitivity and specificity of more than 90% within the first days after onset of symptoms [61]. An international multicenter trial in 104 patients with severe acute pancreatitis has shown that PCT is able to predict serious complications such as pancreatic infections or death with a sensitivity of 79% and a specificity of 93% (PPV 65%, NPV 97%) at a cut-off level >3.8 ng/mL within 48–96 hours after onset of symptoms [71]. This observation was confirmed by a number of subsequent studies which have been subjected to a meta-analysis and a systematic review. Herein, PCT reached a cumulative sensitivity of 80% and a specificity of 90% for predicting infected necrosis in acute pancreatitis [54,72]. Notably, PCT is of little or no value for simple stratification of patients as "mild" or "severe" according to the original Atlanta classification of 1993. PCT measurements are available as fully automated assay for routine use; a semiquantitative strip test is an alternative for fast and easy quantification. On the basis of the data available, PCT is a valuable tool for early stratification and consecutive monitoring of patients at risk of developing the most serious complications in acute pancreatitis.

**Table 21.2** Relevant multiparameter scoring systems and laboratory markers for severity stratification and prediction of specific complications in acute pancreatitis.

| Variable | Severity | Pancreatic infection | Overall prognosis |
|---|---|---|---|
| Ranson/Imrie score | ++ (48 h) | – | ++ (48 h) |
| APACHE II score | ++ | – | +++ (>7 d) |
| SOFA/Marshall score | ++ | – | +++ (>7 d) |
| Hematocrit | ++ (48 h) | – | – |
| Creatinine/blood urea nitrogen | + | – | ++ (>7 d) |
| IL-6 | +++ (<48 h) | – | – |
| IL-8 | ++ (<48 h) | Sept. MODS (monitoring) | +++ (>7 d) |
| CRP | +++ (72–96 h) | – | – |
| PCT | – | +++ (72–96 h) | +++ (72–96 h, >7 d) |

Optimum accuracy after symptom onset of acute pancreatitis:
<48 h: within 48 h after symptom onset
72–96 h: within 72–96 h after symptom onset
>7 d: beyond the first week after disease onset
APACHE II, acute physiology and chronic health evaluation II; SOFA, sequential organ failure assessment; IL-6, interleukin 6; IL-8, interleukin 8; CRP, C-reactive protein; MODS, multiple organ dysfunction syndrome; PCT, procalcitonin.

## Overview

Table 21.2 provides an overview of relevant multiparameter scoring systems and laboratory markers for severity stratification and prediction of specific complications in acute pancreatitis.

## Introduction

Acute pancreatitis secondary to congenital anomalies remains an uncommon cause of childhood abdominal pain, with a more varied etiology than adult-onset pancreatic inflammation. Although several hereditary syndromes have been associated with acute pancreatitis, the most commonly encountered congenital causes are developmental abnormalities of the pancreaticobiliary system, such as pancreas divisum, annular pancreas, ectopic pancreatic tissue sources, enteric duplication cysts, and choledochal cyst [1]. Congenital structural variants of the pancreas occur in up to 10% of the Western population [2], but the majority are silent as the incidence of pancreatitis is two orders of magnitude less [3]. Biliopancreatic ductal system variants encountered during diagnostic evaluation of idiopathic acute pancreatitis plague the clinician with a significant question of relevance regarding consequence and management.

## Pancreas Divisum

The cause, incidence, clinical relevance, and treatment of pancreatitis in patients with pancreas divisum has been hotly debated. In complete pancreas divisum, the ventral and dorsal pancreatic ducts do not communicate, and usually the dorsal pancreatic duct is larger than the ventral (Fig. 22.1a) [4]. Acute pancreatitis may result from obstruction at the minor papilla, a junction in the ductal system, or from localized ductal ectasia in the uncinate process [5]. Pancreatitis is experienced by 0.1% of the population, whereas pancreas divisum is present in 4–5%; this makes pancreas divisum questionable as the inciting source [6–8]. The disparity is likely due to selection bias because some patients are referred after endoscopic retrograde cholangiopancreatogram (ERCP) failure for suspected idiopathic pancreatitis, leading to a possible false association between idiopathic pancreatitis and pancreas divisum.

Whether by sphincteroplasty for acute pancreatitis or longitudinal pancreaticojejunostomy for more distal chronic obstruction, treatment is directed at relief of the obstruction. Accessory papilla sphincteroplasty for stenosis improved symptoms and was best predicted by presentation with pancreatitis and a positive ultrasound-secretin test [9]. Surgical dual sphincteroplasties for dysfunction of the pancreaticobiliary sphincters in pancreas divisum results in good to excellent outcomes [10]. Smaller studies have reported various success rates with endoscopic sphincterotomy and longitudinal pancreaticoduodenectomy, with morbidity rates ranging from 15% to 40% [5,10]. Duodenum-preserving pancreatic head resection in patients with chronic pancreatitis and pancreas divisum demonstrated significant improvement in symptoms (31%) [11]. Three-quarters of adults have a good response to surgery [9,12]. Treatment of pancreas divisum in acute pancreatitis yields better results than in chronic pancreatitis or chronic pain syndrome. Poor postsurgical results in chronic pancreatitis are reported in both adults and children [5,9].

**Figure 22.1** (a) A 15-year-old girl presented with recurrent attacks of pancreatitis. Endoscopic retrograde pancreatography showed pancreas divisum with cystic dilation of the ventral pancreatic duct containing stones. She was treated by pancreaticoduodenectomy. (b) Cholangiopancreatogram in a 12-year-old boy with a choledochal cyst and anomalous pancreaticobiliary junction. The pancreatic duct inserts into the common bile duct more than 2 cm proximal to the ampullary orifice. Such patients are prone to acute and chronic pancreatitis.

## Anomalous Pancreaticobiliary Ductal Union

Anomalous pancreaticobiliary ductal union (APBDU) results from the pancreatic and common bile ducts joining proximally to the ampulla of Vater with a hypothesized resulting admixture of refluxed pancreatic and biliary secretions into the biliary tree or pancreas [13,14] and has been associated with a higher incidence of congenital choledochal dilation (Fig. 22.1b) [14–17]. APBDU has been further defined as a common channel greater than 15 mm in length or a contractile segment totally distal to the biliary and pancreatic ductal union [18,19]. APBDU is further delineated into B-P or P-B subtypes according to the order of insertion of the pancreatic and biliary ducts [19,20]. In B-P, the bile duct enters the main pancreatic duct and in P-B (or in some series, P-C for choledochal) the pancreatic duct enters the common bile duct [19].

APBDU has been considered a factor in the development of pancreatitis, choledochal cyst, and hepatobiliary cancers [19]. APBDU was identified by ERCP in 8.7% of patients with an incidence of 13.2% for biliary pancreatitis and 2.2% for nonbiliary pancreatitis. Patients with B-P subtype associated with choledochal cyst formation whereas the P-B subtype was associated with biliary pancreatitis, gallbladder cancer, and adenomyomatosis. A proposed mechanism for this relatively high rate of pancreatitis and the observation of recurrent pancreatitis in patients with APBDU is sphincter of Oddi dysfunction [21].

Surgical treatment of APBDU relies on disruption of the contiguous anatomical relationships. Roux-en-Y hepaticojejunostomy is offered [22], but cholecystectomy and alternate biliary tract reconstruction [23] or endoscopic sphincterotomy alone can be beneficial [21]. APBDU with choledochal cysts are often managed by cyst excision, although duodenopancreatectomy may be required [24].

## Choledochal Cyst/Choledochocele

Choledochal cysts are noted in 0.1% of adult ERCPs and in 1 in 150 000 North Americans [25,26]. Rates are higher in East Asia and in females, with a male to female ratio of 1:3–4, and associated pancreatitis is more common in younger patients aged 2–16 years (36%) [27]. The classic triad of abdominal pain, jaundice, and a palpable right upper quadrant abdominal mass occurred 6.7 times more frequently in children [28], with 50% of adult patients presenting with abdominal pain diagnosed as pancreatitis or biliary tract pathology prior to cyst identification [29]. Cyst rupture most commonly presents with pancreatitis, cholangitis, and biliary peritonitis [30]. Cysts greater than 5 cm were associated with pancreatitis in 90% of patients and resection led to lower rates of pancreatitis than surgical bypass (50% vs. 80%). Pancreatitis and cancer were more common in patients with both choledochal cyst and APBDU [31]. The possible role of APBDU in causing choledochal cysts is discussed in the previous section.

Choledochal cysts were first classified according to the 1977 Todani system [32,33]. Except in the case of type III disease, in which endoscopic approaches or marsupialization may be indicated, complete excision of the extrahepatic choledochal cyst with hepaticojejunostomy is

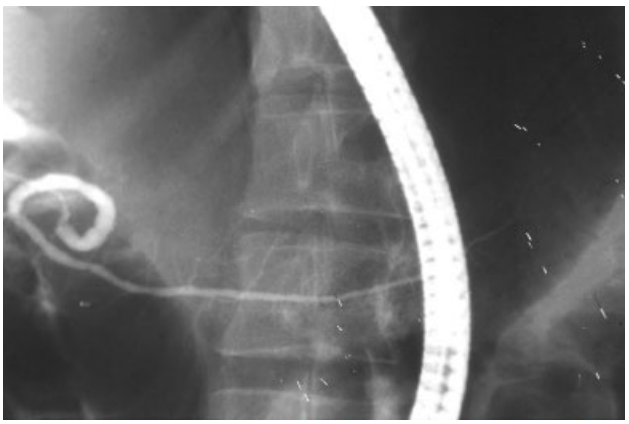
the goal [34,35]. Malignancy is identified increasingly with choledochal cyst retention; therefore internal drainage or bypass procedures should be accompanied by a near-complete resection [27]. Interposition of the jejunum or appendix are unsuitable due to high rates of graft dysfunction and cholangitis [36,37].

## Annular Pancreas

Annular pancreas, potentially arising from dorsal and ventral anlage hypertrophy or abnormal adherence of the ventral duct to the duodenum during rotation, envelops the duodenum (Fig. 22.2a,b) [38]. Obstruction or pancreatic inflammation secondary to annular pancreas occurs in the third decade of life or later with a prevalence of roughly 25% [39,40]. Pancreatitis secondary to annular pancreas is rare in the newborn and presents with duodenal blockage, with bilious emesis and "double bubble" on abdominal films [39,41]. Differentiation between upper obstruction etiologies, such as duodenal atresia, malrotation without volvulus, and annular pancreas, must not delay emergent operative care in the case of volvulus. Annular pancreas is associated with a high rate of congenital anomalies: 70% of infants with annular pancreas will have another anomaly, such as duodenal stenosis or atresia (40%), Down syndrome (16%), tracheoesophageal fistula (9%), or congenital heart defects (7%) [39].

Surgical correction of annular pancreas in childhood is usually undertaken by performing diamond duodenoduodenostomy and leads to faster feeding and discharge when compared to side-to-side anastomosis or duodenojejunostomy [42]. Gastrojejunostomy should be avoided in children as the most anatomic reconstructions are linked to the best growth outcomes [43]. Surgical correction in adults follows suit, with less concern about growth retardation with gastrojejunostomy. Pancreaticoduodenectomy with and without pyloric preservation for resection of annular pancreas and associated ampullary carcinoma has been described [44]. In any case of duodenal obstruction, volvulus must be first excluded as a life-threatening surgical emergency.

(a)



(b)

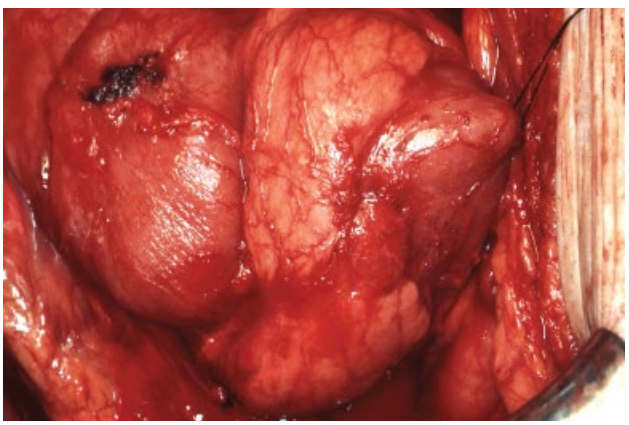


**Figure 22.2** (a) Pancreatogram in a young boy with annular pancreas. The proximal pancreatic duct encircles the duodenum within the annular segment. (b) Annular process.

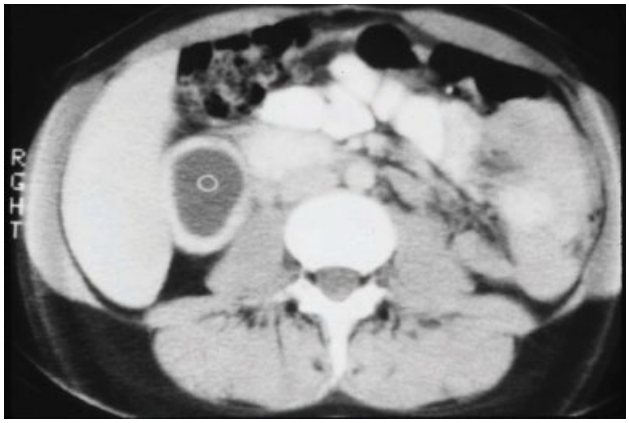
## Ectopic Pancreatic Tissue

Ectopic pancreatic tissue is a relatively common anomaly with an incidence of up to 13% [43,45]. A normally organized aberrant rest of pancreatic tissue is discontinuous with the entopic pancreas. A majority are identified in the submucosa of the stomach, duodenum, and jejunum [38] and although uncommon, come to clinical attention due to intussusception, obstruction, inflammation, or degeneration [46,47]. Inflammation of an ectopic pancreas without pseudocyst with both elevated serum amylase and lipase and ectopic tissue inflammation has been reported [45,48]. In a total of 32 histologically documented cases of ectopic pancreas, half were identified incidentally [49]. The remaining cases were clinically significant for hemorrhage, obstruction, or ulceration. A tentative link between ectopic pancreatitis in the duodenal wall and duodenal stenosis has been established in six pancreaticoduodenectomy specimens [50].

## Enteric Duplication Cysts

Gastrointestinal duplication cysts are congenital foregut anomalies with gastrointestinal mucosa of any type or pancreatic tissue and are named for their anatomic proximity rather than mucosal content [39]. Duplication

(a)



(b)

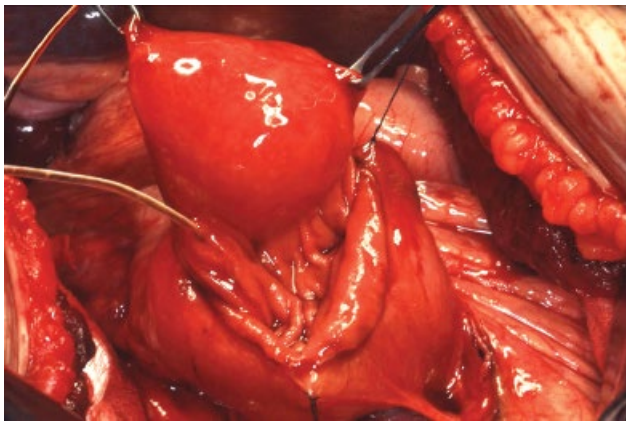


**Figure 22.3** (a) CT scan in a 21-year-old woman with a history of several years of recurrent acute pancreatitis. The white circle marks an abnormal thick-walled cystic structure adjacent to the head of the pancreas. (b) Operative photograph of the pancreatic duplication cyst bulging into the duodenal lumen as previously identified on abdominal CT. The catheter has been introduced through the ampulla into the pancreatic duct. Excision of the cyst with suture ligation of its narrow neck cured her recurrent pancreatitis.

cysts within the pancreas have been reported and are generally termed as duodenal or gastric duplications since they lack a contiguous structure (Fig. 22.3a,b) [46]. Although most enteric duplications do not present with pancreatitis, multiple cases have been identified [51]. Duodenal duplication occurs in 10% or fewer cases and may cause "obstructive pancreatitis" from compression between the duodenal wall and the biliopancreatic duct [52,53]. Juxta-pancreatic duplications with pancreatic ductal communication may shed blood or mucus into the main pancreatic duct, resulting in obstruction [54–56]. Pancreatitis may occur within the duplication itself, as is found in esophageal duplications containing gastric mucosa and pancreatic tissue (43%) [57]. Local resection is preferred; however, marsupialization of cysts with removal of mucosa may be employed if local resection is not possible [58].

## Conclusions

Infrequently, congenital anomalies may be the cause of idiopathic acute pancreatitis. Nonanatomic congenital causes must be assessed by diligent investigation. Regarding anatomic congenital anomalies, strict definition of the anatomic relationships and associated anomalies is necessary to direct appropriate therapy. Because congenital anomalies are often unique, unusual anatomic relationships may be discovered in each case. Previous case series in the literature provide useful longitudinal data to help in predicting outcomes and avoiding known pitfalls.

## Introduction

The Second International Symposium in Marseilles in 1984 defined acute pancreatitis as acute abdominal pain accompanied by the finding of increased pancreatic enzymes in blood or urine [1]. However, the pathophysiology of acute pancreatic inflammation has remained difficult to describe, partly due to the relative inaccessibility of the pancreas on physical examination, and to the frequently nonspecific nature of symptoms resulting from diseases of the pancreas. Despite these difficulties, understanding of adult pancreatitis has increased in an exponential manner in recent decades. Unfortunately, the understanding of the pediatric counterpart has lagged behind, although progress has been made in recent years.

Pediatric acute pancreatitis poses a great challenge to clinicians. Depending on the age and developmental level of a child, it can be extremely difficult to assess the nonspecific symptoms of abdominal pain and nausea or vomiting. Defining the location and nature of the pain and identifying factors that aggravate or alleviate the pain can be particularly challenging in a pediatric patient. Compounding this challenge is that many healthcare professionals do not consider pancreatitis in the differential diagnosis of pediatric abdominal pathology. Hence, children may experience symptoms from pancreatic inflammation and be labeled as suffering from "viral gastroenteritis." For all these reasons, unraveling the complexities of pediatric acute pancreatitis remains an ongoing process.

The challenges in pediatric acute pancreatitis lie in three major areas:

- potential etiologies, many of which are more particular to children;
- diagnosis, including serum biochemistry and imaging techniques;
- assessing and following for disease severity and complications.

This chapter will strive to cover these areas as they pertain to pediatric acute pancreatitis.

## Incidence

The prevailing impression among pediatric specialists is that the incidence of pediatric acute acute pancreatitis is increasing. A number of population-based series have attempted to quantify the incidence of acute pancreatitis [2–8]. These studies suggest that the incidence of acute pancreatitis in children has truly increased over the past several decades. Since the initial study by Lopez showing a steady increase in the absolute number of cases of acute pancreatitis per year in a single institution, a number of other centers throughout the world have reported similar observations [2] (Table 23.1). An estimate of incidence ranged from 1 to 3 cases per 10 000 children. Proposed explanations for the increasing diagnosis of acute pancreatitis in children include increased awareness that the disease occurs in children, a true rise in new cases, increased referral of children to tertiary care centers, and an increase of acute pancreatitis in children with other systemic diseases [2,9,10]. Likely, a combination of these events explains the increased incidence.

## Etiology

An adult presenting with a first episode of acute pancreatitis is questioned and investigated to identify the presence of one of two major etiologies for adult acute

**Table 23.1** Series looking at the incidence of acute pancreatitis. Studies reporting increase in number of cases of acute pancreatitis diagnosed in children over time.

| Location | Years | Author | Incidence in last year | Further study details |
|---|---|---|---|---|
| United States: Children's Medical Center of Dallas | 1993–1998 | Lopez [2] | Not reported | Total cases/yr: 5, 19, 20, 38, 79, 113 (1993–1998) |
| United States: Children's Hospital of Pittsburgh | 1993–2004 | Morinville [9] | 1.3 per 10 000 children | Number of cases increased from 28 to 141 per year |
| Australia: Royal Children's Hospital, Melbourne | 1993–2002 | Nydegger [3] | 0.35 per 10 000 children | Consistent, progressive increase in cases of AP per year over the study period |
| United States: Children's Hospital of Wisconsin | 1996–2011 | Werlin [5] | Not reported | Noted a consistent increase in number of AP cases over study period with the exception of 2001 |
| Mexico: Hospital of Pediatrics, Guadalajara | 1990–2005 | Sanchez-Ramirez [4] | 53 per 10 000 hospitalizations | Reported a nonlinear increase in new cases over the study years |
| United States: Yale-New Haven Hospital | 1994–2007 | Park [10] | 8.9 per 10 000 ED visits | Increase in number of patients admitted for AP over time. Normalization to number of ED visits showed same rate per 10 000 visits |
| United States: Healthcare Cost and Utilization Project Kids' Inpatient Database | 2000–2009 | Pant [6] | 35 per 10 000 hospitalizations | Relied on ICD9 codes to identify 55 012 patients |
| United States: Nationwide Emergency Department Sample | 2006–2011 | Pant [7] | 1.6 per 10 000 ED visits | Relied on ICD9 codes to identify 78 787 patients with ED visits for AP |
| United Kingdom: Liverpool | 1999–2009 | Wilkinson [8] | 0.3 per 10 000 children | Identified patients by ICD10 codes from Hospital Episode Statistics database |

AP, acute pancreatitis; ED, emergency department.

pancreatitis—biliary disease and alcohol ingestion. These, in fact, appear to account for the majority of cases in adults. In children, by contrast, the etiologies of acute pancreatitis are more broadly divided (Table 23.2). Table 23.3 and Fig. 23.1 summarize a number of recently published series of pediatric acute pancreatitis and the breakdown of presumed etiologies [2,5,11–17]. Of note, the large series by Benifla and Weizman included a summation of many previously published series [13]. In general, the largest categories are divided up among idiopathic (22%), trauma (17.3%), systemic (15%), structural (13.5%), and medications (10%). A large series by Tomomasa et al. [11] was not included in the Benifla and Weizman review, partially due to the large preponderance of biliary–anatomic causes reported in Japanese children [11,13]. As a child presenting to a major urban hospital may originate from any location around the globe, the Japanese experience was included in Fig. 23.1. Previously labeled "idiopathic" cases may in fact be related to unidentified infections, drugs, toxins, or trauma, and recent work on genetic influences suggests that many cases of "idiopathic" pediatric acute pancreatitis may in fact represent genetic predispositions [19]. Factors may act alone or jointly to lead to a clinical episode of acute pancreatitis.

## Pathophysiology

The pathophysiology of pediatric acute pancreatitis is believed to be identical to that of adult acute pancreatitis (Chapter 18).

## Investigations

The great diversity of potential etiologies of acute pancreatitis is demonstrated in Table 23.2. Clinical finesse is involved in determining which causes should be considered for each child presenting with a first episode of acute pancreatitis. Unlike many pediatric diseases, the etiology of acute pancreatitis does not vary significantly among individual age groups [20,21]. A stepwise consideration of probable, possible, and rare etiologies in conjunction with elicited history of present illness, past medical history, family history, and findings on physical examination will direct investigations and

**Table 23.2** Potential etiologies of acute pancreatitis. The differential list is extensive. A clinician must consider the particular patient's history of present illness, past medical history, and family history in considering the potential trigger of an attack of acute pancreatitis [2,5,10,11,14–16,20–27].

limit invasive and sometimes painful procedures for the pediatric patient, as well as minimize unnecessary costs.

Children in families already identified as having inherited predispositions to pancreatitis tend to be more quickly investigated for such a possibility. However, physicians should remember that a child may be the proband in a family that has never had a formal diagnosis of pancreatitis despite family members experiencing symptoms compatible with the diagnosis, or having had adult family members diagnosed with alcohol-induced pancreatitis, despite a rather small ingestion of ethanol. A large series of European families with clinical hereditary pancreatitis reported the cumulative risk of having had symptoms by age 10 years as 40.3% and by age 20 years as 72.6% [22]. Although the overall number of persons with inherited causes of acute pancreatitis is small, within these families a large majority will present within the pediatric age range. For this reason, a thorough family history for documented pancreatitis, pancreatic cancer, pancreatic insufficiency including insulin-dependent diabetes, and/or family members exhibiting symptoms that could be consistent with acute recurrent pancreatitis should be sought.

## Diagnosis

In 2012, a multicenter group of pediatric gastroenterologists published a consensus statement defining acute pancreatitis in childhood [18]. The clinical diagnosis of acute pancreatitis requires the presence of at least two out of three criteria:

- a combination of abdominal pain that is consistent with pancreatic origin;
- the presence of elevated amylase or lipase or both to at least three times the upper limit of normal;
- radiological imaging with findings consistent with acute pancreatitis.

Even with these criteria the diagnosis of acute pancreatitis can present challenges for the clinician. History and physical examination findings are variable: there may be epigastric to right upper quadrant pain, left upper quadrant pain, back pain, nausea, vomiting, jaundice, tachycardia, guarding, or even signs of shock. In children under the age of 3, pain may present as increased irritability, and abdominal distension and fever were more common than in older children [15]. Furthermore, there is no absolute cut-off value for amylase and lipase above which a person definitely has acute pancreatitis and below which the diagnosis is excluded. Imaging studies are often normal. Clinicians must maintain a high degree of suspicion, especially in younger children in whom verbal communicative skills may be limited.

A particular pediatric consideration is that newborn levels of pancreatic type isoamylase are very low to nondemonstrable, and total amylase levels reach normal adult values by only approximately 8–16 months of age [29,30]. Pancreatic isoamylase activity might not even

Benifla and Weizman [13] reviewed prior series published between 1965 and 1999 in Canada, Israel, Hong Kong, Switzerland, Taiwan, UK, and USA.
[a] Based on 39 children.
[b] Based on 16 children.
[c] Some of the patients in this study had more than one etiology. The percentages of each etiology are calculated using the number of etiologies reported (253).
For each study, the percentage of cases based on etiologic category is listed. Due to rounding, percentages may not add exactly to 100.

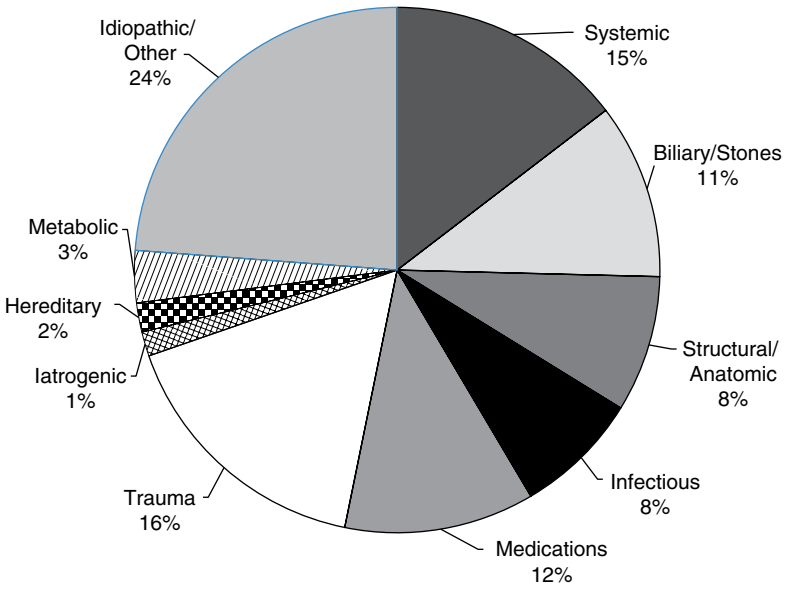

**Figure 23.1** Etiology of acute pancreatitis in 1961 children [2,5,10–17]. In contrast to adults, where biliary tree pathology and alcohol account for more than two-thirds of cases, children have a greater spread among the etiologic categories of acute pancreatitis. Please refer to Table 23.3 for breakdown of categories in each of the included series. The series of 204 children reported by Tomomasa in 1994 was not included in the Benifla review due to the large preponderance of biliary–anatomic causes reported in Japanese children [11,13]. The Japanese experience was included in this figure.

reach adult values until the age of 10–15 years [31]. In a similar fashion, lipase values at birth are significantly lower than those observed for adults and appear to have the greatest increase within the first year of life [32,33]. Hence, in a young patient, amylase and lipase levels may not always reflect potential pancreatic inflammation, particularly if adult ranges of normal enzyme levels are used as references. In addition, as has been demonstrated in adults, absolute elevation of amylase and/or lipase does not directly correlate with clinical severity or with imaging changes [34,35]. Even so, a recent publication demonstrated that serum lipase levels less than or equal to 7 times the upper reference limit were associated with a milder course [36].

Clinical scales are used to classify adults as having mild or severe disease [37–40]. Similar scales have not been widely applied or validated in children. In an attempt to classify the potential severity of acute pancreatitis in children, the Midwest Multicenter Pancreatic Study Group developed and validated a pediatric scoring system [15], in which age (<7 years), weight (<23 kg), admission white blood count (>$18.5 \times 10^9$/L), admission lactate dehydrogenase (>2000 IU/L), 48-hour fluid sequestration (>75 mL/kg per 48 hours), and a 48-hour rise in urea (>5 mg/dL) were each assigned a value of 1 point. Scale scores were found to correlate with disease outcome: a severe course (with associated higher morbidity and mortality) was predicted by a score of greater than 3 [15]. Subsequent authors have cautioned limitations of this severity scale [41]. More recently, a Japanese group published their experience using a pediatric version of a national acute pancreatitis severity scoring system that involves parameters collected 72 hours after onset of pancreatitis [42]. Within this system, base excess ≥ −3 or shock, $PaO_2 \leq 60$ mmHg, blood urea nitrogen (BUN) ≥40 mg/dL, lactate dehydrogenase (LDH) ≥2× upper limit of normal (ULN), platelet count ≤$1 \times 10^5$/mm$^3$, Ca ≤7.5 mg/dL, C-reative protein (CRP) ≥15 mg/dL, pediatric systemic inflammatory response score (SIRS) ≥3, and age <7 years and/or weight <23 kg were the factors of interest, with cut-off for predicting a severe outcome set at three criteria. They compared findings within this new scale to the Ranson, modified Glascow, and DeBanto scores and concluded that their scoring system, despite not being perfect, was sufficient to predict outcomes and identify children with severe acute pancreatitis. These few articles highlight that no single pediatric severity clinical scale has yet gained widespread acceptance and utilization, and thus pediatric severity indices represent an area of necessary research.

## Imaging

Imaging methods may be helpful in (i) diagnosis, (ii) determining severity and complications, and (iii) visualizing any anatomic factors leading to acute pancreatitis.

Transabdominal ultrasonography (TUS) is widely available, relatively inexpensive, and does not expose a child to radiation or contrast agent. In a well-looking child, TUS should strongly be considered as the initial diagnostic modality in suspected acute pancreatitis. It can be performed repeatedly in almost any setting to follow the course of illness and does not require procedural sedation [43]. Ultrasonography may demonstrate enlargement of the pancreas, altered echogenicity, duct diameter abnormalities, and fluid collections (intra- or extrapancreatic) [44], as well as abnormalities of the pancreaticobiliary drainage system, including the presence of a choledochal cyst or common bile duct stones. Limitations include air within the stomach interfering

with image acquisition from the body and tail of the pancreas, and differentiation of normal from abnormal pancreas in cases of pancreatitis where echogenic changes may or may not be present.

Computed tomography (CT) with contrast may be useful in more severe cases of acute pancreatitis and in order to assess for local complications [45–48]. Adult guidelines suggest using CT early in cases of diagnostic uncertainty or for assessment of acute pancreatitis severity 72–96 hours after onset of symptoms [49]. In this school of thought, CT would be best used not at initial presentation but only in necessary instances for assessment of severity in complex cases and for longer term follow-up of complications [5].

The capability of magnetic resonance cholangiopancreatography (MRCP) (with or without secretin) to diagnose most cases of pancreas divisum, choledochal cyst, cholelithiasis, pancreaticobiliary junction anomalies, and obstructive abnormalities has decreased the use of endoscopic retrograde cholangiopancreatography (ERCP) for diagnostic purposes [50–57]. Some have reported limitations in the (nonsecretin-enhanced) MRCP diagnosis of anomalous pancreaticobiliary junctions and so suggest ERCP may have a role in diagnosis of these. The use of certain fruit juices as enteral negative contrast agents may offer improved quality of MRCP images [58]. Although MRCP offers imaging without radiation, there are still pediatric factors to take into consideration. Due to the relatively long duration of the procedure (15–45 minutes), younger children will require sedation, ranging from oral chloral hydrate to intravenous general anesthesia and intubation. In addition, the quality of MRCP images depends on the protocol utilized for image acquisition as well as the radiologist's interpretation of these.

When indicated, pediatric ERCP in experienced hands is reported to be as safe and effective as it is in adults [59,60]. ERCP is particularly useful in assessing pancreatic duct anatomy, abnormalities, and duct disruption [61]. Published pediatric uses include the drainage of nonresolving pancreatic pseudocysts [62], sphincterotomy [63,64], stent placement [65,66], the assessment of trauma-related pancreatic ductal injuries [67], and the management of pediatric acute recurrent pancreatitis [63,68] and chronic pancreatitis [66,69]. An important but seldom encountered indication is urgent ERCP-guided removal of an impacted common bile duct stone leading to cholangitis [23,70]. Recent technological developments are making pediatric ERCP increasingly accessible [24]. Principles for determining when to perform ERCP in a child have paralleled those used in adults [60]. The obvious difficulties with ERCP include the need for sedation (typically general anesthesia), the use of ionizing radiation/fluoroscopy, and the relatively high rate of complications reported in adults.

Experience with pediatric endoscopic ultrasound (EUS) has increasingly been reported in recent years. EUS provides detailed imaging of pancreatic parenchyma and ducts without the use of radiation, but with the need for sedation. Its benefits include not only its role in imaging, but also in interventions, with the capacity to sample tissue and fluid collections through fine-needle aspiration and biopsy, as well as accomplish drainage of fluid collections such as pseudocysts [71,72]. As endoscopists increasingly become comfortable with pediatric use of EUS, its role in diagnosis and management of acute pancreatitis will become better defined.

All radiological and endoscopic tests may offer complementary information regarding the cause or complications associated with pediatric acute pancreatitis. Clinicians must weigh the potential benefits offered by an imaging technology against the drawbacks particular to each technique and decide on an algorithm for a particular patient. Typically, pediatric patients are best first assessed by TUS. Subsequently, with a prolonged acute pancreatitis course, there may be a need for either MRCP or CT to better delineate anatomy and to visualize potential complications. With the need for a therapeutic maneuver, both ERCP and EUS are becoming increasingly child-friendly and experience to date is showing them to be safe and effective.

## Management

The general measures undertaken in children with acute pancreatitis are similar to those in adults. In the majority of pediatric acute pancreatitis cases, clinical improvement occurs within a few days and discharge is possible in less than a week. Several changes in management of patients with acute pancreatitis have occurred in recent years. The International Association of Pancreatology and the American Pancreatic Association have recently published guidelines regarding optimal management of acute pancreatitis in adults [49]. Studies in adults and children suggest that aggressive fluid resuscitation early in the course improves outcomes [70,73–75]. Though, details of intravenous therapy, such as volume, rate, timing and composition of the fluid are not firmly established. In one pediatric study, fluid rates 1.5–2 times maintenance in the first 24 hours shortened length of stay and severity of disease [73]. The other major change in management is the recognition that early enteral feeding, whether by mouth or feeding tube, is safe and improves outcomes [73]. Until recently, all data on early enteral feeding was in adults. Abu-El-Haija et al. reported the results of early enteral feeding in children with acute pancreatitis [76]. All patients had mild acute pancreatitis and those allowed to eat within 24 hours of admission took food orally. Early feeds did not increase pain or

length of stay. Patients with higher fat intake had significantly lower pain scores [76].

## Outcomes

Overall, children generally have a mild clinical course and only a small fraction have severe complications. Pseudocysts represent the most frequent complication occurring in 10–30% of cases [4,5,13]. They typically present as a persistent abdominal discomfort, abdominal mass on physical examination, continued elevation of pancreatic enzymes, or on follow-up imaging. These pseudocysts usually resolve spontaneously and rarely require intervention: percutaneous catheter drainage (radiological placement or surgical), pancreatic duct stenting via ERCP, open surgical cyst–enteric anastomosis drainage and, perhaps, antibiotic therapy [77,78]. In expert hands, pseudocysts may be amenable to EUS intervention [72].

Despite a generally positive outcome for pediatric acute pancreatitis, 6% or fewer children develop multiorgan failure or pancreatic necrosis [23]. Some studies have found an association between particular triggers of acute pancreatitis and serious complications. As might be predicted, it appears that children who have complex medical histories, including those experiencing acute pancreatitis post liver transplantation, or in the context of a systemic disease, are more susceptible to severe and potentially fatal courses [23]. Mortality data have rarely been reported in children. Available data are listed in Table 23.4. The overall death rate for the 3899 reported patients was 6.2%. A database study from 2000 to 2009 of 55 012 children hospitalized with acute pancreatitis reported a mortality rate of about 1.0% [6].

## Acute Recurrent Pancreatitis

Acute recurrent pancreatitis (ARP) may be defined as at least two distinct episodes of acute pancreatitis separated by a return to normal baseline status [18]. It has been estimated that 10–35% of children have recurrent episodes of acute pancreatitis [23]. Upon the first presentation, etiologies that are amenable to therapy should be sought and, if identified, managed appropriately (including hypercalcemia, hypertriglyceridemia, biliary factors, and structural abnormalities). Any reversible cause should be eliminated whenever possible (including culprit medications). With additional attacks other investigations should be considered. Secretin-stimulated MRCP may unveil anatomic abnormalities predisposing

**Table 23.4** Mortality data in pediatric acute pancreatitis series [3–5,10,12–17,79].

| Author | Total subjects | Total deaths (percentage) | Notes about the study |
|---|---|---|---|
| Alvarez Calatayud [12] | 31 | 9.7 | 3 children died as a result of shock.<br>7 required surgical treatment |
| Benifla [13] | 589 | 9.7 | Review of 18 pediatric studies since 1965 |
| Choi [14] | 56 | 0 | Cases between 1994 and 1999 |
| DeBanto [15] | 301 | 2.0 | Deaths occurred in criterion hospitals only |
| Pezzilli [16] | 50 | 2.0 | 9 cases labeled as “severe” |
| Tiao [17] | 61 | 1.6 | 15 cases required surgery |
| Werlin [5] | 180 | 6.1 | All who died had underlying systemic illness |
| Goday [79] | 331 | 0.3 | Patients admitted to PICU with a primary diagnosis of AP |
| Goday [79] | 1695 | 6.8 | Patients admitted to PICU with a secondary diagnosis of AP |
| Park [10] | 271 | 1.9 | Only 1 of 4 deaths related to AP |
| Sanchez-Ramirez [4] | 55 | 0.0 | No deaths |
| Nydegger [3] | 279 | 11.1 | Deaths in patients with underlying disease |

The table lists, whenever available, the reported mortality rates for the pediatric acute pancreatitis series listed in Table 23.3, as well as other reported series without detailed etiologies. Overall, there is a 6.2% death rate reported (240 children out of 3899 total in the 11 studies listed below). Death occurs predominantly in children with co-occurring systemic illnesses (for example, hemolytic uremic syndrome or leukemia). In the series by Tiao, the single death was in a patient with acute necrotizing pancreatitis following L-asparaginase treatment for leukemia [17]. In the series by Pezzelli, the patient who died had developed multiorgan failure [16]. In the series by Goday, the percentage mortality is significantly higher in children admitted to the ICU with a primary diagnosis other than acute pancreatitis versus those admitted with a diagnosis of acute pancreatitis [79].
PICU, pediatric intensive care unit; AP, acute pancreatitis.

to ARP. A recurrence of an "idiopathic" attack of acute pancreatitis should direct the physician to seek for genetic predispositions via one-time comprehensive genetic testing [19,24]. A recent single-study retrospective review found that almost half of children with ARP having genetic testing had at least one mutation identified in *PRSS1*, *SPINK1*, or *CFTR* [25]. In another large multicenter study, almost half of patients with ARP had mutations in *PRSS1, SPINK1, CFTR*, or *CTRC* [76]. Since not all patients had genetic testing or were screened for fewer than four genes in this latter study, the percentage of patients harboring gene mutations is likely higher. In the same study, 75% of patients with chronic pancreatitis had genetic mutations. Mutational analysis is now commercially available for these genetic loci. It is anticipated that a high proportion of children with ARP and chronic pancreatitis will have genetic predispositions eventually identified. Along with mutational analysis, a comprehensive search for rare causes of acute pancreatitis is typically indicated. As it is believed that recurrent attacks of acute pancreatitis may eventually lead to morphological changes of chronic pancreatitis, prevention of further pancreatic injury is a key interventional goal, and identification of etiologic factors represents the first step.

# Acute Pancreatitis Associated With Metabolic Disorders, Infectious Diseases, or Drugs

*Ali A. Aghdassi and Markus M. Lerch*

*Department of Medicine A, University Medicine Greifswald, Greifswald, Germany*

## Introduction

Excessive alcohol consumption and gallstones are by far the most frequent etiologic factors for acute pancreatitis, accounting for up to 70% of all cases. The remaining 30% are patients where no triggering event can be identified (idiopathic pancreatitis, approximately 15%). In 15%, rare causes are identified in association with acute pancreatitis. These include anatomical variants, metabolic disorders, drugs, tumors, genetic abnormalities, and infectious diseases. In this chapter we review some of the rarer causes of acute pancreatitis.

## Metabolic Diseases

Hyperlipidemia and hypercalcemia are the best-known metabolic causes for acute pancreatitis. To a lesser extent, diabetic ketoacidosis (DKA), a severe complication of diabetes mellitus, can cause pancreatitis [1,2].

### Hypercalcemia

Hypercalcemia often results from primary hyperparathyroidism, a disorder of the parathyroid glands that is defined by an inappropriate secretion of parathyroid hormone (PTH) [2]. Elevated calcium levels affect other organs, including the gastrointestinal tract. However, determination of the incidence of hyperparathyroidism-related pancreatitis is difficult because patients often harbor comorbidities such as concomitant alcohol abuse, cholecystolithiasis, or hypertriglyceridemia. In many cases a definite assignment of the etiology of acute pancreatitis is not possible because patients have additional risk factors for acute pancreatitis. A coincidence of pancreatitis has been observed in 1.5–6.8% of patients with primary hyperparathyroidism, for example. The highest incidences were reported from India where a higher predisposition for (tropical) calcific pancreatitis was also observed [3,4]. Mean serum calcium levels are higher in patients with primary hyperparathyroidism and coexisting acute pancreatitis (12.8–13.3 mg/dL) compared to individuals with hyperparathyroidism who do not develop pancreatitis (11.6–12.1 g/dL) [3,5,6].

Hypercalcemia resulting in acute pancreatitis may also be attributed to unrelated disorders of the parathyroid glands, although these cases are extremely rare. Reports of malignant tumors [7,8] and iatrogenic causes of hypercalcemia such as calcium-containing infusions during cardiac surgery [9] or for parenteral nutrition [10] show that high circulating calcium levels predispose to pancreatitis.

The molecular mechanisms of hypercalcemia-induced pancreatitis are gradually being resolved. $Ca^{2+}$ is important for intracellular signaling and homeostasis. Disturbances in intracellular calcium levels impair its signaling function and high cytosolic levels within the exocrine acinar cells trigger premature protease activation [11,12]. Blocking the uptake of calcium into the cells or chelation of intracellular ionized $Ca^{2+}$ largely prevents digestive zymogen activation and pancreatic damage [13,14]. Several clinical trials have been set up to investigate the possibility of reducing the incidence and severity of pancreatitis by interfering with the intracellular effects of calcium.

### Hypertriglyceridemia

It is known that elevated lipid levels are associated with cardiovascular diseases. However, hyperlipidemia is also a rare but well-established cause of acute pancreatitis as

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

well. This is mostly related to hypertriglyceridemia, because hypercholesterolemia by itself does not cause acute pancreatitis. Hypertriglyceridemia and hyperlipidemia in general are becoming more common in industrialized countries and it has been reported that over 1.5% of the US population has severe hypertriglyceridemia (defined as a serum concentration of 500–2000 mg/dL) [15]. Normal triglyceride levels for adults should be less than 150 mg/dL [16].

Acute pancreatitis secondary to hypertriglyceridemia is seen in between 1.3% and 3.8% of patients [17–19]. Typically, triglyceride levels above 1000 mg/dL (or 11.4 mmol/L) precipitate acute pancreatitis with a risk of around 5%. Triglyceride levels exceeding 2000 mg/dL more than double that risk to 10–20%.

Plasma triglycerides can be of exogenous or endogenous origin. Normally, dietary triglycerides are the main source and form the main lipid component in very low-density lipoproteins (VLDL). Once hydrolyzed in the small intestine they are resorbed and incorporated into chylomicrons and transported via lymphatic vessels to peripheral tissues for further utilization [19,20]. Cells of all parenchymal tissues secrete lipoprotein lipase that hydrolyze triglycerides and surface components of chylomicrons and VLDL to release free fatty acids for energy supply. Fatty acids are converted to fatty acid ethyl esters (FAEE) by carboxylester lipase (CEL), an enzyme also expressed in pancreatic acinar cells. FAEE themselves exert toxic direct effects on cells and also raise intracellular $Ca^{2+}$ concentrations that further promote cellular damage [21].

Patients with hypertriglyceridemia often have a concomitant history of diabetes mellitus (72%), hyperlipidemia (I, IV, and V according to Fredrickson's classification, 77%), alcohol abuse (23%), or gallstones (7%). Triglyceride levels are also elevated in the setting of DKA [18,22]. Typically, a lipid abnormality presents as a secondary factor (obesity, diabetes mellitus) whereas isolated hyperlipidemia (usually type I or V) is much less common [20]. Moreover, mild to moderate hypertriglyceridemia is not infrequently seen in alcoholic pancreatitis patients as a secondary effect of excessive alcohol consumption and this is much more common than hyperlipidemia-induced pancreatitis in association with primary or inherited forms of hypertriglyceridemia. Clinically, alcohol abuse still needs to be ruled out as the cause of acute pancreatitis whenever hypertriglyceridemia is diagnosed [20,23].

Diagnosis of hypertriglyceridemia-induced pancreatitis needs to be established early after disease onset because serum triglycerides levels usually fall rapidly after fasting periods and hypocaloric intravenous volume therapy [20].

It still remains controversial whether hypertriglyceridemia-induced pancreatitis tends to have a more severe course. Some data indicate that severe acute pancreatitis and organ complications may be more frequent in the presence of hypertriglyceridemia [23].

Initial treatment of hypertriglyceridemia-induced pancreatitis is the same as for other etiologies and includes fluid resuscitation, analgesia, and controlled oral food intake. In cases of severe acute pancreatitis and sustained excessive elevation of triglyceride levels lipid apheresis might be considered as a therapeutic option, but a clear benefit has not been consistently shown [24]. Emphasis should be laid on lifestyle modifications and lipid-lowering agents, fibrates in the first line, to prevent further attacks of pancreatitis [16].

### Diabetic Ketoacidosis

Acute pancreatitis can arise as a severe complication of DKA with a risk of a high mortality. Unfortunately it is often overlooked because abdominal pain or peritoneal irritation can result from ketoacidosis. Secondly hyperlipasemia/-amylasemia might be unspecifically elevated. Acute pancreatitis occurs in at least 10–15% of patients with DKA [22]. It has also been reported during nonketoacidotic hyperosmolar coma but this is very rare. The pathogenesis of acute pancreatitis in DKA is often attributed to hypertriglyceridemia that frequently occurs in parallel. Normally, hypertriglyceridemia is transient and resolves once DKA is corrected [22].

## Infectious Diseases

Data regarding the influence of microorganisms on acute pancreatitis and their incidence are rare and almost exclusively based on case reports. Sometimes it is not entirely clear whether other causes have been ruled out. Patients with acute pancreatitis based on an infectious agent often have a coexistent immunocompromising disorder or diabetes. The microbes involved include bacteria, viruses, fungi, and parasites (Table 24.1) [25].

### Bacteria

Numerous bacterial pathogens have been mentioned as causing acute pancreatitis but mostly they are described in single case presentations. Reports exist on *Mycoplasma*, *Legionella*, *Leptospira*, *Salmonella*, *Campylobacter*, and *Brucella* species as well as *Mycobacteria tuberculosis*. The pathogenesis of acute pancreatitis is most likely related to released bacterial toxins. Antimicrobial treatment was initiated upon diagnosis of bacteria-related acute pancreatitis in the majority of cases. However, some reports mention a resolution of pancreatitis with only symptomatic treatment.

**Table 24.1** Infectious agents associated with acute pancreatitis.

| Bacteria | Viruses | Fungi | Parasites |
|---|---|---|---|
| *Mycoplasma pneumoniae* | Paramyxovirus | *Aspergillus* | *Ascaris lumbricoides* |
| *Legionella pneumophila* | Hepatitis virus A–C, E | *Candida albicans* | *Toxoplasma gondii* |
| *Salmonella enteritidis* | Human immunodeficiency virus (HIV) | | *Cryptosporidium parvum* |
| *Campylobacter jejuni* | Varicella zoster virus<br>Coxsackievirus (most severe) | | *Plasmodium falciparum* |
| *Leptospira interrogans* | Herpes simplex virus | | *Strongyloides stercoralis* |
| *Brucella melitensis* | Cytomegalovirus | | *Fasciola hepatica* |
| *Mycobacterium tuberculosis* | Influenza virus (H1N1) | | *Clonorchis sinensis* |

### Viruses

Of all the infectious agents, most reports exist on mumps virus and its relation to acute pancreatitis. Paramyxovirus causes mumps and although this disease usually has a mild course, pancreatitis was reported in around 4% of mumps patients [26,27].

The association between hepatitis A, B, and C viruses and acute pancreatitis has also been described. Hepatitis E infections are increasingly diagnosed in Western countries and reports on associated acute pancreatitis have been published [28]. Acute pancreatitis usually has a favorable outcome when related to viral hepatitis.

Human immunodeficiency virus (HIV)-positive patients with the diagnosis of acquired immune deficiency syndrome (AIDS) are also at risk for acute pancreatitis. So far, data are not conclusive whether these patients suffer from a more severe course of the disease. Severe acute pancreatitis was reported in 10–50% of patients with AIDS [29]. Modern therapeutic regimens for HIV/AIDS are associated with a much lower incidence of acute pancreatitis and a lesser degree of severity than earlier regimes that included the use of high pentamidine and didanosine concentrations [30].

By far the greatest severity of pancreatitis via a non-HIV virus is that associated with coxsackievirus B infections, for which experimental animal models have also been established. Other suspected viruses include varicella zoster virus, causing chickenpox [30], influenza [31], herpes simplex, Epstein–Barr, and cytomegalovirus [25].

### Fungi

Data on fungal infections causing acute pancreatitis are extremely rare; more often fungi manifest as a late infectious complication of severe acute pancreatitis with infected necrosis. *Candida* sp. is the most common fungal microorganism that is seen secondary to pancreatitis [32]. There is one review that mentions *Aspergillus* species as a potential causative agent for pancreatitis [25]. Most fungal infections involving the pancreas are superinfections of pancreatic or extrapancreatic necrosis and thus secondary events. Once they occur they have a negative effect on outcome and mortality. Prior antibiotic treatment of (bacterially) infected necrosis does not appear to increase the rate of fungal infection of necrosis.

### Parasites

Some case reports exist on acute pancreatitis caused by *Toxoplasma*, *Cryptosporidium*, *Ascaris*, *Plasmodium falciparum* infections or helminths (*Strongyloides*) [25,33,34]. An immunomediated mechanism is discussed as being the underlying mechanism but even immunocompetent individuals can develop pancreatitis. For parasites such as *Ascaris lumbricoides*, *Fasciola hepatica*, and *Clonorchis sinensis* the disease mechanism is identical to that of gallstone-induced pancreatitis: impaction in the duodenal papilla and obstruction of the pancreatic duct. They account for up to 5% of cases of "biliary" pancreatitis in some parts of Asia and China and endoscopic removal of the parasite from the papilla remains the therapy of choice.

## Drug-Related Diseases

According to the World Health Organization (WHO) more than 525 drugs have been reported to cause acute pancreatitis as a potential side-effect. It is expected that the number of medications will increase in parallel with the approval of new drugs and accumulating case reports [35]. However, the level of evidence differs as knowledge is essentially extrapolated from case reports with varying strength in quality [36,37]. By definition, case reports only produce the lowest level of evidence in epidemiological studies. Moreover, drug-related acute pancreatitis is usually not accompanied by other clinical

or laboratory signs of adverse drug reactions, such as a rash, lymphadenopathy, or eosinophilia. Therefore diagnosis is often difficult to establish [38]. A rechallenge with the suspected drug and induction of an additional attack of pancreatitis (after initial withdrawal) allows researchers to conclude potential causality but is not definitive proof. Apart from this challenge, ethical considerations limit the use of re-exposure to a drug in order to trigger a second attack of pancreatitis with its potential complications.

The incidence of drug-induced pancreatitis is low and is estimated to account for 0.1–2% of all cases [39,40]. Very young and older people, women, and patients with immunosuppressive disorders (such as HIV) or inflammatory bowel disorders are at higher risk. Risk increases in these groups by up to fourfold and is most probably related to immune-mediated reactions and the types of drugs prescribed for these disorders [35,37,41].

There are different ways to classify drugs according to their risk of causing adverse events. With regard to acute pancreatitis the classification model of Badalov and coworkers from 2007 is currently the most frequently used. It subdivides drugs into four groups (class I–IV), based on the quality of published evidence for each agent reported as having caused acute pancreatitis [42]:

- *Class I*: Group with the highest level of evidence and the presence of a positive rechallenge test for the drug. Class I drugs can be further subdivided into those in which other potential causes for acute pancreatitis (i.e., alcohol, gallstones, hypertriglyceridemia) have been ruled out (Ia) and those where other causes were not excluded in the relevant reports (Ib).
- *Class II*: At least four case reports for the particular drug are required. In addition, ≥75% of the cases must show a consistent drug latency, meaning that time of onset of pancreatitis is within a reasonable time frame after drug consumption. The mean interval between initial drug intake and start of symptoms is around 5 weeks, with a wide range of 2–36 weeks [43].
- *Class III*: At least two case reports exist but there is neither a consistent latency among the cases nor a published rechallenge test.
- *Class IV*: Weakest level of evidence based on a single case report, no rechallenge test was done.

Alternatively, drug-related adverse effects are classified by application of the Bradford Hill criteria. Nine different criteria evaluate the evidence of causation and one of them is the claim for biological plausibility, meaning that the proposed causality must have been shown in an experimental laboratory setting [44].

A third classification system groups drugs according to a definite, probable, or possible causality for an adverse reaction. The main characteristics include (i) a reasonable temporal relationship from drug intake to onset of symptoms, (ii) a known underlying pharmacological mechanism, (iii) presence or absence of other causes for the particular side-effect, and (iv) recurrent disease after rechallenge [45]. Depending on the quality of the case report, it can happen that a suspected medication might be classified once as a definite and once as a probable risk factor [37].

The underlying mechanism of drug injury on the pancreas is likely based on idiosyncratic reactions. This type of reaction is characterized as being unpredictable, dose independent, and with varying latency. From a pathophysiological point of view idiosyncratic reactions are often mediated by an immunologic or cytotoxic mechanism of the specific compound or its metabolites. Unfortunately, they are difficult to reproduce in experimental animal models, whereas effects of intrinsic toxicity are mimicked more easily. Intrinsic toxicity implies organ damage in a dose-dependent way and is usually seen as toxicity after drug overdoses. With regard to the pancreas there are only a few reports based on an intrinsic mechanism covering acetaminophen, erythromycin, and carbamazepine [42].

A list of drugs often named in association with acute pancreatitis is given in Box 24.1. In addition, some of the most frequently cited drugs and their corresponding potential pathophysiological mechanisms are discussed here.

Nonsteroidal anti-inflammatory drugs (NSAID) have been proposed to induce acute pancreatitis, probably due to inhibition of prostaglandins. Prostaglandins seem to have a protective and membrane-stabilizing effect on pancreatic cells, as shown in experimental models [35,46]. The highest risks were reported for diclofenac (odds ratio [OR] 5.0) and the lowest for naproxen (OR 1.1). Use of selective COX-2 inhibitors can lower the risk for acute pancreatitis [37,47] and unselective NSAID given prophylactically as suppositories have been shown to lower the rate of endoscopic retrograde cholangiopancreatography (ERCP)-induced pancreatitis, at least in very high-risk patients.

Estrogens, which are also used in oral contraceptives, may induce acute pancreatitis by reducing lipoprotein lipase activity, which then increases serum triglycerides and fatty acids. These components are known to be precipitating factors for acute pancreatitis [48].

Angiotensin-converting enzyme (ACE) inhibitors such as captopril, enalapril, lisinopril, and others decrease degradation of bradykinins that are released during acute pancreatitis. Bradykinins cause a local angioedema that could favor tissue edema or pancreatic duct obstruction and subsequent organ damage. There is also evidence for a direct toxic effect of ACE inhibitors on the pancreas [49,50].

**Box 24.1 Drugs definitely and probably associated with acute pancreatitis**

**Definite association**

- Asparaginase
- Azathioprine
- Carbamazepine
- Cytarabine
- Didanosine
- Enalapril
- Erythromycin
- Estrogens
- Furosemide
- Lamivudine
- Mercaptopurine
- Mesalamine
- Opiates
- Pentamidine
- Pravastatin
- Steroids
- Sulfasalazine
- Trimethoprim/sulfamethoxazole
- Tetracycline
- Valproic acid

**Probable association**

- Cyclopenthiazide
- Oxaliplatin
- Mesalazine
- Rifampin
- Octreotide
- Metformin
- Hydrochlorothiazide
- Propofol
- Tamoxifen

*Source:* Adapted from Nitsche et al. 2012 [37] and Hung and Abreu Lanfranco 2014 [35].

Several studies report on the side-effects of azathioprine and 6-mercaptopurine, and these include acute pancreatitis. Interestingly azathioprine-induced pancreatitis is almost never reported outside the field of inflammatory bowel disease (IBD), especially Crohn disease [37]. Presumably the drug's toxicity is associated with the underlying disease. Affected individuals carry an up to 8- to 13-fold increased risk of acute pancreatitis [51,52]. With regard to 6-mercaptopurine, 3.25–6% of patients with IBD being treated with that drug develop acute pancreatitis [53,54]. It is noteworthy that 5-aminosalicylic acid (OR 0.7) and sulfasalazine (OR 1.5), which are also frequently used for IBD treatment, were not associated with significantly increased pancreatitis risk in a recent report [55].

3-Hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (commonly known as statins), such as simvastatin, pravastatin, and atorvastatin, are thought to have direct toxic effects and in a number of cases drug interactions involving cytochrome P450 3A4 (CYP3A4) seem to contribute to pancreatitis [50,56]. However the overall risk for acute pancreatitis is rather low with an OR ranging from 1.01 to 2.02, so statins seem to be of low importance for drug-induced pancreatitis [56].

Nucleoside reverse transcriptase inhibitors, such as didanosine, lamivudine, and stavudine, have a toxic effect on the pancreas. In addition they cause metabolic disturbances [50]. HIV patients with a low CD4 count are at a higher risk [37].

Consumption of valproic acid or other antiepileptic drugs is associated with an increased risk for acute pancreatitis, presumably mediated by direct toxic effects and an increase in reactive oxygen species [37,50]. According to recent studies and in contrast to older reports, selective serotonin reuptake inhibitors (SSRI) do not increase the risk of acute pancreatitis [57].

Soon after introduction of incretin mimetics (glucagon-like peptide-1 [GLP-1] agonists) safety concerns arose about the potential of acute pancreatitis as a side-effect, especially for exenatide and sitagliptin. Reports were also published on dipeptidyl-peptidase-4 (DPP-4) inhibitors [58,59]. Recent analyses failed to find an unequivocal effect on the incidence of pancreatitis and were explained by the fact that people with diabetes already at increased risk of developing acute pancreatitis [35,60,61]. A higher prevalence of gallstone disease or hypertriglyceridemia is also seen in this patient group [62]. Summing up, the role of incretin mimetics is not conclusively answered: preexisting risk factors such as diabetes mellitus and cardiovascular disorders explain most pancreatitis cases in this group and the large safety trials on DPP-4 inhibitors have largely calmed the initial concerns about an association with pancreatitis [63].

For all drug-associated forms of pancreatitis management consists of drug discontinuation and supportive care, as for other types of acute pancreatitis. If necessary, a drug of a different class will be selected for further therapy. However, drug-induced pancreatitis remains a rare entity and physicians should at first rule out other causes of acute pancreatitis including occult gallstone disease [64], immoderate alcohol consumption [65], and underlying genetic changes [66]. A critical review of the patient's medication profile is mandatory before assuming a drug to be causative for pancreatitis.

# Radiologic Diagnosis and Staging of Severe Acute Pancreatitis

*Yoshihisa Tsuji*

*Department of Clinical Education, Shiga University of Medical Science, Otsu, Shiga, Japan*

## Introduction

The role of imaging is important in diagnosis and evaluation of severity in patients with known or suspected acute pancreatitis. Common imaging techniques for the evaluation of the pancreas include transabdominal ultrasonography (US), computed tomography (CT), and magnetic resonance imaging (MRI). Angiography and positron emission tomography (PET)-CT are sometimes used to diagnose special complications in acute pancreatitis patients. This chapter deals with these imaging techniques in the diagnosis of local and systemic inflammation associated with acute pancreatitis.

## Classification of Acute Pancreatitis

Acute pancreatitis represents a spectrum of inflammatory disease ranging from clinically mild to severe acute pancreatitis [1]. In recent years a radiological approach has been commonly used to diagnose acute pancreatitis and evaluate severity. For these purposes, CT is one of the most popular methods. Abdominal CT has been commercially available since the 1970s.

In 1983, Kivisaari et al. reported that pancreatic necrosis in acute pancreatitis could be diagnosed using CT [2]. Bradley et al. [3] and Johnson et al.[4] also reported the usefulness of CT in diagnosis of pancreatic necrosis in acute pancreatitis patients, in 1989 and 1991, respectively. These studies regarded pancreatic necrosis as one of the most important factors in predicting a poor prognosis (Table 25.1).

In contrast, based on broadening of inflammation, Balthazar et al. [5] established a CT grading system to define the severity of acute pancreatitis in 1985. This is called Balthazar's CT grade, and it became one of the most popular image-based grading systems of severity of acute pancreatitis. It was partially modified in 2002 [6]. In 1985 the Balthazar system classified acute pancreatitis into five grades: A—normal, B—focal or diffuse enlargement of the pancreas, C—peripancreatic inflammation with intrinsic pancreatic abnormalities, D—intra- or extrapancreatic fluid collections, and E—two or more large collections of gas in the pancreas or retroperitoneum. In the 2002 version, grades D and E were modified: D—single fluid collection and E—two or more fluid collections and/or retroperitoneal air, respectively.

The two concepts that assist in diagnosis—local pancreatic damage and evaluation of broadening of inflammation—were combined into the CT severity index to predict prognosis (see section on CT severity index later in this chapter).

According to these moves to diagnose and evaluate acute pancreatitis using CT, a newer classification of acute pancreatitis was discussed at the Atlanta conference in 1992 [7]. In Atlanta, following previous symposia [8–10], severity of acute pancreatitis was classified into two grades: mild and severe. In this classification, severe acute pancreatitis was associated with organ failure and/or local complications, such as pancreatic necrosis, pancreatic fluid collection, acute pseudocyst, or pancreatic abscess. Since it was considered that CT could diagnose these local complications accurately, descriptions of the Atlanta classification were largely devoted to diagnostic criteria of local complications on CT. Following this symposium, radiological findings associated with acute pancreatitis were described in medical reports based on these terminological definitions.

The Atlanta classification was universally applied for two decades from 1992. During these two decades, two important insights were reported. First, Casas et al.

reported that the early CT, which was performed within 3 days from the onset, could not diagnose pancreatic necrosis accurately [11]. Second, a new concept, "walled-off necrosis (WON)," was proposed [12,13]. Early pancreatic complications (e.g., pancreatic and peripancreatic necrosis) could develop WON 4 weeks later than the onset. The concept of WON has clarified our understanding of pseudocysts (Table 25.2). Our improved knowledge of the pathophysiology of organ failure and necrotizing pancreatitis and their outcomes, as well as improved diagnostic imaging, made it necessary to revise the Atlanta classification.

The Atlanta classification was also revised in 2012 [14]. According to this classification of acute pancreatitis, known as the "revised Atlanta classification," the severity of acute pancreatitis is categorized into three groups: mild, moderate severe, and severe. In patients without local and systemic complication, the severity is judged to be mild. Patients with local complication without organ failure or transient organ failure which can be controlled within 48 hours from induction of treatment are classified in the moderate severe group. Patients with organ failure that resists treatment resulting in persistence for 48 hours or more are classified as severe (Table 25.2).

At the same time as the revised Atlanta classification, the determinant-based classification [15] was also published by another group. As with the revised Atlanta classification, the aim of this classification was to revise the original Atlanta classification. However, the determinant-based classification regards (peri)pancreatic necrosis as the more important factor to predict prognosis, compared to the revised Atlanta classification. According to determinant-based classification, the severity of acute

**Table 25.2** Diagnosis of local complications on imaging.

| Image on CT | | | | | | Terminology | | | |
|---|---|---|---|---|---|---|---|---|---|
| **Location** | **Density** | **Wall** | **Perfusion** | **Timing from onset** | **Pathology** | **Atlanta** | **Revised Atlanta** | **Determinant-based** | **Late complication** |
| Pancreatic | Heterogeneous and nonfluid density | None | None or less | <3 days | Ischemic tissue | Pancreatic necrosis | ANC | (Peri) Pancreatic necrosis | Healing without necrosis or WON |
| | | | None | <4 weeks | Pancreatic necrosis | | | | WON |
| | | | | | Fat necrosis | | | | |
| | | | | | Inflammatory tissue | Pancreatic fluid collection | | | Resolving |

| | | | | | Infected | | | | |

ANC, acute necrotic collection; APFC, acute pancreatic fluid collection; PPC, pseudocyst; WON, walled-off necrosis.

pancreatitis is categorized into four groups: mild, moderate, severe, and critical. If the patient has neither (peri) pancreatic necrosis nor organ failure, severity is judged to be mild. The patient with sterile (peri)pancreatic necrosis and/or transient organ failure is classified as moderate. The patient with infected necrosis or persistent organ failure (more than 48 hours from start of treatment) is classified into the severe group. The patient with both infected necrosis and persistent organ failure is classified into the critical group (Table 25.2).

Between the revised Atlanta and determinant-based classifications, there is a difference with regard to the radiological definition of pancreatic necrosis. According to determinant-based classifications, (peri)pancreatic necrosis is nonviable tissue without a radiologically defined wall. In contrast, the revised Atlanta classification makes categorizes pancreatic necrosis into two types according to a diagnosis of well-defined wall: acute necrotic collection (ANC) and WON (Table 25.2). In the determinant-based classification, there is no description with regard to necrotic tissue with radiologically well-defined wall, which was categorized into "acute pseudocyst or pancreatic abscess" and "pancreatic pseudocyst or walled-off necrosis" in the Atlanta and revised Atlanta classifications, respectively. Thus, it appears that the concept of pancreatic necrosis in the determinant-based classification is not the same as that in the revised Atlanta classification.

In both the revised Atlanta and determinant-based classifications, the development of persistent organ failure (48 hours or more from start of treatment) is needed to diagnose severe or critical acute pancreatitis. Thus, in the emergency room we can use only two grades of severity: mild or moderate. From this point of view, a patient with moderate acute pancreatitis is potentially at high risk of developing severe or critical acute pancreatitis. Accurate diagnosis of pancreatic necrosis is one of the most important factors to perform in the emergency room for appropriate triage based on the severity of recent classifications.

## Radiographic Diagnosis of Severe Acute Pancreatitis

Two major types of acute pancreatitis are known: acute edematous and necrotizing pancreatitis [14]. Since the prognoses and strategies of treatment of these two are totally different, it is necessary to diagnose them accurately.

### Acute Edematous Pancreatitis

According to Klöppel [16], the pancreas is enlarged without necrosis on gross pathology in acute edematous pancreatitis, although microscopic areas of parenchymal fat necrosis may also be found. Lack [17] stated that hemorrhage and intraparenchymal necrosis is absent in the pancreas. Importantly, in acute edematous pancreatitis, where fat necrosis does not come into contact with a blood vessel, it does not damage the vessel wall, leading to macroscopic pancreatic necrosis [16]. Thus contrast enhancement of pancreatic parenchyma is usually normal on contrast-enhanced CT (CE-CT). In addition, the revised Atlanta classification [14] described that CE-CT shows pancreatic swelling with relatively homogeneous enhancement in acute edematous pancreatitis (Fig. 25.1).

In the Atlanta classification [7], the macroscopic feature of mild acute pancreatitis was interstitial edema. Therefore, in those days, mild acute pancreatitis was

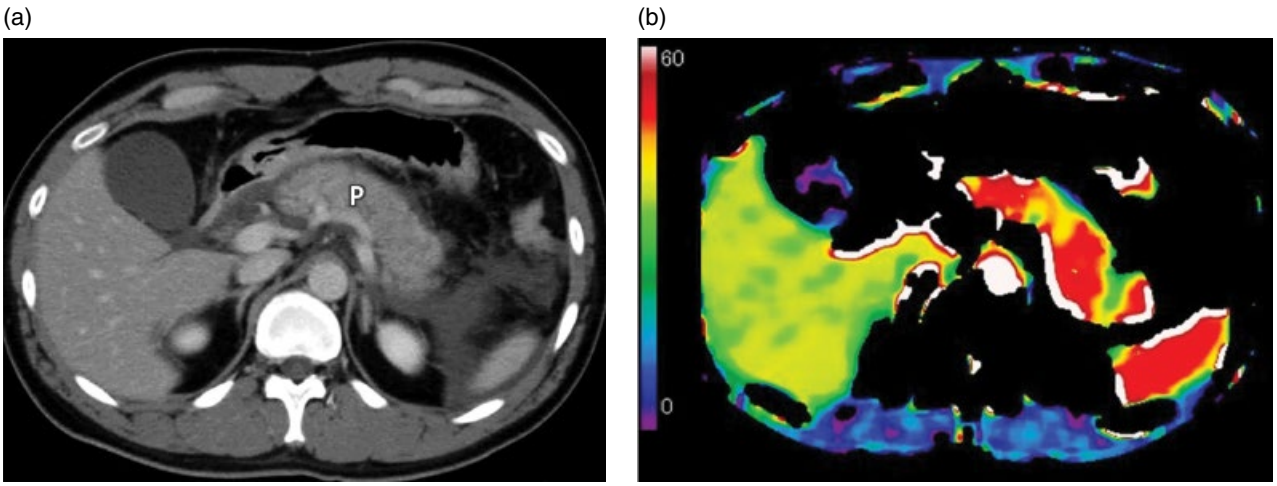

**Figure 25.1** Acute edematous pancreatitis. (a) Contrast-enhanced CT shows enlargement of pancreas (P). At the same time as (a), perfusion CT was obtained. (b) Tissue blood flow was demonstrated based on the left-sided scale bar. Pancreatic blood flow was red-yellow (about 40 mL/100 g/min), which indicates that pancreatic blood flow was high.

nearly equal to acute edematous pancreatitis. One of the important things to note is that the revised Atlanta classification [14] changes the definition of mild acute pancreatitis to "pancreatitis with no organ failure and no local or systemic complications." In the revised Atlanta classification, local complications are redefined as acute peripancreatic fluid collection (APFC), pancreatic pseudocyst (PPC), acute necrotic collection (ANC), and walled-off necrosis (WOF). Thus, using the revised Atlanta, acute edematous pancreatitis with APFC, one of the local complications, is classified into moderate severe acute pancreatitis, not mild. The prognosis of patients with acute edematous pancreatitis is much better than that of those with local complication.

### Acute Necrotizing Pancreatitis

Approximately 2–10% of acute pancreatitis patients develop necrosis of pancreatic parenchyma and/or peripancreatic tissue [14,18]. Both in the Atlanta and the revised, acute necrotizing pancreatitis is defined as "acute pancreatitis with pancreatic necrosis which involves pancreatic parenchymal necrosis and/or peripancreatic fat necrosis." Reports put the mortality rate for acute pancreatitis patients with pancreatic necrosis at roughly 30% [19].

Development of pancreatic parenchymal necrosis consists of three steps: acinar injury, vascular injury, and tissue injury. The initial pathway in the development of pancreatitis is ectopic activation of trypsinogen in acinar cells and/or activation of macrophages [20–23] or neutrophils [24]. The activation of trypsinogen in acinar cells leads to the acinar cells being destroyed, followed by releases of trypsin and damage-associated molecular pattern molecules (DAMP) [25] into the pancreatic vessels. Vascular epithelial cells are injured by the released trypsin and/or DAMP, resulting in damage to the coagulant–fibrinolytic system of the endothelial cells. In combination with this endothelial damage, periarterial fat necrosis, interstitial edema, and/or bleeding due to inflammation reduces tissue perfusion by compressing vessels. If this reduction of perfusion continues and/or ischemic–reperfusion damage occurs, serious tissue damage often develops, leading to acute necrotic collection (ANC) [26,27]. At 4 weeks or more later, ANC may develop WON. Since ANC and WON are irreversible, attempts to prevent the development of ANC or WON should be started based on a diagnosis of pancreatic ischemia [28] (see sections on acute necrotic collection and walled-off necrosis later).

To diagnose pancreatic necrosis (pancreatic ischemia, ANC, and WON), CE-CT, MRI, or CE-US are used. According to CE-CT criteria in the revised Atlanta classification, acute necrotizing pancreatitis is diagnosed based on lack of pancreatic parenchymal enhancement by intravenous contrast agent and/or presence of peripancreatic necrosis (Table 25.1) [2–4,7,11,27,29–36].

## Diagnosis of Local Complications of Acute Pancreatitis

As was described earlier, local complications are divided in to four types: APFC, ANC, WON, and PPC in the revised Atlanta classification.

### Acute Peripancreatic Fluid Collection

In the Atlanta classification [7], pancreatic fluid collections occurred early in the course of acute pancreatitis, were located in or near the pancreas and always lacked a wall of granulation or fibrous tissue. The precise composition of such collections was not known pathologically. Instead of the term "pancreatic fluid collections" [7], the use of the term APFC was suggested in the revised Atlanta classification [14]. APFC is peripancreatic fluid association with interstitial edematous pancreatitis and without necrosis. In CE-CT, APFC is a homogeneous collection with fluid density, without abnormal peripancreatic fascial planes, without defined wall encapsulating the collection, and without intrapancreatic extension (Table 25.2, Fig. 25.1).

### Acute Necrotic Collection

ANC includes parenchymal necrosis of pancreas and peripancreatic fat necrosis. Thus, acute pancreatitis with ANC is the same as acute necrotizing pancreatitis. A collection contains variable amounts of both fluid and necrotic tissues. As was previously described, ANC is a pre-stage of developing WON. The border between ANC and normal tissue is gray (Fig. 25.2).

Parenchymal necrosis of pancreas appears as a low attenuation or non-enhancing area on CE-CT [4,5,37]. Early studies reported that CE-CT was highly accurate for the detection of pancreatic necrosis [3,4,29]. These studies mostly included surgical cases, so very few patients in the early stage of acute pancreatitis were included. Four previous studies reported the accuracy of CE-CT in predicting pancreatic necrosis in the early stages of acute pancreatitis [11,33,34,38]. One study showed that pancreatic necrosis was not detected in any of 49 patients with acute pancreatitis on CE-CT performed within 72 hours of onset (sensitivity: 0%) [33], while the three other studies [11,34,38] showed that CE-CT had a sensitivity of 63%, 72%, and 75%, respectively, for the early phase of acute pancreatitis (within 1 day of admission or 72 hours of onset).

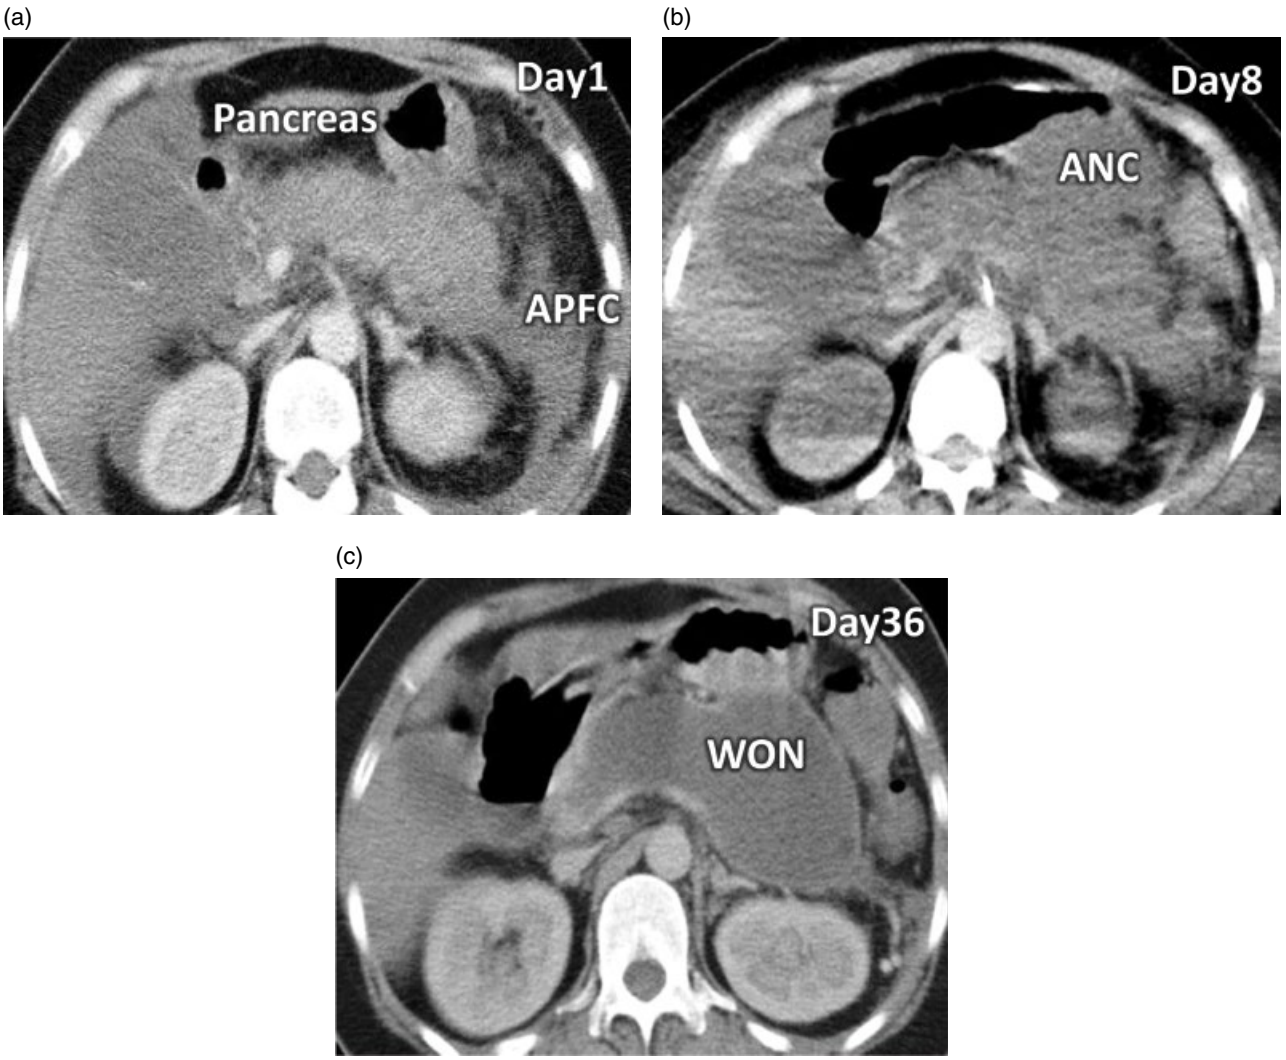

**Figure 25.2** Acute necrotizing pancreatitis and its natural history. Due to serious complications of acute pancreatitis, this patient had three CT scans during the course of the disease. Contrast-enhanced CT shows homogeneous enhancement of pancreas at day 1 (a). On day 8 (b), enhancement of pancreas was markedly reduced, so this case was diagnosed as acute necrotizing pancreatitis. (c) On day 36, the scan shows acute necrotic collection (ANC) and altered walled-off necrosis (WON), which was surrounded by a well-defined wall.

As Klöppel described previously [16], pancreatic inflammation can reduce pancreatic blood flow, resulting in development of pancreatic necrosis. Using angiography, Takeda also showed that pancreatic parenchyma with vasospasm of the intrapancreatic artery develops parenchymal necrosis with high ratio [27]. Perfusion CT [39,40], which can measure parenchymal blood flow accurately, has shown promise as a method that can accurately detect pancreatic necrosis at an early stage of acute pancreatitis with an estimated sensitivity of 88–100% and specificity of 84–100% [32,35,36] (Fig. 25.3). Perfusion CT can differentiate reversible from irreversible ischemic tissue, and thus has been used widely for diagnosing acute brain stroke (Fig. 25.1). According to Yadav et al. [35], pancreatic parenchyma with poor blood flow (cut-off value about 20 mL/100 g/min or less and normal pancreas 100 mL/100 g/min or more) could develop pancreatic necrosis with high ratio. At 24 hours from onset, Pienkowska et al. [36] showed that perfusion CT can predict development of pancreatic necrosis accurately. This suggests that the parenchymal blood flow is decreased even at an early stage of acute pancreatitis in areas of impending necrosis (Fig. 25.4 and 25.5).

Dynamic contrast-enhanced magnetic resonance imaging (CE-MRI) [41] may be an alternative to CE-CT for detecting pancreatic necrosis. Indeed, MRI has certain advantages over conventional CE-CT, including greater sensitivity in detecting ischemia. Moreover, when MR angiography is performed in conjunction with MRI, assessment of vessel patency is also possible.

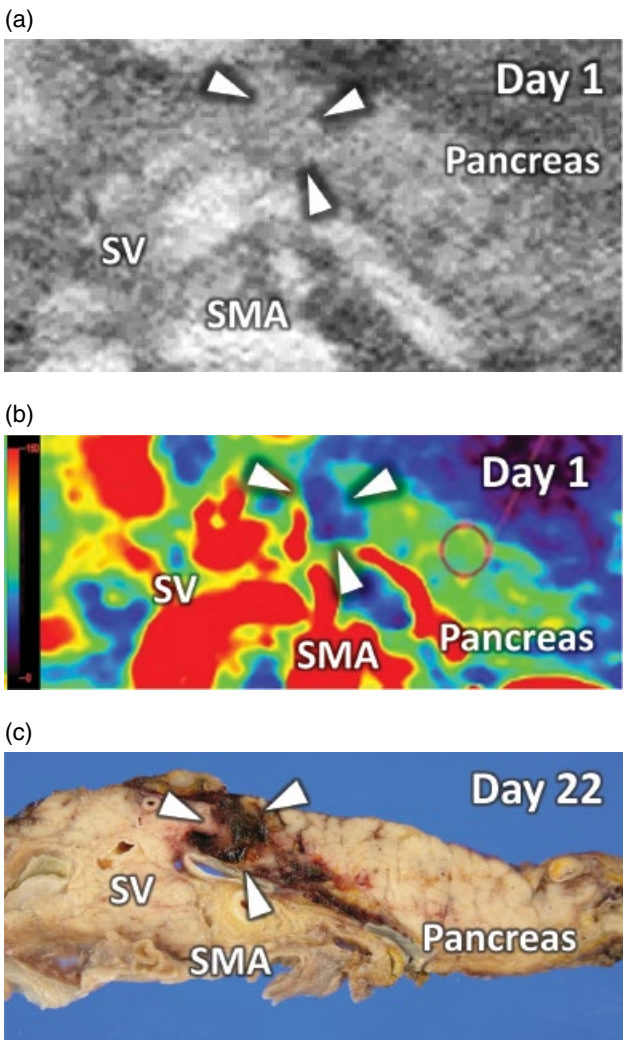

**Figure 25.3** Difficulty in identifying pancreatic parenchymal necrosis using conventional CT. (a) Using contrast-enhanced CT (day 1), regional necrosis on the pancreatic head was not identified (arrowheads). (b) However, perfusion CT showed markedly reduction of pancreatic perfusion. (c) The poor perfusion area on perfusion CT (b) was concordant with an area of pancreatic necrosis at autopsy.

### Walled-Off Necrosis

WON is defined as a mature, encapsulated collection of pancreatic and/or peripancreatic necrosis that has a well-defined wall [12–14]. It arises secondary to ANC and usually occurs at >4 weeks after onset of acute pancreatitis. On CE-CT, WON often appears heterogeneous, with liquid and nonliquid density with varying degrees of loculations [14]. Ultrasound (both percutaneous and endoscopic) or MRI is better for diagnosing the heterogeneity of WON compared to CE-CT, because the identification of the liquid area in necrosis by MRI or ultrasound is more accurate than that by CE-CT.

Compared to ANC, WON has well-defined walls at marginal zone of necrosis, and therefore the border is clear. WON develops liquefaction of necrotic area heterogeneously and gradually [17]. Some areas of WON have inner walls, and WON can thus be separated into various sizes. In addition, WON develop in many areas, side by side or separately. Therefore, in acute pancreatitis patients with local complications, there is a possibility that many areas of WON will develop in the abdominal cavity.

In cases of suspected ANC/WON infection, rapid enlargement of the necrotic area, inflammatory changes in the neighboring fat, gas in the necrotic area, and surrounding paralytic ileus may help to diagnose the location of the infection (Fig. 25.6). One study suggests that PET-CT may be useful in identifying infected WON [42], although it is expensive.

### Pancreatic Pseudocyst

It should be noted that the definition of the term PPC has recently changed. Previously, PPC included both WON and encapsulating fluid [7]. In the latest international classification, the revised Atlanta [14], PPC is redefined as an encapsulating collection of fluid with a well-defined inflammatory wall. PPC usually occurs more than 4 weeks after onset, as well as WON. Any solid region is not identified as PPC, thus (endoscopic) US or MRI is useful to diagnose it (Fig. 25.7).

## Radiologic Staging of Severe Acute Pancreatitis

The concept of radiologic staging of severity of acute pancreatitis is based on two important findings: extent of inflammation and necrosis (ANC/WON).

### CT Severity Index

Combining the findings of broadening of inflammation and local pancreatic damage on CT, the CT severity index (CTSI) was published in 2002. In the CTSI, Balthazar CT grade A (normal pancreas) scores 0, grade B (enlargement of pancreas) scores 1, grade C (inflammatory changes in pancreas and peripancreatic fat) scores 2, grade D (single fluid collection) scores 3, and grade E (two or more poorly defined fluid collections) scores 4. The pancreatic condition is independently evaluated: no pancreatic necrosis on CT scores 0, pancreatic necrosis less than/equal to 30% of pancreas scores 2, >30–50% scores 4, and >50% scores 6. Grading severity is based on a CTSI score of 0–10: mild

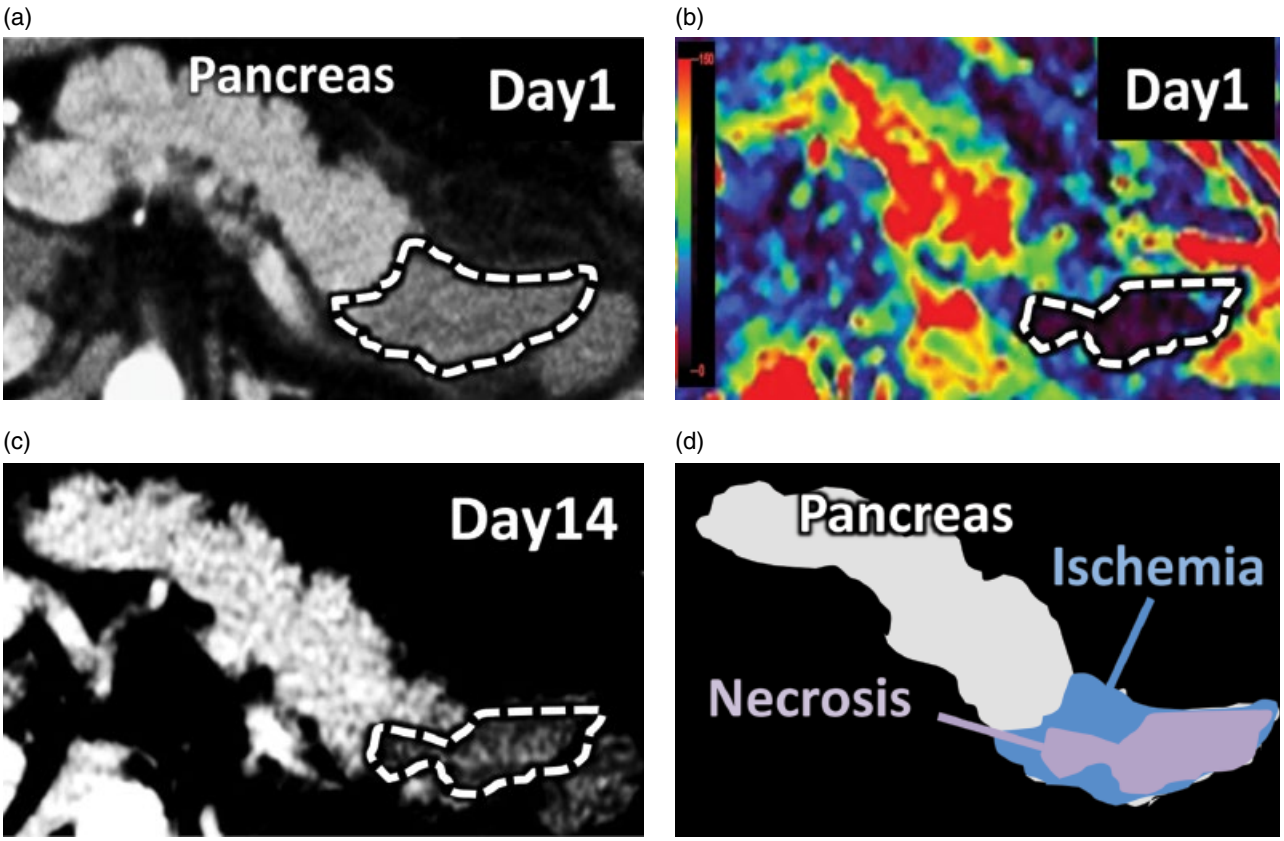

**Figure 25.4** Reversible ischemia and necrosis in early stage of severe acute pancreatitis. (a) Contrast-enhanced CT (day 1) showed a lack of enhancement of the pancreatic tail (area surrounded by dotted line). (b) Perfusion CT showed a poorly perfused area in the pancreatic tail, which was smaller than the area with lack of enhancement on contrast-enhanced CT. (c) The area with poor perfusion in the perfusion CT developed pancreatic necrosis. (d) Based on these findings, the schema shows that the marginal zone of pancreatic necrosis could have been reversible ischemia.

(score 0–3), moderate (score 4–6), and severe (score 7–10) [5,6]. The CTSI was modified in 2004 by Mortele et al. (MD-CTSI) [43]. The MD-CTSI resulted in higher interobserver agreement ratio, correlation with length of hospital stay, need for invasive therapy, incident organ failure, and the occurrence of infection (Table 25.3).

### Japanese CT Severity Index

In the latest Japanese definition of severe acute pancreatitis [44], Hiroto et al. established the JPN-CT severity score. In the definition, severe acute pancreatitis can be diagnosed either by the laboratory/clinical severity criteria or JPN-CT. The case mortality rate of patients with severe acute pancreatitis diagnosed by JPN-CT score was 14.8%. The case fatality of severe acute pancreatitis that fulfilled JPN-CT severity criteria (severity score ≥2 points) was as high as 30.8%.

## Limitations and Pitfalls of Radiological Diagnosis of Acute Pancreatitis

### Diagnosis of Early Necrosis of Pancreatic Parenchyma

The accuracy of CE-CT to diagnose pancreatic parenchymal necrosis within 3 days of onset is not adequate [11,37]. One potential explanation for this disappointing performance of CE-CT is that the attenuation of pancreatic parenchymal necrosis is similar to that of viable enhancing parenchyma on CE-CT in the early stages of acute pancreatitis, and the CT attenuation of pancreatic necrosis decreases over time as nonviable parenchyma liquefies [12,31]. Moreover, because the CT attenuation of pancreas may be altered by hemorrhage in necrosis or fatty infiltration, evaluation of regional variability in pancreatic enhancement becomes difficult with CE-CT.

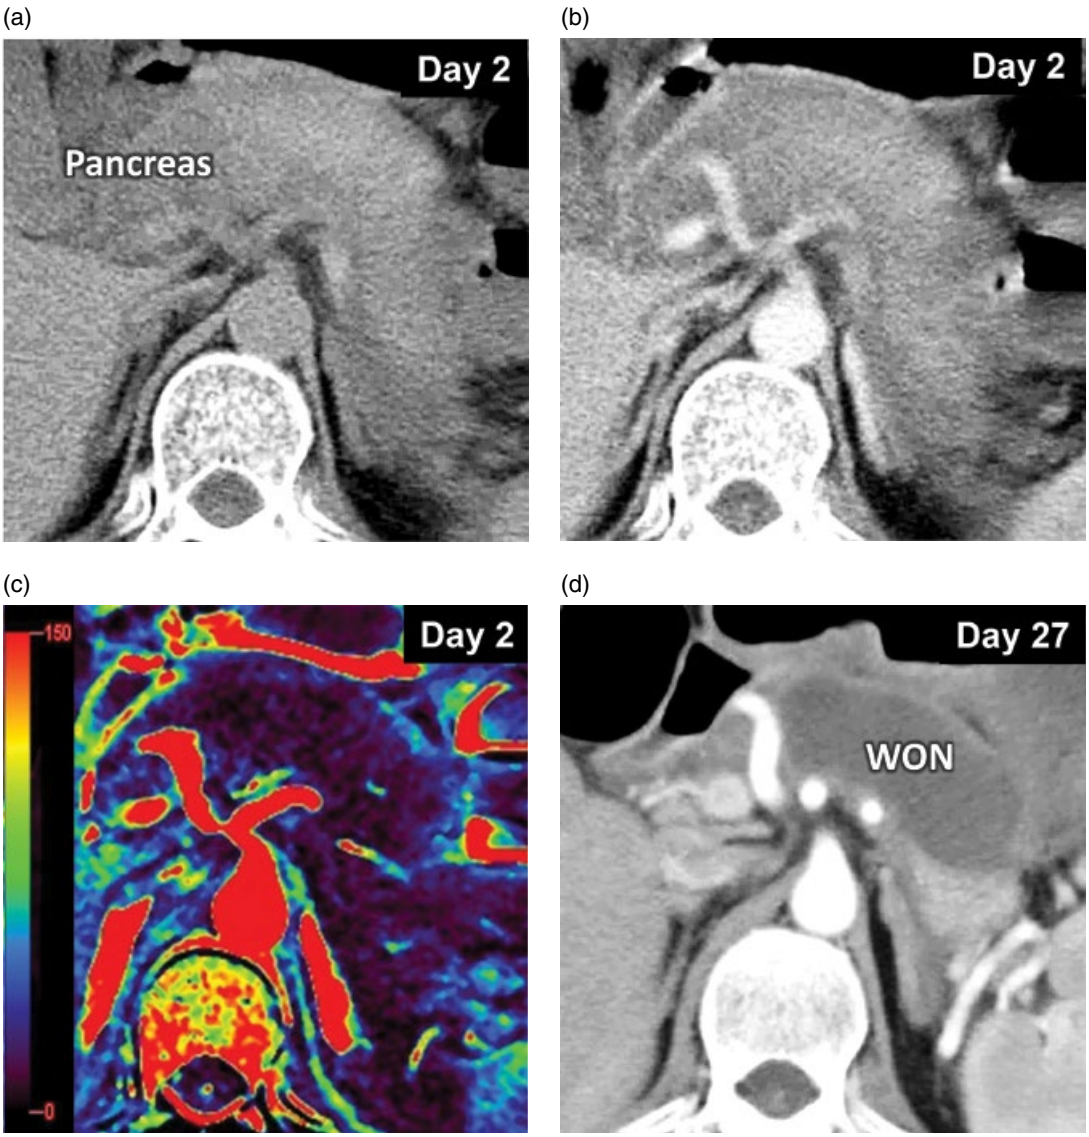

**Figure 25.5** Tissue hemorrhage makes it difficult to diagnose necrosis using contrast-enhanced CT alone. (a) Noncontrast CT showed elevation of CT values in pancreatic body. (b) On CE-CT alone, it is difficult to judge whether the elevation of CT value of pancreatic parenchyma was due to hemorrhage or enhancement by contrast agent. (c) Perfusion CT showed that pancreatic blood flow of the whole pancreatic body was extremely low. These findings show that the pancreatic body had already developed necrosis on day 2. (d) The poorly perfused area with slight elevation of CT values on noncontrast CT was concordant with the area with later necrosis.

Another reason why CE-CT may not be accurate in predicting parenchymal necrosis in the early stages may involve the difficulty of evaluating the effectiveness of contrast-enhanced material. Since the border of early parenchymal necrosis that is included in the ANC is not clear, selecting specific of areas with suspicious parenchymal necrosis in the case of early acute pancreatitis poses difficulties, in contrast to analyses of enhancements in well-defined lesions, such as a WON.

Although the detection of pancreatic parenchymal necrosis with CT imaging has led to the improved prognostic stratification of patients using the CT severity index [45], the inaccurate prediction of parenchymal necrosis using CE-CT and its large interobserver variability [43,46] may also lead to recent recommendations questioning the routine use of CT at an early stage of acute pancreatitis [47,48].

Despite the advantages discussed earlier, MRI is underused in the evaluation of patients with severe acute pancreatitis. This underutilization can be attributed to practical considerations—patients with severe acute pancreatitis have difficulty withstanding the lengthy MRI procedure. In addition, removal of all the magnetic instruments (e.g., sphygmomanometer,

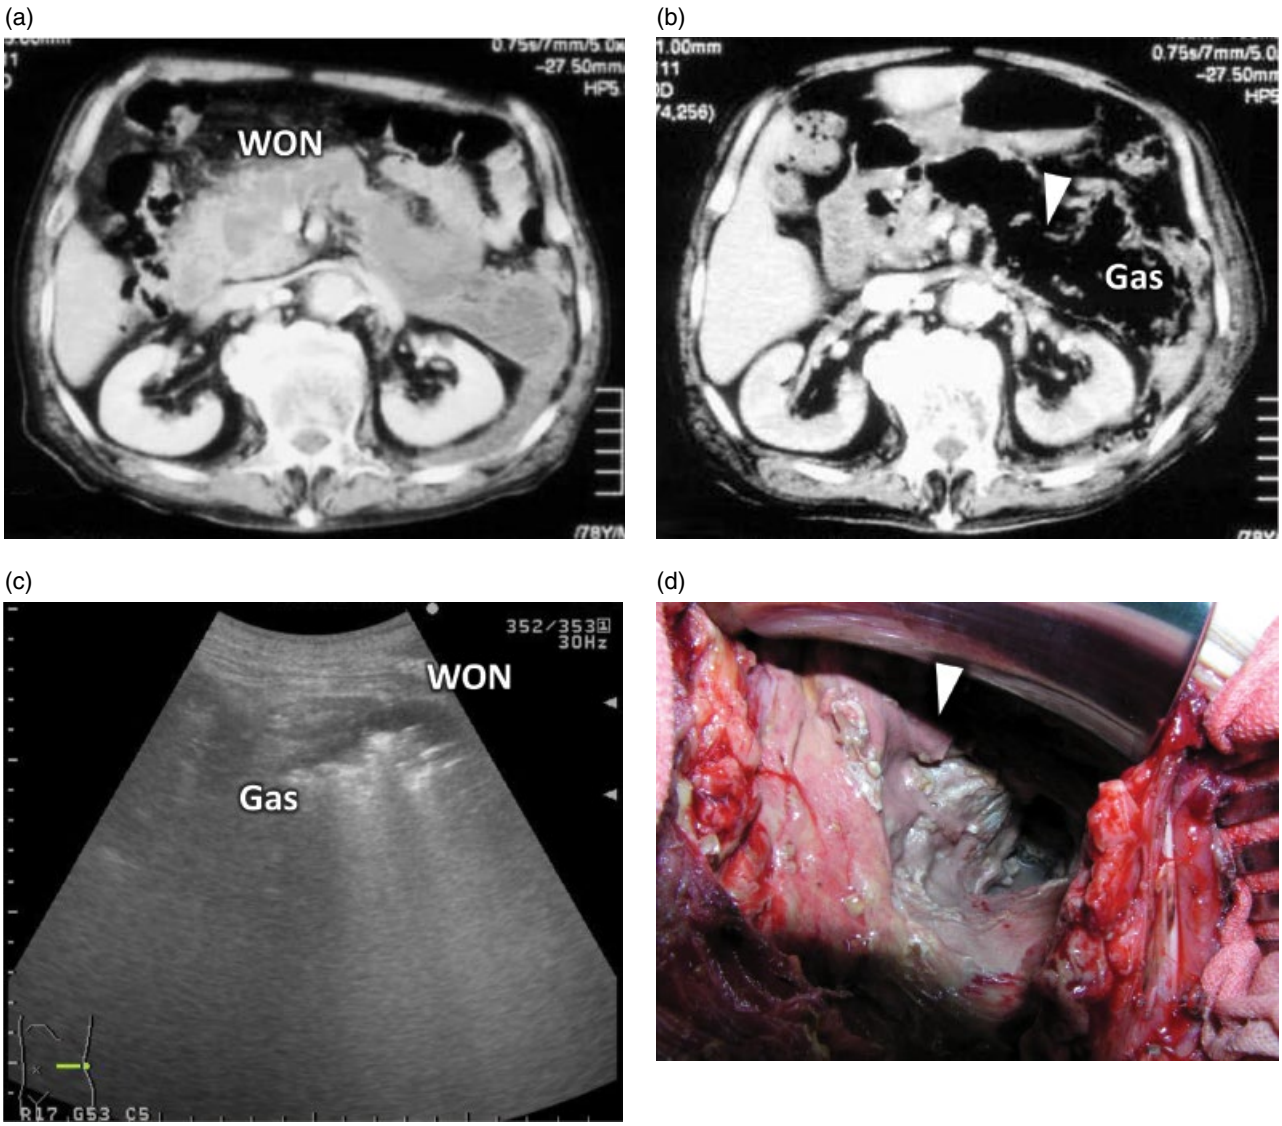

**Figure 25.6** Infected walled-off necrosis (WON). (a) Presented case has WON on contrast-enhanced CT. (b) Most of the WON on the pancreas body and tail was replaced with gas, due to infection. In the gas cavity of WON, the inner wall (arrowhead) was detected. (c) Percutaneous ultrasound showed high spotty areas due to gas in WON. (d) Surgical treatment was performed and a part of the inner wall (arrowhead) was shown in the cavity. The patient recovered 6 months later.

saturation monitor, multiple infusion pumps, etc.), which cannot be taken away from patients with severe acute pancreatitis even for a short period, must be done before the procedure is performed.

## Nephrotoxity of Contrast Material of CE-CT and CE-MRI

One of important systemic complications of acute pancreatitis is acute renal failure. Because CE-CT and dynamic CE-MRI has some nephrotoxicity, use of dynamic CE-MRI and CE-CT should be decided with care [41]. Perfusion CT is obtained from analysis of blood flow after a bolus injection of much less contrast materials (approximately 30–40%) than those used for conventional CE-CT [49]. Therefore, the nephrotoxity of perfusion CT is lower than that of CE-CT and dynamic CE-MRI.

Rickes et al. have recently shown that CE-US [50], which does not have a bad effect on the kidney, can also be used to diagnose pancreatic parenchymal necrosis reliably. However, a whole pancreatic scan with ultrasound is often difficult, because a common complication of acute pancreatitis patients is paralytic ileus. Pancreatic parenchyma with inflammation is often surrounded by digestive canal with gas [14], and so the accuracy of ultrasound for evaluating severity of pancreatitis is limited.

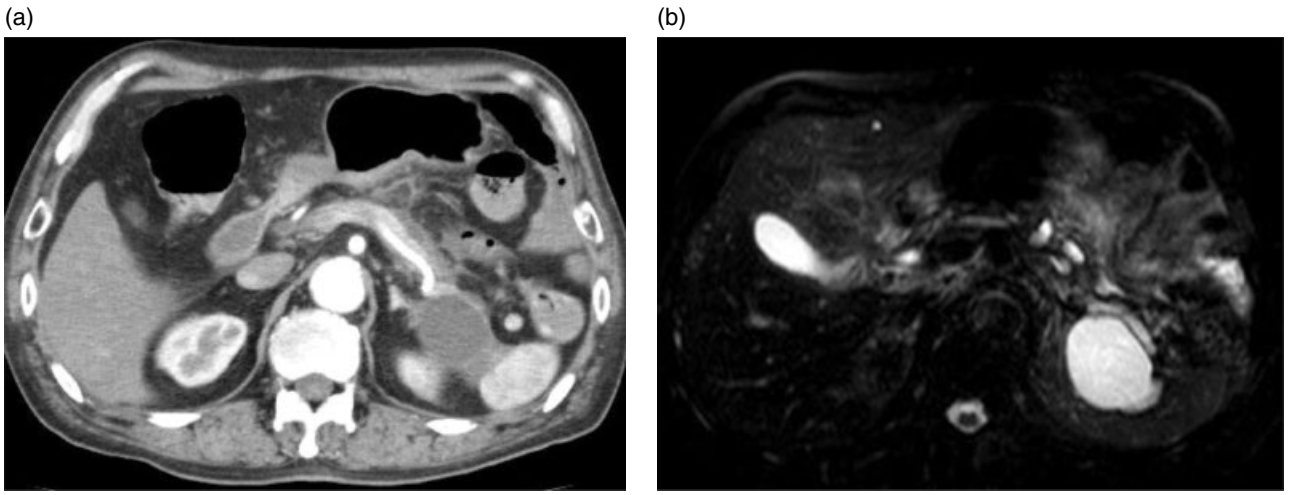

**Figure 25.7** Pancreatic pseudocyst. (a) After 4 weeks from onset of acute pancreatitis, a low-density area with well-defined wall was identified by contrast-enhanced CT. (b) Using MRI (T2 weighted), a low-density area including liquid contents was identified, so the patient was diagnosed with pancreatic pseudocyst.

**Table 25.3** Modified CT severity index.

| Radiological findings | Points |
|---|---|
| Normal pancreas | 0 |
| Intrinsic pancreatic abnormalities with or without peripancreatic inflammatory change | 2 |
| Pancreatic/peripancreatic fluid collection or peripancreatic fat necrosis | 4 |
| Pancreatic necrosis | |
| None | 0 |
| ≦30% gland necrosis | 2 |
| >30% gland necrosis | 4 |
| Extrapancreatic complications, i.e., pleural effusion, ascites, vascular or gastric involvement, parenchymal complications | 2 |
| CTSI score and disease severity of acute pancreatitis | |
| Score 0–3: mild | |
| Score 4–6: moderate | |
| Score 7–10: severe | |

### Radiation Dose of CE-CT and Perfusion CT

The radiation doses of CE-CT and perfusion CT should not be ignored. However, recent techniques regarding noise reduction and registration make it possible to perform CE-CT and perfusion CT using much lower radiation dose protocols. Radiation doses used for recent pancreatic perfusion CT were lower than those used for triple phase CT [49,51].

### Needs for Diagnosis of Pancreatic Necrosis in the Early Stage

As reported in a previous publication, neither APACHE II nor CE-CT give accurate predictions for patients in the early stages of acute pancreatitis [52]. Because of the absence of an ideal and established method for evaluating severity at an early stage, therapies often begin only after the patient has sustained serious damage. Since serious tissue damage (e.g., necrosis) may be irreversible, such treatments may be of limited benefit at later stages. Early and accurate predictions appear critical in establishing effective early care strategies. Accurate predictions of the severity may improve the accuracy of triage assignments and allow intensive treatment to begin earlier. Early inductions of aggressive fluid therapy [53] and enteral nutrition [54] may improve outcomes for patients with severe acute pancreatitis. Importantly, there is no strong evidence that early and accurate evaluations of severity can actually alter prognosis in acute pancreatitis. Prospective intervention trials based on early accurate predictive methods would be required to confirm this.

# Clinical Course and Medical Treatment of Acute Pancreatitis

## 26

## Conservative Therapy of Acute Pancreatitis: Volume Substitution and Enteral and Parenteral Nutrition

*Timothy B. Gardner*

*Section of Gastroenterology and Hepatology, Dartmouth-Hitchcock Medical Center, Lebanon, NH, USA*

## Introduction

Acute pancreatitis is an often devastating inflammatory condition of the pancreas which leads to extensive worldwide morbidity and mortality [1–4]. In fact, in the United States, acute pancreatitis is the most common reason for patients to be hospitalized for a digestive illness [5]. The substantial human costs of this disease, with billions in annual healthcare dollars spent worldwide, has led to extensive efforts to establish a pharmacologic treatment for this disease. Unfortunately, as of 2016, there is no specific medical therapy that specially targets acute pancreatitis and has been useful to improve important clinical outcomes.

Over the past 50 years, extensive efforts have been made to develop targeted pharmaceutical products, but none have demonstrated benefit in randomized controlled trials. Agents directed at reducing pancreatic secretions, including histamine-2 blockers, such as cimetidine, glucagon, atropine, somatostatin and its analog octreotide, do not reliably affect morbidity or mortality [6–9]. Antiprotease therapy with aprotinin and gabexate mesilate are equally ineffective, as is therapy with lexipafant, a platelet-activating factor antagonist [10,11].

Recently, as discussed elsewhere in this textbook, rectal nonsteroidal anti-inflammatory drugs (NSAID) have been demonstrated to be helpful in reducing the risk of post-endoscopic retrograde cholangiopancreatography (ERCP) pancreatitis due to regulation of proinflammatory mediators in acute pancreatitis. Rectal NSAID work by inhibiting phospholipase A2 activity, including arachidonic acid products and platelet-activating factors [12–14]. One NSAID in particular, rectal indomethacin, has been used extensively since 2012 following the publication of a randomized, placebo-controlled trial in patients undergoing ERCP considered to be at high risk for pancreatitis [13]. The trial found that a single 100 mg dose of rectal indomethacin significantly reduced the risk of pancreatitis from 16.9% in those receiving placebo to 9.2% in those receiving indomethacin.

However, with the exception of rectal indomethacin, there are currently no specific pharmacologic therapies advocated for the treatment of acute pancreatitis [15,16]. Supportive measures, including the use of fluid resuscitation, nutrition, and aggressive intensive care unit care, have become the cornerstone of conservative therapies in treating this disease.

This chapter focuses specifically on the conservative therapies of fluid resuscitation and enteral and parenteral nutrition. It will review the importance of the pancreatic microcirculation and how this affects the pathogenesis and prognosis of acute pancreatitis. It will discuss animal and human clinical trials which have evaluated the role of different types, volumes, and rates of fluid resuscitation. Finally, current recommendations in regard to administering fluids in acute pancreatitis will be provided. The second part of the chapter will focus specifically on the role of enteral and parenteral nutrition in the treatment of acute pancreatitis, with a review of clinical trials and important recommendations for nutritional care on patients with this disease.

## Fluid Resuscitation

### The Pancreatic Microcirculation and Acute Pancreatitis

It is critically important to understand the intricacies of the pancreatic microcirculation when discussing the role of fluid resuscitation in acute pancreatitis. The arterial

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

supply to the pancreas is derived from the two main proximal trunks of the aorta: the celiac trunk and superior mesenteric artery. The splenic and common hepatic arteries (as well as the left gastric artery which does not supply the pancreas) arise from the celiac trunk. The splenic artery gives rise to the penetrating branches of the body and tail of the pancreas, while the common hepatic artery, via its branch the gastroduodenal artery, supplies the pancreatic head through the anterior and posterior superior pancreaticoduodenal arteries. The anterior and posterior inferior pancreaticoduodenal arteries, arising from the superior mesenteric artery, supply the head and neck of the pancreas, and form vascular anastomoses with the superior pancreaticoduodenal arteries. This vascular network features extensive collateralization, thus ensuring adequate pancreatic tissue perfusion.

From these large arteries arise the intralobular arteries, which run within the pancreas often parallel to the pancreatic ducts. The intralobular arteries give rise to the pancreatic microcirculation, a vast network of capillaries and venules which supply the pancreatic acinus with a rich blood supply [17]. An exocrine lobular plexus with multiple fine capillaries represents the basic vascular unit within the pancreas and flow from the vascular plexus is almost 20 times more likely to prefer the pancreatic islet cells than the acinus. Because of this, the pancreatic acinus is extremely prone to low vascular flow states when there is lack of circulating blood flow to the pancreas [18]. This is why the pancreatic acinus can be so prone to damage with even a slight perturbation in systemic blood flow.

Disturbance to the blood flow within the pancreatic microcirculation due to acute pancreatitis can occur for several reasons: hypovolemia, increasing capillary permeability, and hypercoagulability causing microthrombi, among others [19–22]. The generation of oxidative free radicals with subsequent capillary endothelial damage has also been implicated. This alteration in microcirculation significantly increases the degree of pancreatic ischemia, irrespective of etiology, thus exacerbating the systemic inflammatory response syndrome (SIRS) and leading to multisystem organ failure.

Once significant acinar blood flow has been disturbed, acinar cell injury occurs. Acinar cell injury than causes the release of multiple proinflammatory cytokines and vasoactive mediators, including tumor necrosis factor α, histamine, bradykinin, interleukin 1 (IL-1), IL-2, IL-6, platelet-activating factor, and endothelin-1, are recruited to the pancreatic microcirculation and delivered to the acinar cells [23–25]. Once this proinflammatory cascade is set into motion, the systematic sequalae of acute pancreatitis, including the collapse of the systemic circulation leading to multisystem organ failure, can occur. Once initiated, this process is exceedingly difficult to reverse.

The role of aggressive fluid resuscitation is essentially to try to adequately perfuse the acinar tissue in the face of such overwhelmingly antagonism of the normal physiologic maintenance of adequate tissue perfusion pressure. Although fluid resuscitation by itself does not have an effect on the proinflammatory mediators leading to circulatory collapse, the sequalae of maintaining adequate tissue perfusion may seek to slow or ameliorate at least part of the inflammatory cascade. The hope for intravenous fluid resuscitation in acute pancreatitis is that adequate tissue perfusion will perfuse the pancreatic microcirculation so that pancreatic necrosis and its subsequent complications can be minimized or even prevented.

## Animal Studies

There have been extensive animal studies in the pathophysiology and treatment of acute pancreatitis, specifically in regard to establishing a definitive pharmacologic therapies for blunting the proinflammatory content of this disease. However, despite the important role of fluid resuscitation in acute pancreatitis, relatively few animal studies have been exclusively devoted to this subject. The critical question asked by animal studies in acute pancreatitis are the same as in human studies—How much fluid should be given? What type of fluid should be given? Is colloid or crystalloid fluid a better choice? What are the complications of using overly aggressive fluid resuscitation?

Two animal studies have demonstrated the importance of aggressive fluid resuscitation, irrespective of the type of fluid utilized. Juvonen and colleagues, using a pig model of Na-taurocholate-induced pancreatitis, showed that the signs of splanchnic hypoperfusion can be prevented with fluid resuscitation [26]. The investigators found that the $PCO_2$ gap increased and portal venous blood flow decreased in pigs with acute pancreatitis, but did improve significantly with resuscitation. Niederau et al. have also demonstrated in a choline-deficient, ethionine-supplemented diet mice model that hydration by subcutaneous fluid markedly improved survival and normalized the hematocrit without having significant biochemical or morphologic effects [27].

Crystalloid resuscitation has been studied only sparingly in animal studies of acute pancreatitis. Knol et al. evaluated the effect of low and high infusion rates of lactated Ringer's solution in 14 dogs with bile trypsin pancreatitis [28]. They found that pancreatic blood flow decreased to a greater extent in the low infusion group compared to the high infusion group. Crystalloid resuscitation with a balanced salt solution adequately restored

plasma volume, supported tissue perfusion and prevented excessive hemodilution without detrimental effects on pulmonary pressures or oxygenation in a canine model of acute hemorrhagic pancreatitis [29].

The majority of animal studies dealing with fluid resuscitation have used colloid solutions, most notably dextran, and generally found improved outcomes compared with crystalloid resuscitation. One suspected reason for improved outcomes with colloids has been that they are not as permeable to leakage in the pancreatic microcirculation compared with crystalloids. By remaining in the luminal environment, circulatory blood flow is better maintained, and inflammatory mediators are less able to access the acinus [30–34].

Thus, in summary, animal studies have been relatively sparse, and the majority of these have been completed with colloid rather than crystalloid solutions. However, these studies have not been able to effectively answer the questions of which solution is most appropriate, what is the optimal rate of fluid resuscitation, and what are the consequences of overly aggressive resuscitation. Surprisingly, as detailed below, the clinical studies in humans have not appreciably answered these questions satisfactorily either.

## Human Studies

Despite the universally accepted paradigm that aggressive fluid resuscitation is an important element of supportive care in acute pancreatitis which leads to improvements in important clinical outcomes, few studies have been performed on this and even a rarer number of randomized controlled trials. Questions about the rate of resuscitation, type of fluids, and consequences of over-aggressive resuscitation remain unanswered. However, in the last decade more attention had been focused on this important clinical area, and several randomized trials are planned to try to answer these critically important questions.

The original investigation in humans about the importance of aggressive fluid resuscitation was carried out by Baillargeon, Banks, and colleagues in the 1990s. They emphasized the importance of resuscitation in improving clinical outcomes. In a retrospective cohort study, they found that hemoconcentration with an admission hematocrit >47% or failure of admission hematocrit to decrease at approximately 24 hours were strong risk factors for the development of pancreatic necrosis [35]. Multiple subsequent studies have validated these findings, including the Banks group which performed a retrospective study to determine whether fluid resuscitation could prevent pancreatic necrosis among patients with hemoconcentration at the time of admission [36–41].

As these data suggest, inadequate fluid resuscitation leading to poor pancreatic microcirculatory perfusion has been associated with acute necrotizing pancreatitis [39]. Specifically, we now know that early fluid resuscitation has more of a therapeutic effect than delayed fluid resuscitation. Although early fluid resuscitation is generally agreed upon as an intervention of paramount importance, there are currently no standard guidelines on the optimal fluid type, volume, rate, or duration of treatment. Although human studies on the rate of hydration consistently show decreased morbidity and mortality with aggressive hydration in the first 24 hours, the total volume of hydration at the 48-hour mark seems to have a limited effect on patient outcomes.

The current American College of Gastroenterology (ACG) guidelines recommend 250–500 mL/h of isotonic crystalloid solution in the first 12–24 hours, with frequent re-evaluation every 6 hours and an ultimate goal of decreasing the blood urea nitrogen (BUN) levels [42]. Some experts recommend that in addition to the 1–2 L fluid bolus given in the emergency department, the starting infusion should be at a rate of 250–300 mL/h or enough to produce a urine output of at least 0.5 mL/kg per hour [43]. The goal within the first 24 hours is a total infusion volume of 2.5–4 L, with adjustments to be made based on the patient's age, weight, physical exam, and comorbid conditions [44].

The type of resuscitation fluid has not been satisfactorily studied. However, in a widely cited manuscript Wu and colleagues found that the use of lactated Ringer's solution, in place of normal saline, resulted in less SIRS and a decreased C-reactive protein at 48 hours [45]. However, this study was limited by the fact that is was conducted in only 40 patients. In patients undergoing ERCP, aggressive fluid resuscitation using lactated Ringer's solution has been shown to be an effective deterrent for the development of post-ERCP pancreatitis [46,47]. Thus, although they are not in the same exact clinical scenario as patients not undergoing ERCP, these results do suggest that the use of lactated Ringer's solution has a beneficial effect.

The issue of over-aggressive hydration and risk of poor outcomes, particularly the development of abdominal compartment syndrome, has been highlighted by two studies. The first, a retrospective evaluation of 99 patients with severe acute pancreatitis in Sweden, determined that patients receiving 4000 mL or more of fluids during the first 24 hours ($n = 32$) developed more respiratory complications (66% vs. 53%; $P$ 0.001) than patients who received less than 4000 mL of fluid [48]. Mao and colleagues have also reported improved survival rates by controlling the amount of fluid resuscitation within the first 72 hours in 83 patients with severe pancreatitis [49]. In addition, in a randomized controlled trial of patients with predicted severe pancreatitis whose hematocrit was

**Table 26.1** Important human studies of fluid resuscitation in acute pancreatitis.

| Study type | Number of patients | Comparison group | Outcome |
|---|---|---|---|
| Retrospective [35] | 65 | Aggressive (Hct <47) vs. nonaggressive | Hct >47 developed necrosis |
| Retrospective [48] | 99 | Aggressive (4 L) vs. nonaggressive | Aggressive with more respiratory complications and increased ICU care |
| Retrospective [40] | 45 | Early vs. late resuscitation | Increased mortality in late |
| Retrospective [41] | 434 | Early vs. Late resuscitation | Less SIRS, organ failure, ICU admissions, LOS in early |
| RCT [45] | 40 | LR vs. normal saline | LR had decreased SIRS and CRP at 24 h |
| RCT [46] | 62 | Aggressive (3 mL/kg per h) vs. nonaggressive using LR in ERCP | Less hyperamylasemia and abdominal pain in aggressive group |
| RCT [50] | 115 | Aggressive (<35 Hct in 1st 24 h) vs. nonaggressive | A higher incidence of sepsis and decreased survival in aggressive group |

Hct, hematocrit; ICU, intensive care unit; SIRS, systemic inflammatory response syndrome; LOS, length of stay; LR, lactated Ringer's solution; CRP, C-reactive protein.

aggressively lowered upon admission, those with aggressive lowering of their hematocrit had greater morbidity and mortality [50].

Thus, although important inroads have been made into the role of aggressive fluid resuscitation in the critical issue of supporting the pancreatic microcirculation in acute pancreatitis, several questions remain, particularly how best to monitor the rate of resuscitation and at what point the critical juncture of over-resuscitation occurs. Lactated Ringer's solution appears to represent an important breakthrough in the type of crystalloid solution to be used in this regard but further randomized controlled trials stratifying by the type of crystalloid solution are necessary. Continued animal studies into the effects of crystalloid and colloid solutions on the pancreatic microcirculations are in order as well as carefully designed human clinical trials using varying fluid solutions and rates, with an emphasis on patient monitoring and safety (Table 26.1).

## Enteral and Parenteral Nutrition

Nutritional supplementation has long been an important component of conservative treatment in acute pancreatitis. Since most patients with acute pancreatitis must be "nothing by mouth" for at least part of their hospitalization, the mechanism of nutritional supplementation and type has been an active area of clinical research for many decades. Although the standard of care for many years included nothing per mouth and "resting" the pancreas by limiting enteral intake, recent studies have proved that early enteral feeding appears to be of significant benefit to clinical outcomes.

The problem with maintaining patients nothing by mouth is that bowel rest is associated with intestinal mucosal atrophy and increased infectious complications due to bacterial translocation [51]. In order to maintain gut barrier function, therefore, enteral feeding is preferred over parenteral feeding in the management of acute pancreatitis.This has been proven in multiple randomized controlled trials dating back to the early 1990s, and meta-analyses have consistently demonstrated the importance of enteral versus parenteral nutrition in both interstitial and predicted severe acute pancreatitis [52–54]. Currently there is no rationale to use parenteral over enteral nutrition in the setting of acute pancreatitis. Even in patients who cannot tolerate a full enteral diet, at least some degree of enteral nutrition should be provided to maintain gut barrier function.

In mild acute pancreatitis, early initiation of oral intake with a low-fat soft solid diet is often tolerated and has been demonstrated to be just as efficacious as tube feeding [55]. Further study has also demonstrated that even in patients with predicted severe acute pancreatitis, early oral versus on-demand tube feeding has demonstrated equivalent efficacy in a randomized controlled trial [56]. Enteral feeding is recommended within 3 days of hospitalization, typically after cessation of nausea, vomiting, discontinuation of parenteral analgesics, reduction in abdominal pain, and return of bowel sounds. Feeding can also be started with a low-fat solid diet and does not need to be initiated using the archaic clear liquid, mechanical soft, and low-fat method [57].

The choice between nasojejunal or nasogastric feeding has been debated for quite some time with nasjojejunal feeding being favored, again because of the issue of

achieving pancreatic rest. However, recent studies have suggested that nasogastric feeding may be just as efficacious and well tolerated as nasojejunal feeding when evaluated in a randomized controlled setting [58]

The issue of type of feeding has been inadequately studied, but there has been a meta-analysis evaluating 20 randomized controlled trials comparing different formulations [59]. The authors concluded that the use of polymeric, rather than (semi)elemental, formulation does not lead to a significantly higher risk of feeding intolerance, infectious complications, or death in patients with acute pancreatitis. Neither the supplementation of enteral nutrition with probiotics nor the use of immunonutrition significantly improved the clinical outcomes. A Cochrane Database review also found similar low-quality evidence differentiating the types of formulations and their benefit in acute pancreatitis [60]. In addition, a recent study of the use of probiotics in acute pancreatitis demonstrated worsening mortality due to bowel ischemia in the group receiving probiotics and thus it is advised that probiotics should not be used in patients with acute pancreatitis [61].

Thus, in summary, enteral feeding is favored over parenteral feeding in acute pancreatitis based on improvement in important clinical outcomes. Oral feeding should be initiated with 72 hours of admission in all patients using a low-fat diet. If patients cannot tolerate oral feeding, nasoenteric feeding, usually with a nasogastric feeding tube, can be employed. In those patient in whom appropriate enteral feeding is not tolerated, low-level "trickle" feeding should be used to help prevent gut translocation of bacteria which can lead to infected necrosis. Patients should not be given probiotics, as these formulations have demonstrated an increased risk of mortality due to mesenteric ischemia.

## Conclusions

Supportive care in acute pancreatitis is critical to achieving optimal patient outcomes in the context of no targeted pharmacologic options in this disease. Aggressive fluid resuscitation and the initiation of early enteral feedings have revolutionized the care of the patient with acute pancreatitis. Further study, specifically targeting the type of fluids and enteral nutrition formulations in a randomized controlled trial format are needed, however, to further optimize conservative care for these patients.

## Introduction

Acute pancreatitis remains a complex, progressive, and variable acute inflammatory syndrome. In some cases the inflammatory response is so severe that a sequence of systemic inflammation defined by the systemic inflammatory response syndrome (SIRS), vascular leak syndrome (VLS), multiorgan dysfunction, shock, and death may occur. Patients with life-threatening complications should be managed in the intensive care unit (ICU), where early intervention and support may result in better outcomes. This chapter will focus on management following a general clinical pathway to emphasize the sequence of common events and evidence behind clinical decisions.

## Pre-ICU Management

Optimal treatment begins in the clinic or emergency department (Fig. 27.1). The primary goals in early evaluation include confirming the diagnosis, detecting early signs of organ dysfunction, and initiating fluid resuscitation. Fluid resuscitation (see Chapter 26) may be the most important early intervention for stabilizing and treating patients with evolving severe acute pancreatitis.

The initial physical examination is central to assessment and proper triage. The clinical histories are variable, but sudden onset of severe, sharp, unrelenting pain with nausea and vomiting is common. In addition to a routine physical examination the clinician should focus on early signs of severe acute pancreatitis, including severe pain, anxiety, confusion, scleral icterus, diaphoresis, dry mouth, tachycardia, thready pulses, acrocyanosis, tachypnea, lung rales, and abdominal tenderness with or without rebound pain. Postural changes (e.g., supine to standing) resulting in dizziness or tachycardia suggest significant intravascular hypovolemia [1].

The initial laboratory assessment should include standard diagnostic tests in addition to standard laboratory tests (Box 27.1). These tests serve both as baseline values for future comparisons and early biomarkers of organ dysfunction that may require ICU management. A chest X-ray may provide early evidence of pulmonary edema [2,3].

Early morbidity and mortality are complications of SIRS, especially when it leads to VLS [4] and organ dysfunction involving the lungs, cardiovascular system, intestines, and kidneys [5–8]. Early management focuses on fluid resuscitation and oxygenation. Patient comfort centers on treatment of pain and nausea.

Life-threatening hypovolemia in acute pancreatitis develops as a consequence of VLS, which occurs in an unpredictable subset of patients. The mechanism of hypovolemia in acute pancreatitis appears to overlap with trauma and VLS [4,9]. Blood pressure may not become significantly decreased until the patient has lost 30–40% of circulating blood volume [10]. Therefore, blood pressure correlates poorly with both blood volume and cardiac output. Furthermore, significant hypovolemia may be masked by splanchnic vasoconstriction and shunting of blood from the viscera to maintain circulation to the brain and heart.

Hypoperfusion and/or ischemia of visceral organs create two additional challenges to the problem of generalized tissue ischemia. First, hypoperfusion may continue long after systemic volume resuscitation has

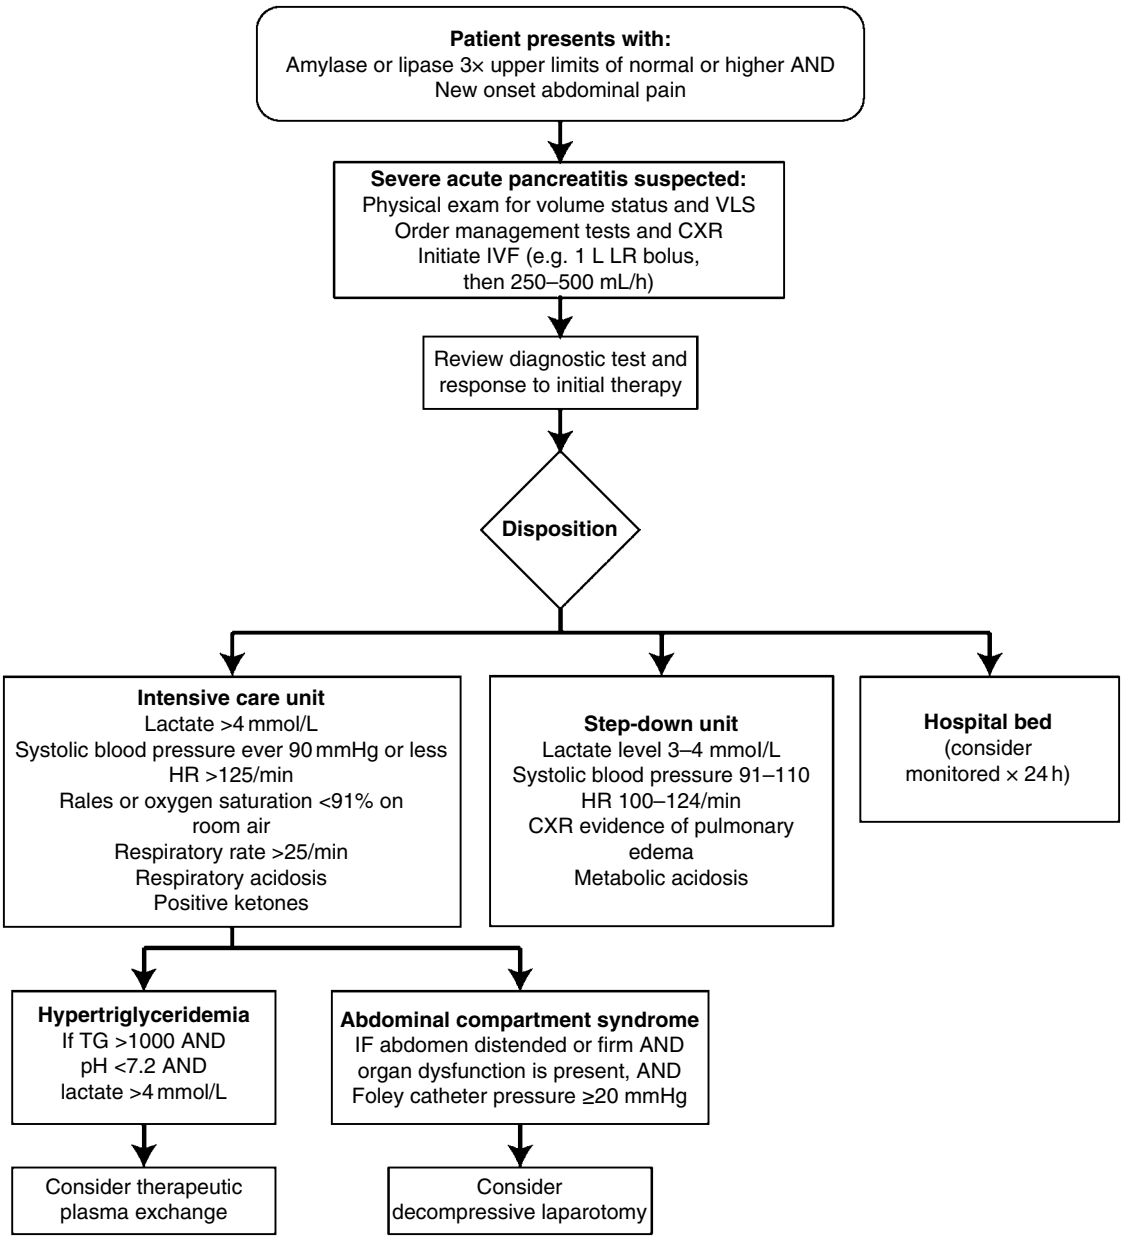

**Figure 27.1** An illustrative clinical pathway for managing patients during the initial evaluation and possible admission into the intensive care unit. CXR, chest X-ray; HR, heart rate; LR, lactated Ringer's solution; TG, triglyceride level; VLS, vascular leak syndrome.

occurred, resulting in continued ischemic stress on intestinal mucosal epithelial cells, the most vulnerable cells of the gut [11,12]. Second, mucosal epithelial cell injury results in breakdown of the mucosal barrier and translocation of bacteria and toxic factors that enter the circulation via the mesenteric lymphatics and drive SIRS [13–15]. Thus, in some patients, a vicious cycle develops with systemic inflammation leading to VLS, which causes intravascular hypovolemia and splanchnic vascular bed ischemia, leading to translocation of proinflammatory toxins from the gut lumen into the lymphatics that further drives systemic inflammation. Interruption of this cycle should begin with minimizing or preventing intravascular hypovolemia.

The usual systolic blood pressure of adults varies widely, so the relative change in both blood pressure and heart rate may be more important than an absolute value. A systolic blood pressure <90 mmHg, however, is likely to be a *late* sign of severe intravascular hypovolemia [16]. An elevated hematocrit indicates hemoconcentration and implies significant extravasation of serum from the bloodstream and is a harbinger of impending organ

failure [17]. Elevated lactate levels also suggest that tissues may already be in shock [18]. We believe that optimal treatment includes the prevention of hypotension and shock, and resuscitation should not be delayed until signs of hemoconcentration and shock develop.

Treatment and prevention of progressive intravascular hypovolemia must begin before the patient is transferred to the ICU. We recommend that a liter of balanced salt solution should be given rapidly, as soon as the diagnosis of acute pancreatitis is made, with modifications for patients with existing comorbidities. In patients with a fluid deficit, repeated boluses and/or fluid support at rates of 250–500 mL per hour should be consider until the patient's cardiovascular system is stabilized [5,19]. Urinary output may be useful in determining fluid status.

Early use of supplemental oxygen is warranted with continuous monitoring of oxygen saturation via pulse oximetry or intermittent arterial blood gas analysis. The pulmonary edema seen in patients with severe acute pancreatitis and VLS is usually due to capillary injury and extravasation of plasma, not fluid overload. Therefore, the treatment should be positive pressure ventilation and not diuresis, unless the patient is absolutely volume overloaded.

For pain we recommend hydromorphone 0.5–2.0 mg intravenously every 15 minutes while the respiratory rate is >10 and systolic blood pressure is >90 mmHg. However, no differences between opiates were demonstrated in systematic reviews of variable quality clinical studies [20,21]. For nausea we give ondansetron 4–8 mg intravenously every 6 hours as needed.

## Special Considerations

As in trauma, management decisions made in the early minutes and hours of care have significant downstream consequences. The emergency in severe acute pancreatitis is fluid management and tissue oxygenation within the context of systemic inflammation. But unlike trauma where the insult is rapid and finite, the systemic inflammation of acute pancreatitis evolves, so continued attention to the evolution of the process over the first 24 hours is critical.

We strongly discourage the use of contrast computed tomography (CT) scan in early severe acute pancreatitis. The diagnosis can almost always be made by the combination of typical pain and elevated serum levels of pancreatic digestive enzymes [6,8]. Although contrast-enhanced CT scan remains useful for detecting and quantifying pancreatic necrosis and/or fluid collections, there are no urgent interventions, and the evaluation can be delayed for days. Early contrast CT poses at least two risks. First, the contrast may worsen the severity of pancreatic necrosis, as well as kidney injury in patients, especially if there is poor perfusion from hypovolemia and/or shunting of blood from visceral organs. Second, the process of obtaining a CT may interrupt evaluation and treatment, or delay transfer to the ICU. However, CT or other abdominal imaging modalities may be required if the diagnosis is in question.

Gallstone pancreatitis occurs when small gallstones become lodged at the sphincter of Oddi and trigger intrapancreatic digestive enzyme activation and acute pancreatitis. In some cases the gallstone remains lodged, whereas in others the stone passes on its own. Although there used to be great enthusiasm for urgent endoscopic retrograde cholangiopancreatography, biliary sphincterotomy, and stone removal, randomized studies failed to demonstrate a benefit for early intervention [22,23]. The exceptions are cases where an impacted gallstone results in ascending bacterial cholangitis [22]. This condition represents an urgent complication that requires a therapeutic intervention. In this setting, antibiotics should be started immediately. However, the priority of an ERCP is secondary to fluid resuscitation, airway management, and patient stabilization.

## Indications for ICU Admission

Early and appropriate treatment of patients with acute pancreatitis may result in rapid resolution of signs and symptoms of more severe disease. In these cases it is reasonable for patients to be treated and monitored on a step-down unit until the clinical course of the patient dictates a change in care level.

We recommend ICU admission for patients with persistent organ dysfunction who require a high level of care with frequent adjustments to the care plan. Examples include patients with lactate >4 mmol/L, systolic blood pressure at any time <90 mmHg, need for vasopressors, an ongoing heart rate of >125 per minute, rales on lung exam or oxygen saturation <91% on room air, a respiratory rate >25 per minute, any respiratory acidosis or positive serum ketones. In addition, patients with SIRS and VLS may require ICU admission for invasive monitoring of intravascular volume, and impending cardiac and/or pulmonary dysfunction.

## ICU Treatment of Severe Acute Pancreatitis

The evolution of severe acute pancreatitis dictates the concerns and management strategies over the first days of disease. The initial phase (0–48 hours after onset of pain) reflects the magnitude of the acute inflammatory response with SIRS, vascular leak, and early organ dysfunction of the cardiovascular system, lungs, and kidneys. The second phase (48–120 hours after onset of pain) focuses on managing recovery of organ systems from injury and preventing secondary problems such as infection in immunocompromised patients from the compensatory anti-inflammatory response syndrome (CARS) [24].

## Early ICU Management (0–48 Hours from Onset of Pain)

Managing patients with acute pancreatitis who require ICU admission is best done by a multidisciplinary team including intensivists and specialists in the medical and surgical management of pancreatitis.

### Management of Cardiovascular Dysfunction

Hypotension may be the result of inadequate cardiac output from intravascular volume depletion, reduced systemic vascular resistance, or both. Early therapy should center on restoration of adequate circulating blood volume to ensure adequate oxygen delivery. Ongoing hypotension despite volume resuscitation will require vasopressor support. We guide our volume resuscitation and the initiation of pressors based on repeated physical exam, biochemical markers of perfusion (lactate and mixed venous oxygen saturations), and dynamic measures of preload responsiveness, such as pulse pressure variation on the arterial line of intubated patients [25–27].

If the patient remains hypotensive after preload is optimized, we initiate pressors for maintenance of perfusion pressure. We target a mean arterial pressure of ≥65 mmHg. Once again, there are few study results to guide us in our choice of pressor. The literature suggests that neither norepinephrine nor epinephrine have a mortality benefit for patients with septic shock [18,28]. However, epinephrine may increase lactate levels despite achieving adequate perfusion pressure, so we start with norepinephrine. We do not routinely add vasopressin unless the patient exhibits significant complications from high-dose catecholamine therapy such as tachyarrhythmias [29].

### Management of Pulmonary Dysfunction

Acute respiratory distress syndrome (ARDS) is a well-recognized complication of acute pancreatitis. Initial management with supplemental oxygen may prove inadequate and many patients with ARDS will require more aggressive care. High-flow oxygen through a nasal cannula provides heated and humidified oxygen at flow rates high enough to develop some continuous positive airway pressure. In addition, high-flow oxygen may be more comfortable than noninvasive ventilation [30].

All patients who require intubation and mechanical ventilation for ARDS should be initially managed with a tidal volume of 6 mL/kg predicted body weight. Respiratory rates are adjusted to achieve a pH between 7.30 and 7.45 if possible. Positive end-expiratory pressure (PEEP) and fraction of inspired oxygen ($FiO_2$) should be titrated to maintain an arterial $PaO_2$ of between 55 and 80 mmHg [31]. Titrating PEEP or $FiO_2$ to achieve a $PaO_2 > 80$ mmHg may improve arterial blood gas values, but has not been shown to improve survival [32]. If hypoxia persists (i.e., a $PaO_2/FiO_2$ ratio of <150 mmHg) and PEEP and $FiO_2$ levels exceed 10 and 0.6, respectively, we start both neuromuscular blockade [33] and prone position ventilation [34] early.

### Management of Abdominal Compartment Syndrome

Abdominal compartment syndrome is a pathophysiologic process arising from increased tissue fluid within the peritoneal and/or retroperitoneal space. Like other compartment syndromes, when the abdominal cavity can no longer expand, further fluid collection results in increases in abdominal pressure with subsequent decreases in perfusion and ischemia to intra-abdominal organs. In patients with acute pancreatitis, swelling from pancreatic necrosis, ileus with gas distension, fluid collections, and volume overload from resuscitation may lead to abdominal compartment syndrome. Abdominal

compartment syndrome is suspected on physical examination when the abdomen is firm and/or distended.

Intra-abdominal pressure is the steady-state pressure within the abdominal cavity and is measured by instilling 25 mL of sterile saline through the Foley catheter and measuring the resultant pressure at end expiration in the complete supine position after ensuring that abdominal muscle contractions are absent and with the transducer zeroed at the level of the midaxillary line [35]. A normal intra-abdominal pressure in critically ill adults is 5–7 mmHg. Intra-abdominal hypertension is a sustained pressure ≥12 mmHg.

Abdominal compartment syndrome is a sustained intra-abdominal pressure of ≥20 mmHg with new organ dysfunction or failure. Although some patients may respond to a trial of sedation and neuromuscular blockade (relaxing the abdominal wall and thereby decreasing intra-abdominal pressure) and nasogastric tube decompression, many patients with acute pancreatitis and abdominal compartment syndrome will need a decompressive laparotomy.

## Management of Metabolic Derangements

### Hypertriglyceridemia

Hypertriglyceridemic acute pancreatitis represents a spectrum of underlying genetic disorders and metabolic risks such as diabetes mellitus and obesity. Triglycerides alone are rather inert. However, it is believed that in the presence of lipase(s), the triglycerides are hydrolyzed to free fatty acids (FFA), and it is the FFA that are toxic, especially unsaturated FFA [36]. Hypertriglyceridemia is associated with more severe acute pancreatitis and persistent organ failure [37], and may require special attention. Thus, while the focus of physicians treating hypertriglyceridemic acute pancreatitis in the past has often been on reducing the triglyceride levels, the focus should be on clearing FFA [36]. Serum concentrations of FFA are a function of production and clearance. The lipolysis of triglycerides normally occurs within tissues such as muscle, fat, and visceral organs by lipoprotein lipase (LPL), a regulated enzyme. FFA are cleared by these tissues, with excess FFA binding to albumin and transported to the liver where FFA are transferred from albumin to the hepatocytes. In acute pancreatitis, the controlled hydrolysis of triglycerides by LPL is disrupted with the addition of pancreatic lipase(s) that also catalyzes triglycerides to FFA in an unregulated way, overwhelming the capacity of the body to manage the FFA pool generated by LPL, and leading to lipotoxicity. In this case, management of the FFA-associated toxicity should focus on prevention of hydrolysis of triglycerides by LPL (e.g., fluid resuscitation and maintaining good hydration, avoiding heparin) by (theoretically) inhibiting pancreatic lipases [36], and by facilitating clearance of FFA from the serum with insulin infusion or apheresis/plasma exchange [38]. In addition to driving SIRS, FFA can block mitochondrial function, leading to lactic acidosis (pH <7.2, lactate >4 mmol/L), often seen with low calcium (e.g., calcium <8.3 mg/dL). This requires emergency intervention in the ICU, especially in the presence of liver and/or kidney dysfunction. Note that a similar syndrome of lactic acidosis occurs with complications of metformin use [39].

### Diabetic Ketoacidosis with Acute Pancreatitis

Acute pancreatitis often develops in patients with diabetic ketoacidosis (DKA). The mechanism triggering acute pancreatitis appears to be linked to low pH. In a study of 100 subjects with DKA the subjects with coexisting acute pancreatitis had more severe metabolic acidosis (mean pH 7.15 vs. 7.31; $P = 0.0001$) and higher anion gap (38.17 mEq/L vs. 25.16 mEq/L; $P = 0.0001$) [40,41]. These patients may also have hypertriglyceridemia [42]. In these cases, addressing insulin deficiency, acidosis, and hydration generally results in rapid improvement.

Nutrition support is covered in Chapter 26.

## Late ICU Management (>48 Hours After the Onset of Pain)

Visceral organs share a compartment and, to some extent, regulation of blood flow. Thus, damage to one organ should raise awareness of damage to others. The easiest organ to monitor is the kidney by following serum creatinine levels and blood urea nitrogen (BUN). The increase of serum creatinine and BUN levels over the first 24 hours remain among the best predictors of pancreatic necrosis and persistent organ failure [43,44]. We hypothesize that acute kidney injury in acute pancreatitis represents one component of a common mechanism of injury for multiple visceral organs (i.e., kidneys, pancreas, and intestine) that are damaged by hypoperfusion and ischemia. Intestinal ileus may be a parallel sign of visceral organ ischemia. Early recognition of high risk for pancreatic necrosis determines future management strategies, and thus further evaluation is warranted.

After resuscitation and stabilization, abdominal imaging remains central to the eventual evaluation of pancreatic morphology, intra-abdominal fluid collections, and other complications. The radiologic evaluation and

staging of severe acute pancreatitis is covered in Chapter 25.

### Alcohol Withdrawal Syndrome

Alcohol abuse is a common cause of severe acute pancreatitis and alcohol withdrawal may be a complication encountered in the late ICU phase. We start treatment with escalating doses of benzodiazepines [45]. Maximal doses of benzodiazepines are defined by their diluent, propylene glycol, which can have potentially toxic effects. For benzodiazepine-resistant alcohol withdrawal syndrome, we add either phenobarbital or ketamine.

## Management of Infectious Risks

The use of antibiotics is discussed in Chapter 28. The management of infected pancreatic necrosis is discussed in Chapters 29–31.

## Transition Planning

As the clinical course of the patient becomes clear and the intensity of organ support is reduced, transition out of the ICU must be considered. We consider transfer out of the ICU when the organ system dysfunction that necessitated ICU admission has resolved.

# Use of Antibiotics in Severe Acute Pancreatitis: Indications and Limitations

*Rainer Isenmann*[1] *and Mathias Wittau*[2]

[1] *Department of Surgery, St.-Anna-Virngrund-Klinik, Ellwangen, Germany*
[2] *Department of General and Abdominal Surgery, University of Ulm, Ulm, Germany*

## Introduction

Although 85% of patients with acute pancreatitis experience an uneventful recovery, this disease bears a high risk for severe and even lethal complications. Cardiocirculatory, pulmonary, or renal failure, alone or in combination, are common problems in patients with severe acute pancreatitis. The treatment is conservative, including mechanical ventilation, hemofiltration, or hemodialysis as well as cardiocirculatory support, if required. The majority of patients respond to such an approach. Nevertheless, mortality of severe acute pancreatitis remains at about 10%.

The poorest prognosis is observed in patients with necrotizing pancreatitis who develop local bacterial infection. Surgical or interventional management is generally required in these cases and mortality rates exceeding 30% been reported [1,2]. Despite progress in our understanding of the pathology of pancreatic sepsis and in intensive care treatment, the mortality rates of infected pancreatic necrosis have not changed in recent decades. Recent attempts with nonsurgical or interventional treatment have been promising [1,3] but there is no doubt that bacterial infection will remain a life-threatening complication in patients with necrotizing pancreatitis.

The recently revised Atlanta classification of acute pancreatitis discriminates between mild acute pancreatitis, moderately severe acute pancreatitis, and severe disease, depending on the occurrence of organ failure and/or local and systemic complications [4]. In contrast to former classification systems, where the term "infected pancreatic necrosis" has been used for all locally infected pancreatic entities, the revised classification distinguishes between morphologically different local infectious complications.

## Infectious Complications

During the course of acute pancreatitis, either systemic or local pancreatic infections may occur. The incidence of these complications varies widely, depending on definition and patient selection.

### Local Pancreatic Infection

In approximately 30–40% of the patients with necrotizing pancreatitis local infections of the necrotic areas develop [5]. Bacterial infection of pancreatic necrosis is the most important determinant of outcome [6]. The revised Atlanta classification discriminates between different morphological entities and comprises acute peripancreatic fluid collections (APFC), pancreatic pseudocysts, acute necrotic collections (ANC), and walled-off necrosis (WON). These morphologic entities have a variable potential for bacterial infection (Table 28.1) with pancreatic necrosis and WON bearing the highest risk.For our understanding of relevance of infectious complications and the role of antibiotics in the treatment algorithm, discrimination between these morphologies therefore is important. Irrespective of the morphologic differences, bacterial infection is a phenomenon of the later phase of acute pancreatitis, commonly observed after the third or fourth week after onset of the disease. This might be one of the reasons why all efforts to reduce the infection rate by prophylactic antibiotics have failed. There is a wide time frame for infection and it is difficult to impossible to define the exact period when prophylactic antibiotics might be effective.

**Table 28.1** Complications of severe acute pancreatitis with the potential risk of bacterial infection, according to the current revised Atlanta Classification [4].

| | Characterization | Estimated potential for infection |
|---|---|---|
| Necrotizing pancreatitis | Inflammation associated with pancreatic parenchymal necrosis and/or peripancreatic necrosis | High |
| Walled-off necrosis (WON) | Necrotic tissue surrounded by a wall of tissue, usually >4 weeks after onset of pancreatitis | High |
| Acute necrotic collection (ANC) | Collection of necrosis and fluid during the first 4 weeks of AP | Moderate |
| Pancreatic pseudocyst | Walled of fluid collection weeks after AP. May require surgical drainage if persistent | Low–moderate |
| Acute peripancreatic fluid collection (APFC) | During the early phase of AP, resolve spontaneously | Low |

AP, acute pancreatitis.

### Systemic Bacterial Infection

Extra-abdominal bacterial infection is a common finding during severe acute pancreatitis. Its incidence varies widely in different studies. In a multinational European study, more than 40% of the patients had extra-abdominal infections, with respiratory tract infections being the most frequent ones (28%), followed by bloodstream infections (14%), and catheter-related infections as well as genitourinary tract infections (4%) [7]. In the author's own investigation, 25% of the patients of the control group (not treated with antibiotics) had extrapancreatic infection, with pneumonia being the most frequent one [8].

The clinical relevance of extrapancreatic infection has been clearly demonstrated: it increases mortality and adversely affects the outcome of acute pancreatitis [9]. Whether its relevance is equal to that of pancreatic sepsis is subject to discussion.

## Spectrum of Bacteria

In the first description of infected pancreatic necrosis in the 1980s, the bacterial spectrum of infection was dominated by gram-negative enteric germs [5]. During the past three decades, there has been some change, but gram-negative bacteria still play a dominant role in the bacterial spectrum. Nevertheless, gram-positive microorganisms, especially staphylococci and enterococci are increasingly coming into focus. The bacterial spectrum is polymicrobial and comprises anaerobic bacteria as well (Table 28.2).

The role of multidrug resistance among these germs has recently been addressed. Many gram-positive species are resistant to methicillin, as are many extended spectrum beta-lactamase (ESBL)-producing gram-negative germs. In one recent study, 63% of the patients with infected pancreatic necrosis were infected with multiresistant germs [12]. As in other infectious pathologies, these multiresistant germs are of therapeutic and prognostic importance. Their isolation should prompt treatment with an adequate antibiotic drug according to the tested bacterial susceptibilities.

In addition, a considerable percentage of patients with necrotizing pancreatitis develop fungal infections. The prognostic impact of this has been discussed extensively during the past decade. Most often, fungal infection is caused by *Candida* species and is regarded to be predictive of worse outcome. It is generally accepted that antibiotic treatment promotes overgrowth of unaffected or resistant pathogens and is thus regarded to be a risk factor of both fungal and multiresistant infection [13,14].

## Rationales for Antibiotics in Acute Pancreatitis

The use of antibacterial agents in acute pancreatitis has been debated since the 1970s. At first, antibiotics were regarded as a part of the treatment regime without clear definition of their indication. Our increasing knowledge about the impact and relevance of infection during the 1980s and 1990s has led to the definition of two potential settings for the use of antibiotics: for prevention of infection and for treatment of infection.

### Prevention of Infection

The clinical relevance of bacteral infection with its poor prognosis supports treatment algorithms for its prevention. This led to the idea of prophylactic administration of antibiotics with the intention of preventing bacterial

**Table 28.2** Development of the bacterial spectrum of infected pancreatic necrosis during the past 30 years. Selected strains from different studies. Note the increase in the incidence of enterococci and fungi.

| | Beger 1986 [5] | Isenmann 2004 [6] | Dellinger 2007 [10] | Schmidt 2014 [11] |
|---|---|---|---|---|
| No. of isolates | 75 | 19 | 30 | 88 |
| **Percentage of strains** | | | | |
| Enterococci | 8% | 11% | 23% | 28% |
| *E. coli* | 32% | 32% | 7% | 26% (Enterobacteriaceae) |
| *Pseudomonas* | 7% | – | 10% | 7% |
| Anaerobic bacteria | 7% | – | 3% | n.d. |
| Fungi | 4% | 10% | 10% | 14% |

n.d., no data.

superinfection. In recent years, there has been considerable scientific effort to prove such a concept as discussed later in this chapter.

### Treatment of Infection

In combination with surgical debridement, antibiotic treatment is the mainstay in the treatment of any intra-abdominal infection, including infected pancreatic necrosis. It is well known that inappropriate antibiotic treatment in severe sepsis results in a fivefold increase in mortality [15]. For acute pancreatitis a selective uptake of antibiotics into the pancreas has been described [16], which should be taken into account. As a consequence the antibiotics for treatment of pancreatic infection should not only be chosen according to the bacterial spectrum and their antibacterial activity, but also according to their ability to penetrate into the infectious focus [16,17].

## Clinical Studies with Antibiotics

During the past 20 years, there have been numerous controlled and uncontrolled, blinded and unblinded studies addressing the issue whether early administration of antibiotics in severe acute pancreatitis could reduce the incidence of local bacterial infection and consequently could improve the prognosis of the disease (Table 28.3). Among these, four had adequate scientific power for meaningful conclusions [8,10,18,19]. None of them has been able to give a definite answer to this question and according to the latest meta-analyses, there is no evidence to support the routine use of prophylactic antibiotics in patients with severe acute pancreatitis [20,21].

Consequently, neither the current guidelines of the International Association of Pancreatology/American Pancreatic Association [33] nor of the American College of Gastroenterology recommend prophylactic antibiotics in severe acute pancreatitis [34].

What are the reasons for our inability to demonstrate a beneficial effect of prophylactic antibiotics on the infection rate in acute pancreatitis? First, acute pancreatitis is a heterogeneous disease with highly variable course ranging from mild and self-limiting to devastating with severe septic complications. The majority of patients with acute pancreatitis will never develop infectious complications. To date, there are no reliable parameters which allow the identification of patients at risk for developing pancreatic sepsis. Second, pancreatic infection is a phenomenon of the later course of the disease. Thus the ideal timing and optimal duration of antibiotic administration as prophylaxis is not clear. Antibiotics given too early and too long may be uneffective and promote bacterial resistance. Third, new concepts in the therapy of acute pancreatitis such as early enteral nutrition and treatment of organ dysfunctions may directly or indirectly affect the incidence of septic complications.

These facts, together with others, make it unlikely that we will ever be able to elaborate pathways for the prophylactic use of antibiotics in severe acute pancreatitis [35].

## Indications for Antibiotic Treatment

The main indications for initiation of antibiotic treatment in acute pancreatitis are evidence or strong suspicion of local and/or systemic bacterial infection. Therefore, all current guidelines aim at the timely identification of infected necrosis. The recommended standard comprises close monitoring of infectious parameters, imaging by contrast-enhanced computed tomography and, in cases with strongly suspected bacterial infection, the fine-needle aspiration for Gram stain and culture (FNA) [34]. Pancreatic infection

**Table 28.3** Studies on antibiotic prophylaxis in severe acute pancreatitis. Note that only a few had adequate scientific power for meaningful conclusions.

should be suspected in patients with pancreatic or extrapancreatic necrosis and clinical deterioration or failure to improve over 7–10 days.

## Antibiotic Treatment on Demand

The experience from the Severe Acute Pancreatitis Study group (ASAP) study [8] showed that antibiotic treatment was initiated in a considerable percentage of patients with clinical deterioration. The criteria for initiating this so-called "antibiotic treatment on demand" in this study were:

- newly developed sepsis/SIRS;
- newly developed organ failure (pulmonary, renal, cardiocirculatory);
- increase in serum C-reactive protein and strongly suspected/proven extrapancreatic infection;
- increase in serum C-reactive protein and strongly suspected/proven pancreatic infection.

In 37% of the patients of this study, the double-blind study medication was terminated and switched to open antibiotic treatment. The low rate of infected pancreatic necrosis (10.5%) as well as the favorable outcome (mortality 6% in the overall study) can be taken as rationale to initiate antibiotic treatment at these given indications.

## Choice of Antibiotics

The choice of antibiotics in necrotizing pancreatitis has to be taken into consideration:

- the bacterial spectrum,
- the antibiotic concentrations at the site of infection, and
- the results of clinical studies.

Based on these criteria, carbapenems, chinolones, and broad-spectrum cephalosporins are first choice drugs for the initial treatment of pancreatic infection. The latter two should be combined with metronidazole as they lack sufficient antibacterial activity in the anaerobic spectrum. Based on their pharmacokinetic properties, acylaminopenicillins/beta-lactamase inhibitor combinations can be regarded to be effective as well, although there are no clinical studies with these drugs.

Following initiation of an empirical antibiotic therapy, a step down should be followed as soon as the results of bacterial susceptibility testing are available.

Up to now, there is no rationale to initiate a "blind" antifungal therapy. Antifungal agents should only be given when bacterial smears yield fungal infection.

## Limitations of Antibiotic Treatment

Antibiotic treatment is an essential part of the therapeutic regime in patients with infected pancreatic necrosis, but is not enough on its own for successful treatment of these critically ill patients. The mainstay for success is source control of the infectious focus and debridement of the infectious material is an essential part of the treatment regime.

Today, open or laparoscopic surgical debridement and interventional drainage are subject to debate. Scientific evidence suggests that a "step-up approach" might provide favorable results as the best surgical approach in pancreatic infection [1]. Following such an approach, the patient is managed by conservative treatment as long as possible. In the case of strongly suspected or proven pancreatic infection, percutaneous drainage is used as an initial approach for source control. If this fails, surgical necrosectomy (minimally invasive or open) follows [36].

Whether or not pancreatic infection can be treated with antibiotics alone and without debridement is under current investigation. The first studies following such an approach have been criticized [37], but a recent meta-analysis shows that in selected patients this can be safely done with low mortality [3]. Nevertheless, it is necessary to define criteria that characterize the group of patients who are eligible for such a conservative approach.

Most recently, a global overview on the use of antibiotics among physicians indicated that their use, both as prophylaxsis and as treatment in acute pancreatitis, is widespread [38]. Irrespective of the national treatment guidelines for the disease, antibiotics are frequently given without clear indication, even in mild pancreatitis or when pyrexia is present. This overuse poses not only healthcare problems in terms of unnecessary expense but also risks for the patients, including antibiotic-associated side-effects and selection of multiresistant bacteria.

# Interventional and Surgical Management of Acute Pancreatitis

## 29

## Indications for Interventional and Surgical Treatment of Necrotizing Pancreatitis

*Thomas E. Clancy*

*Department of Surgery, Brigham and Women's Hospital, Boston, MA; Harvard Medical School, Boston, MA, USA*

### Introduction

Whereas interstitial acute pancreatitis is typically a self-limited disease process that usually responds to supportive care, the more severe necrotizing pancreatitis can be seen in approximately 20% of patients. This is characterized by necrosis of the pancreatic parenchema or peripancreatic tissue, manifestations of the systemic inflammatory response syndrome (SIRS), with risks for infection and multiorgan failure [1]. High rates of morbidity are associated with mortality of up to 15% in the setting of necrotizing pancreatitis and as high as 30% in the subset of patients who develop infected pancreatic necrosis [2,3]. A variety of surgical and interventional approaches have been used in an attempt to limit the substantial morbidity and mortality of necrotizing pancreatitis.

Over the last few decades, there has been a significant change in the indications for intervention in necrotizing pancreatitis, timing of intervention, and methods of surgical, minimally invasive, radiologic, and endoscopic intervention. Recent revision of the 1992 Atlanta classification of acute pancreatitis [4] to more precisely describe the clinical behavior and imaging characteristics of acute pancreatitis [5] has occurred in parallel with a progressively less interventional and less invasive approach to necrotizing pancreatitis. Although no universally accepted management algorithm exists to guide management, evidence-based consensus continues to develop [6].

### Interventions for Pancreatic Necrosis: Historical Perspective

Just a few decades ago, the association of pancreatic necrosis with systemic inflammation and secondary infection led to the goal of surgically removing all necrotic pancreas regardless of the presence of infection [7–9]. In 1991, Bradley and Allen published a small series of 11 patients successfully managed nonoperatively with sterile pancreatic necrosis [10]. The general acceptance of nonoperative management for sterile pancreatic necrosis was facilitated by the publication of large series demonstrating favorable overall mortality and complications [11,12]. In this new paradigm, intervention was primarily limited to surgical debridement for cases of infected pancreatic necrosis as demonstrated by computed tomography (CT)-guided fine-needle aspiration (FNA) of the pancreas. Banks et al. showed a sensitivity and specificity of 96.2% and 99.4%, respectively, for detection of infected necrosis, with a positive predictive value of 99.5% and a negative predictive value of 95.3% [13]. The presence of infection or positive Gram stain on CT-guided pancreatic aspiration, however, was considered an absolute indication for debridement, as superinfection of the necrotic parenchyma had been associated with a mortality of virtually 100% without debridement [14].

The absolute necessity of surgical debridement for infected necrosis was subsequently questioned with the

Companion website: www.wiley.com/go/beger/thepancreas

demonstration of successful nonoperative management in some patients. Runzi et al. [15] showed in a series of over 80 patients with documented infected pancreatic necrosis that initial conservative therapy can be instituted, including antibiotic therapy and maximal supportive care. Mortality in patients managed with surgery was identical to that in those managed nonoperatively. Surgical therapy, when required, was often delayed to a later stage of disease, when the systemic inflammatory response has been stabilized and necrotic pancreas had become demarcated. In other patients, surgical therapy was avoided altogether. Subsequent studies have confirmed this strategy: Garg et al. describe a 10-year series of 80 patients with infected pancreatic necrosis in whom 47 were treated with antibiotics alone [16]. The paradigm of urgent surgical debridement for all patients with infected pancreatic necrosis is therefore no longer considered valid.

## Indications and Timing of Intervention

Unlike the prior delineation of pancreatic necrosis to infected and sterile versions, the revised Atlanta classification [5] divides collections associated with necrotizing pancreatitis according to time of disease onset. A collection that develops early and lacks a discrete wall is referred to as an acute necrotic collection (ANC), whereas a collection that persists after 4 weeks is referred to as walled-off necrosis (WON). Both forms may be sterile or infected. Although the presence or absence of infection is crucial for prognosis and affects management decisions, the presence of clinical symptoms rather than suspicion of infection is considered paramount for intervention.

## Pancreatic Necrosis with Infection

Despite demonstrated success with nonsurgical management for infected necrosis, many if not most patients with infected pancreatic necrosis require some form of intervention. Some series suggest that clinically stable and relatively asymptomatic patients with infected necrosis can be managed with antibiotics alone [15–17]. Nonetheless, patients with infection are prone to clinical decline and require surgical, endoscopic, or radiographic intervention with the onset of clinical signs not responding to medical management. In the era of surgical management, delayed intervention was far preferable to early surgery. A randomized trial has shown that early surgical intervention is associated with higher morbidity and mortality than when intervention is delayed at least 12 days [18]. Other reviews have confirmed lower mortality with delayed surgical intervension [19,20] and other data suggest that early surgery is in fact an independent predictor of poor outcome in necrotizing pancreatitis [21].

Expedited intervention may be required in patients demonstrating progressive systemic sepsis or hemodynamic instability. In the absence of such systemic signs, clinically stable patients may generally be managed at least temporarily with antibiotics to allow further organization of the inflammatory process. Delayed surgical, endoscopic, or radiologic management may then proceed if clinical symptoms do not improve [6].

Delayed surgical intervention of infected pancreatic necrosis has been facilitated by the use of percutaneous catheter drains. A 1998 series by Freeney et al. [22] demonstrated that some patients with infected pancreatic necrosis might have surgical management delayed or potentially avoided altogether with the use of large-bore percutaneous catheters placed under CT guidance. This strategy was validated in a multicenter trial in which patients were randomized to standard pancreatic debridement versus a "step-up" approach in which debridement was used only if necessary [23]. Using a "step-up" approach, complications were significantly lower, and about one-third of patients were treated with catheter drainage alone.

Infected necrosis is suspected with clinical deterioration of a previously stable patient with acute pancreatitis or pancreatic necrosis. Some patients may demonstrate gas within necrotic debris on abdominal imaging via the presence of gas-forming organisms or via a fistula to the colon, small bowel, or stomach. Alternatively, infection may be proven by culture or Gram stain obtained by image-guided FNA [24]. Although a Gram stain positive for organisms was previously thought to mandate surgical early intervention [11], patients with suspected infection are increasingly managed with antibiotics and supportive care to allow less invasive and delayed management of a walled-off collection [3]. Diagnostic FNA is therefore used less routinely in the management of suspected infection.

## Symptomatic Pancreatic Necrosis/ Walled-Off Necrosis

The precise role of radiographic drainage, endoscopic or surgical debridement in sterile pancreatic necrosis is less clear. Although most patients with sterile pancreatic necrosis respond to supportive care without the need for intervention, others will experience clinical decline,

including organ failure despite the presence of demonstrable infection. Historically, some authors had therefore suggested the need for surgical debridement in patients with progression of disease or failure to improve, regardless of the status of infection [25,26]. Unfortunately, no uniform criteria defined which patients with sterile pancreatic necrosis might benefit from debridement. In the era of surgical debridement as the primary intervention for necrotizing pancreatitis, some authors suggested criteria for intervention including the extent of necrosis of more than 50% of the pancreatic parenchyma [25], rapid clinical deterioration with multiple organ failure [27], or the presence or persistence of organ failure [28,29]. However, evidence is lacking to support the use of these criteria as an absolute indication for debridement or drainage. Close analysis of one study of 89 patients with severe sterile necrosis identified only two patients who died that might have theoretically benefitted from earlier surgical debridement, though no clinical parameters were able to easily differentiate these patients from others with severe sterile necrosis [12].

As noted above, in the absence of clinical confirmation of infection by image-guided FNA or suggestive imaging, intervention is typically based on the clinical course and trajectory. Patients are therefore often brought to intervention for not just documented infection, with positive pancreatic FNA, but also for suspected infection based on persistent sepsis or progressive clinical deterioration [30]. Given the additional morbidity and mortality associated with open surgery, radiologic or endoscopic drainage is used prior to surgical intervention [31].

The process of walled-off pancreatic necrosis recognized in the revised Atlanta classification was previously described by Baron as "organized pancreatic necrosis" [32]. In this condition, an intrapancreatic or extrapancreatic heterogeneous semisolid collection develops in the context of acute necrotizing pancreatitis and has an encapsulated wall [5]. A subset of patients with WON may experience a prolonged clinical course marked by persistent pain, malaise, and inability to eat. This symptom complex was described by Warshaw as "persistent unwellness" [33]. The precise indications and timing of intervention are not precisely defined for these patients.

Asymptomatic WON does not require intervention regardless of the size of the collection, and may resolve with conservative management (Fig. 29.1). Symptomatic WON, however, can be marked by pain, intestinal, or biliary obstruction, or later infection. In one series, approximately 10% of patients with sterile pancreatic necrosis underwent surgery for persistent pain and organized necrosis at a mean of 29 days after initial presentation [12].

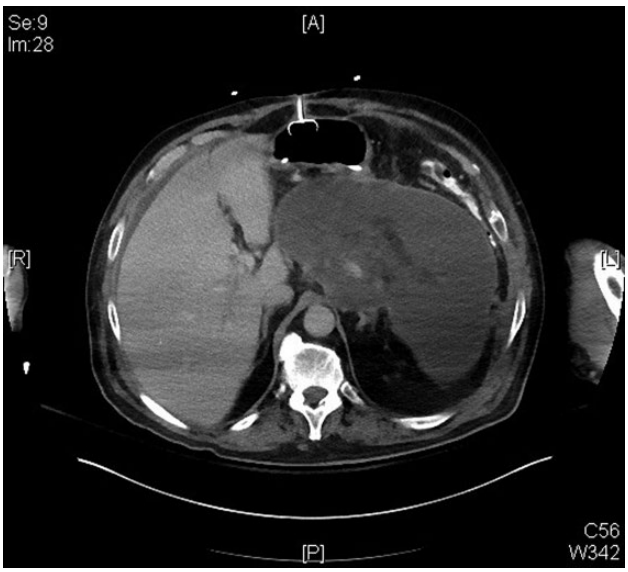

**Figure 29.1** Walled-off necrosis. A 55-year-old man presented with severe acute pancreatitis and an acute necrotic collection. He was managed conservatively, and imaging 6 weeks after presentation revealed a large area of walled-off necrosis involving the entire body and tail of the pancreas. The patient remained asymptomatic and no intervention was pursued.

## Surgical and Interventional Procedures

The use of various radiologic, surgical, and endoscopic interventions for necrotizing pancreatitis will vary among institutions [6]. Although open surgical necrosectomy was previously considered the definitive management, a number of minimally invasive techniques have been developed. As noted above, delayed intervention is preferable in all patients if possible, particularly when open surgical management is used [34]. However, interventional radiologic techniques may be performed earlier with suspected infection [19]. Even in the setting of suspected or known infection, there is a growing trend to treat with supportive care and antibiotics unless there are signs of sepsis, until the pancreatic collection becomes walled off [3].

## Surgical Debridement

Open surgical debridement for years was considered the gold standard of surgical intervention for pancreatic necrosis, by removing necrotic pancreatic and peripancreatic tissue and establishing a means of postoperative drainage while preserving viable pancreatic parenchyma. Methods have included debridement with closure over drains, debridement with open packing of the pancreatic

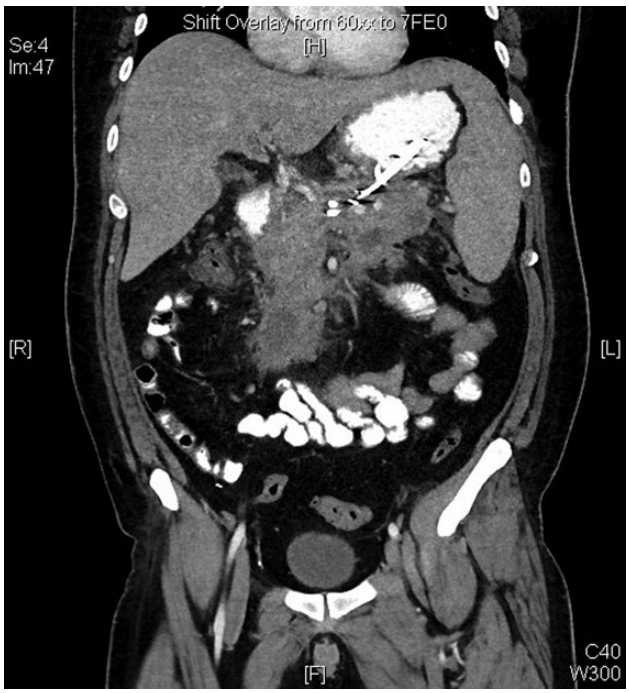

**Figure 29.2** Undrained mesenteric abscess after endoscopic debridement. A 50-year-old man underwent uncomplicated endoscopic debridement for symptomatic walled-off pancreatic necrosis. He represented with fevers, pain, leukocytosis, and a phlegmonous abscess tracking down into the small bowel mesentery. Endoscopic debridement and CT-guided drainage were not felt to be possible. Surgical debridement was required.

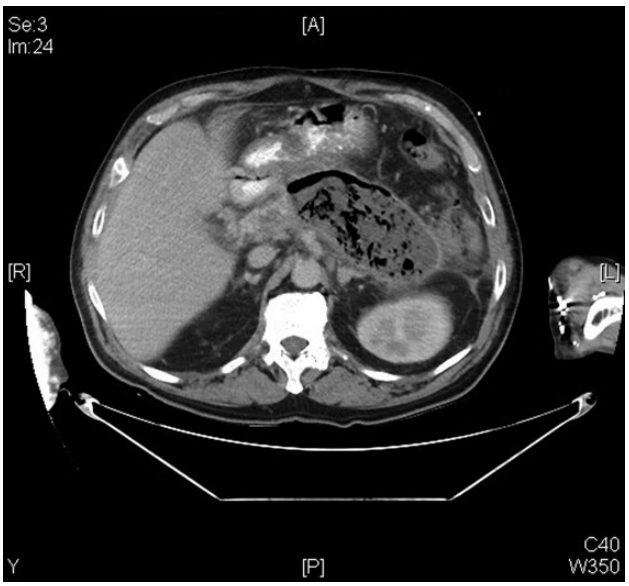

**Figure 29.3** Infection of walled-off necrosis with fistula to colon. The patient in Fig. 29.1 presented 12 months after his original episode of pancreatitis with fever and bacteremia. Imaging demonstrated gas in the area of walled-off necrosis, consistent with infection. Endoscopic debridement was attempted, though contrast injection to the cavity demonstrated a fistula to the transverse colon. Open surgical debridement was pursued.

bed, or debridement with closure over irrigation drains [9,35–37]. Mortality and complication rates for published series utilizing these techniques vary widely, although comparisons between studies are confounded by the lack of standardization of disease severity or operative indications.

One advantage of open surgical necrosectomy is that it may offer the best chance to completely remove all necrotic tissue and address other associated complications in a single procedure. Due to its invasiveness and associated perioperative complications, open surgery is typically reserved for patients in whom less invasive methods have failed.

In the setting of minimally invasive options such as image-guided catheter drainage and direct endoscopic necrosectomy as described below, several important potential indications for surgery remain. In some cases, collections may not be accessible via image-guided techniques, may be multifocal, or persistent after minimally invasive necrosectomy (Fig. 29.2). In other instances, a patient may not be deemed clinically stable for minimally invasive measures. Surgical therapy in these instances should be delayed as long as possible given the increased risk of early surgical intervention. Other indications for surgical debridement include the presence of bowel perforation, obstruction, fistula to a hollow viscus such as the colon, and abdominal compartment syndrome [38] (Fig. 29.3).

Of note, minimally invasive forms of surgical debridement have been used in addition to traditional "open" necrosectomy. Laparoscopic approaches are well described, and may be more successful in completely removing all necrotic material compared to other minimally invasive methods [39]. Video-assisted retroperitoneal debridement is a procedure by which the retroperitoneal collection is accessed via the tract of a percutaneous catheter [40]. This avoids the pneumoperitoneum and peritoneal seeding possible with a laparoscopic procedure, but multiple interventions may be required for complete drainage [6]. While open necrosectomy can be avoided in many patients, limited data are available comparing outcomes of these procedures [41].

## Percutaneous Catheter Drainage

Percutaneous catheter drainage (PCD) can be performed either as a "step-up" toward endoscopic or surgical necrosectomy once WON has developed, or in some cases as definitive therapy [23]. One significant advantage

of PCD is the opportunity to address symptomatic or infected necrotic collections before WON has developed. PCD may be particularly useful in patients deemed unfit for surgical intervention, or to address residual collections after debridement [6]. Catheters are placed using CT or ultrasound guidance, using either a transperitoneal or retroperitoneal approach. Often multiple catheters are required, and follow-up procedures are often indicated to place additional or larger catheters [40].

As noted, catheter drainage alone is often effective without necrosectomy. In the PANTER trial, use of catheter drainage resulted in significantly decreased morbidity with equal mortality compared to surgical necrosectomy [23]. Other studies have shown an approximately 50% success rate in treating necrotizing pancreatitis, whether sterile or infected [42]. PCD is less likely to be successful as a definitive intervention in patients with duct disruption, who may require eventual surgical or endoscopic therapy [43].

## Direct Endoscopic Necrosectomy

Endoscopic necrosectomy is a recognized alternative to surgical debridement, though its availability is limited to specialized centers. A series of 104 patients at six centers showed resolution of WON in 91% with endoscopic necrosectomy, with only 4% requiring surgical debridement [44]. Furthermore, data suggest that endoscopic necrosectomy is associated with fewer complications, less organ failure, and decreased periprocedural inflammation [30].

Similar to PCD, multiple procedures may be required, and not all patients may be candidates for endoscopic therapy. Ideally, collections for endoscopic access are not only walled off but also are adjacent to the gastric or duodenal lumen. Some acute necrotic collections cannot be approached endoscopically due to lack of abutment of the stomach or duodenum. Early collections are not ideally suited for endoscopic therapy due to the risk of intra-abdominal spread of an infected collection, and multifocal collections are less easily approached in this manner.

## Pancreatic Necrosis

Pancreatic fluid collections (PFC) can occur as a complication of acute pancreatic injury (acute pancreatitis, trauma, surgical resection, or injury to the pancreas during abdominal surgery) or chronic injury (chronic pancreatitis, autoimmune pancreatitis). At the basis of this pancreatic injury is disruption of the main pancreatic duct and/or side branches. Acute necrotizing pancreatitis is at the severe end of a spectrum of inflammation associated with pancreatitis, resulting in cell death. Pancreatic necrosis is defined as nonviable pancreatic parenchyma usually with associated peripancreatic fat necrosis. It is reported by some to occur in approximately 15–20% of all episodes of pancreatitis [1]. The resultant devitalized tissue becomes a potential bed for infection. Approximately 30% of patients with pancreatic necrosis develop infection [2,3]. The amount of necrotic tissue is the strongest predictor of mortality in necrotic pancreatitis. Fortunately, with early recognition and improvements in critical care most patients survive the early phase of systemic inflammatory response syndrome and many survive multisystem organ failure.

In the acute period, pancreatic necrosis can be an acute necrotic collection in which there is a variable amount of fluid and necrosis [4]. It is detected radiographically on contrast-enhanced computed tomography (CT) by the presence of nonenhancing pancreatic parenchyma. By around 4 weeks after onset the collection continues to evolve and may expand the initial area of necrosis. Such collections contain both liquid and solid debris and are referred to as walled-off necrosis (WON) or walled-off pancreatic necrosis (WOPN), in which the collection is defined by a fibrotic and inflammatory wall. The term infected necrosis refers to bacterial invasion of necrotic pancreatic tissue and can lead to clinical infection, and sepsis and death. Infected necrosis is rare during the first week [5,6]. Most of the evidence suggests no absolute correlation between the extent of necrosis and the risk of infection and duration of symptoms [2,5]. The mortality rate approaches 100% if intervention and drainage are not undertaken for infected necrosis. Even with aggressive intravenous fluid replacement, nutritional support, and early intervention of pancreatic necrosis, the presence of pancreatic necrosis is associated with an overall increase in mortality. The mortality rate from sterile pancreatic necrosis is 10% and rises to 30% when infected [7]

## Mechanical Intervention

Mechanical intervention for pancreatic necrosis can take the form of surgical, percutaneous, and endoscopic debridement. Open surgical therapy is no longer considered the gold standard [8] and has been replaced by minimally invasive approaches [9,10] using flexible endoscopic, and rigid endoscopic [11], percutaneous and laparoscopic approaches, alone or in combination [6]. It has been almost 20 years since the first report of endoscopic drainage of pancreatic necrosis [12]. Optimal management of necrotizing pancreatitis requires a multidisciplinary team including dedicated surgeons, interventional radiologists, and gastrointestinal endoscopists. Such a multidisciplinary team needs to be involved from the onset of the disease to decide if, when, and how an intervention needs to be performed.

Recent guidelines state that there is no need for intervention in asymptomatic patients with sterile necrosis,

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

regardless of its size, location, and extension [13,14]. In the vast majority of patients, the necrosis will resolve spontaneously. An intervention for sterile pancreatic collections is only indicated in patients with persistent gastric outlet, intestinal, or biliary obstruction due to mass effect of WOPN at least 4–8 weeks after onset of symptoms. In case of persistent symptoms such as pain and "failure to thrive" intervention is more debated and current guidelines suggest that in such cases, intervention can be considered 8 weeks after onset [14]. In case of infected, but minimally symptomatic necrosis, it is advisable to delay any surgical, radiologic, or endoscopic approach for more than 4 weeks in order to facilitate the formation of WOPN with liquefaction of the contents. Infected necrosis with clinical instability requires immediate drainage in order to avoid fatal complications. In these cases, minimally invasive methods of necrosectomy should be preferred to open surgery. The distinction of sterile from infected necrosis is difficult but very important as it greatly affects prognosis and management. Routine percutaneous fine-needle aspiration (FNA) of pancreatic and peripancreatic collections for the detection of infection should not be routinely performed. It may postpone interventions, give false negative results, or induce secondary infection [6]. Suspicion of infection is usually based on clinical deterioration despite medical support, high fever with rising inflammatory markers, and/or positive blood cultures. The presence of gas on imaging studies is highly suggestive of infection, likely due to fistula, but it is only present in a minority of cases [15,16]. Infection can be confirmed by FNA or through cultures obtained at the time of drainage, and can be used to guide antibiotic therapy [13,14].

The goals of endoscopic therapy for infected WOPN are (i) drainage of fluid and removal of solid components using a transmural approach (transgastric or transduodenal) and (ii) treatment of pancreatic ductal leaks and/or disruptions using a transpapillary approach, in selected patients. Theoretically, addressing pancreatic disruptions may lead to better long-term outcomes [17]. Transpapillary endoscopic drainage as primary therapy of WOPN is not an adequate method to remove solid debris. Removal of solid debris is vital to any type of intervention during transmural drainage, which can be "mechanical," by irrigation, or a combination.

Endoscopic access is best performed when the wall is mature, usually 4 weeks or more after the episode of pancreatitis. This period of time between onset of the disease and intervention is suggested to be associated with lower mortality and intervention is delayed if the clinical condition allows [2]. As necrotic collections become organized into WOPN, they are more amenable to intervention. In case of proven or suspected infected necrotizing pancreatitis, intervention should be delayed where possible until at least 4 weeks after initial presentation [2,14]. An endoscopic transgastric access can be created even as early as 2–3 weeks after the onset of acute pancreatitis in the setting of sepsis and acute necrotic collection as long as they are organized as determined by CT or magnetic resonance imaging.

## Transmural Drainage

The evolution of endoscopic therapy of WOPN began with pseudocysts drainage using small-diameter transmural tracts (8 mm), placement of 10Fr stents and a nasocystic irrigation tube [12]. Early in the endoscopic experience many patients required adjunctive percutaneous drains, especially to treat large paracolic gutter extensions [18]. In patients who were intolerant to nasocystic irrigation tubes and/or in whom it was anticipated that irrigation may be required for many weeks, an alternative to nasocystic lavage was the placement of a percutaneous endoscopic gastrostomy tube (PEG) with placement of a "jejunal" extension tube into the collection [19]. Larger diameter transmural dilations were then added to the irrigation approach. Nasocystic irrigation tubes can be used for continuous flushing with sterile fluid per 24 hours or lavaged every 3–4 hours for several days to weeks depending on the amount of debris present and patient tolerance and may avoid the need for subsequent necrosectomy [20]. However, they are uncomfortable, and with the advent of large-diameter transluminal metal stents, their use is not mandatory. Such nasocystic irrigation tubes are no longer routinely placed [21].

Direct endoscopic necrosectomy (DEN) was introduced by Siefert et al. [22], and subsequently Seewald et al. [23], as a method to remove necrotic tissue by passing forward- or side-viewing endoscopes transmurally into the collection; baskets, grasping forceps, and snares are used to remove solid debris [20,24]. Transmural placement of large-diameter covered (esophageal) self-expandable metal stents (SEMS) [25,26] or 15 mm lumen self-expandable lumen-apposing metal stents can facilitate necrosectomy and avoid the need for repeated balloon dilation of the gastric or duodenal wall (Figs 30.1, 30.2, and 30.3) [24]. Hydrogen peroxide may facilitate the removal of necrotic debris during DEN and reduce the likelihood of further necrosectomies [27].

In conjunction with interventional radiology, several hybrid approaches have also been described [28]. In some patients with peripheral collections that are not accessible from a transluminal approach, a percutaneous

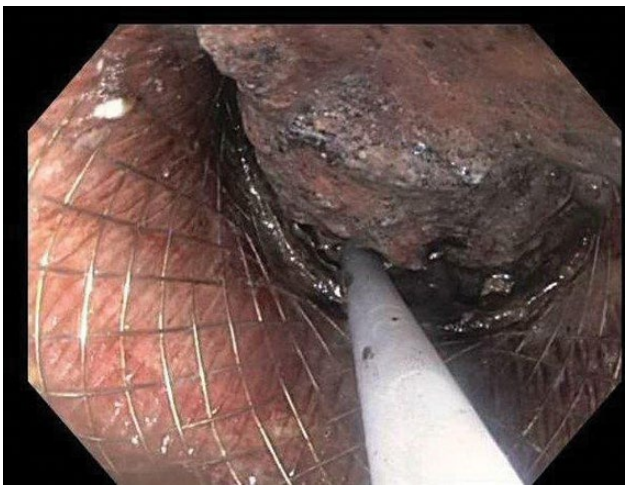

**Figure 30.1** Endoscopic view of pancreatic necrosis. The endoscope is positioned just in front of a recently deployed fully covered self-expandable 15 mm luminal apposition stent. A snare is being used to evacuate solid debris.

**Figure 30.2** Necrotic debris evacuated from the patient presented in Fig. 30.1.

drain is placed. Subsequently, a large-bore SEMS is placed through the percutaneous tract to allow for DEN with a flexible endoscope.

Gluck and colleagues at the Virginia Mason Medical Center in Seattle, Washington, USA described a dual-modality drainage technique. CT-guided percutaneous irrigation/drainage catheter placement is followed by endoscopic transmural drainage. The percutaneous catheter is used for irrigation, with egress internally. This allows avoidance of DEN. In their institution this approach resulted in decreased length of hospitalization and number of radiologic and endoscopic procedures compared with either modality alone [29]. This method

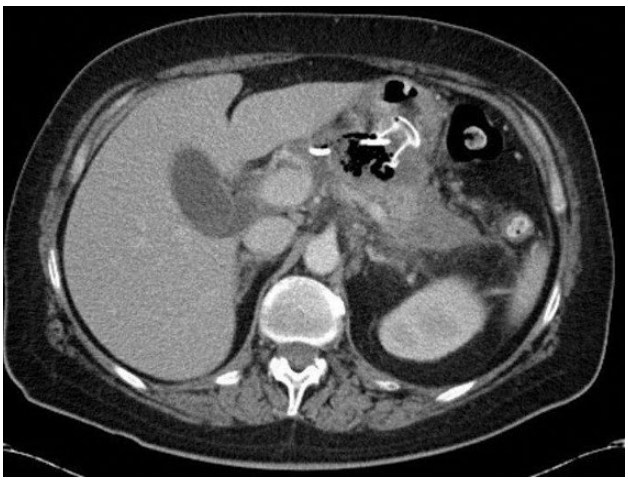

**Figure 30.3** CT scan from the patient shown in Figs 30.1 and 30.2 shows the expandable stent in place and near resolution of necrotic cavity.

of treatment was reported to be superior to a strictly percutaneous approach, not only in speeding resolution, but also in precluding the development of external fistulas [26] and bleeding.

For complex organized necrosis, Varadarajulu and colleagues described an endoscopic ultrasound (EUS)-guided multi-gateway approach [30], which utilizes two or more transmural entry approaches to permit irrigation, aiming to improve drainage of the often multiseptated necrotic collections. Nasocystic irrigation enters one site and egresses from another. Following the procedure, 200 mL of saline is irrigated every 4 hours through the nasocystic tube, shifting patient position between flushes.

## Transmural Entry Devices

Devices used to perform transmural puncture of WOPN can be divided into cautery and noncautery devices. Cautery devices include standard diathermy wires (needle knifes), specialized fistulotomy devices (cystotome, CST-10, Cook Endoscopy, Winston-Salem, NC, USA) and specialized stent delivery systems with cautery incorporated (AXIOS EC, Boston Scientific, Marlborough, MA, USA). Noncautery devices include 19-gauge EUS-FNA needles and other miscellaneous aspiration needles (Marco-Haber variceal injector needle MHI-21, Cook Medical).

Most often the collection is punctured transmurally using EUS guidance. Fluid is aspirated to confirm entry and is sent for fluid analysis including Gram stain and culture. Correct positioning during entry can also be confirmed by contrast injection into the collection under fluoroscopy.

### Stent Placement

Plastic stents are not ideally suited to drain WOPN. Recently, the use of fully covered SEMS [31] are used instead. Specially designed biflanged short stents (Axios, Boston Scientific), either with or without electrocautery-incorporated delivery systems, seem to have a high technical and clinical success rates. Due to its ease of use, such devices have simplified and streamlined EUS-guided management of PFC, particularly for endoscopic debridement of WOPN. These devices have also promoted more widespread adoption of transmural drainage as an alternative to surgery [32,33].

If a noncautery device is used to enter into the collection, the transmural tract must then be traversed (over a 0.025–0.035″ guidewire) either with a biliary dilating balloon (4 mm diameter to allow passage of the delivery system) or with a 10 F cystotome; the metal stent is then deployed. When the recently commercially available electrocautery-tipped SEMS delivery system is used, the procedure is done in a single step (puncture and stent deployment). Particular care should be taken with regard to proper device deployment, particularly the final, crucial step involving proximal flange release. According to the manufacturer's instructions, the endoscope should be pulled back slightly in order to directly visualize 2–3 mm of the black catheter shaft marker in the gastrointestinal tract before deploying the proximal flange. An alternative option that does not sacrifice a stable scope position or risk placing excessive traction on the SEMS involves releasing the proximal flange while it is still inside the endoscope, and the endoscope tip remains close to the puncture site. At that point, advancing the delivery system while gently withdrawing the endoscope allows the proximal flare to spring open as the stent exits the endoscope. However, even with electrocautery-tipped SEMS delivery systems, it is important to secure an ample length of guidewire into the collection with at least one complete loop of wire. A double pigtail stent placed through or alongside the metal stent lumen may help to prevent migration and occlusion due to impaction of necrotic material [34,35].

Anticoagulant or antiplatelets drugs should preferably be discontinued prior to transmural drainage, and certainly prior to necrosectomy. In case of severe bleeding during the procedure which cannot be treated endoscopically, immediate assistance of an interventional radiologist should be requested. Endoscopic drainage and necrosectomy are preferably performed with patients under deep sedation or general anesthesia. DEN should be routinely performed using a forward-viewing endoscope at the time of the first endoscopic procedure; schedule debridements should be performed with the interval ranging from days to weeks depending upon the inpatient or outpatient status, anticipated volume of residual necrosis, and follow-up CT. Internal drains are endoscopically removed several weeks after complete resolution of the collection and removal of external drains (if placed). Patients with infected necrosis continue antibiotic therapy, either empirically or based upon culture data obtained during drainage and/or debridement. All procedures should be performed with carbon dioxide ($CO_2$) insufflation since fatal gas embolism has been described.

## Results of Endoscopic Therapy of Pancreatic Necrosis

There are increasing series showing that endoscopic treatment of WOPN is successful in achieving nonsurgical resolution in the majority of patients [34]. Retrospective studies have shown a treatment success rate of 45–63% for endoscopic drainage [17,20]. In a review of 10 series on endoscopic necrosectomy, the overall treatment success was 76%, mortality 5%, and procedure-related morbidity 27% [36]. Minimally invasive techniques were evaluated by a randomized trial [2,6], which showed lower morbidity rates, faster recoveries and shorter hospital stays. Evidence in favor of endotherapy is supported by others [34]. A recent systematic review considered DEN a safe (mortality rate of 6% and complication rate of 36%) and effective minimally invasive treatment (80% treatment success) in infected necrosis [37]. However, most of the studies included did not report on the most relevant parameters of disease severity or outcome measures. Guidelines now advocate that if an intervention is indicated in patients with infected necrosis, initial treatment should consist of either image-guided percutaneous catheter drainage or endoscopic transluminal drainage [14].

## Adverse Events of Endoscopic Therapy of Pancreatic Necrosis

Life-threatening adverse events may arise following attempted endoscopic drainage of pancreatic necrosis. It is recommended that endoscopic drainage is performed with the availability of surgical and interventional radiology support. The most feared adverse events of transmural drainage are bleeding and perforation. Bleeding after transmural drainage may be managed supportively, endoscopically, surgically, or with angiographic embolization. If perforation occurs during attempted transgastric drainage and is limited to the gastric wall (does not involve the collection), it may be

successfully managed nonsurgically if a stent is not mistakenly placed through the perforation and outside the gastric wall. If egress of gastric contents is prevented, the gastric wall rapidly closes with conservative treatment consisting of nasogastric suction and antibiotics. Large-diameter (esophageal) SEMS can be used to close perforations [38] and in some cases tamponade bleeding. Infectious adverse events usually occur from inadequate drainage of fluid and/or solid debris. Stent migration into the collection through the gastric or duodenal wall may occur during or after endoscopic stent placement. Endoscopic retrieval is possible if the collection has not completely collapsed and the transmural tract is still patent. Fatal air embolism has been reported following DEN [39]. This has prompted the use of $CO_2$ rather than air insufflation during drainage.

Endoscopic therapy may be associated with adverse events and/or failures that require surgical management. It is possible that the outcome of surgical therapy may be adversely altered when compared to those patients undergoing primary surgical therapy.

What is clear is that if endoscopic therapy is undertaken, commitment is required by the endoscopist, clinical care team, and, most importantly, the patient. Endoscopic debridement is a time-consuming, labor-intensive process not for the uncommitted [40] or faint of heart since adverse events occur more commonly than in any other pancreaticobiliary intervention and have the potential to be fatal. Therefore, even more importantly, perhaps, is the need for support from intensivists, endoscopists, surgeons, and interventional radiologists to manage these complicated patients.

## Introduction

Pancreatic necrosis occurs in approximately 20% of patients with acute pancreatitis [1] with infection developing in approximately 30% [2,3]. Infected pancreatic necrosis is associated with considerable morbidity and a mortality rate of up to 32% [3]. Current International Association of Pancreatology (IAP)/American Pancreatic Association (APA) guidelines recommend intervention for necrotizing pancreatitis when there is conformation or suspicion of infected pancreatic necrosis with clinical deterioration [2]. In addition, intervention may be required for persistent sterile necrosis with organ failure and a lack of progress. Intervention should ideally be delayed until the necrosis has become walled off, typically after 4–6 weeks [4].

In recent years there have been multiple series and trials recommending a minimally invasive approach to pancreatic necrosectomy [5–9] and this has now become the standard approach for most centers. Studies have shown a significantly reduced incidence of postoperative organ failure and lower complication rates for patients undergoing minimally invasive treatment compared to an open necrosectomy. A nonsignificant reduction in mortality is demonstrated in many reports but these studies do not have the numbers required for this to be statistically significant [5,8,10].

## Technique

Multiple different techniques for minimal access necrosectomy have been described. This chapter will review retroperitoneal and laparoscopic approaches; endoscopic necrosectomy is discussed elsewhere.

Laparoscopic transperitoneal necrosectomy was first reported in 1996 [11] and several small-volume case series have been reported [12–14] but the technique is declining in popularity and no large series currently exist. The collection is visualized laparoscopically and debridement is performed, either with a hand-assisted or laparoscopic port. The necrotic cavity may be approached either directly, through the transverse mesocolon or gastrocolic omentum, or via a transgastric route. Approximately 20% of patients require reoperation either by open or laparoscopic routes [11,14]. The potential advantages of this technique include the ability to perform a simultaneous cholecystectomy [4,15] and a reduced length of stay compared to other minimal access techniques [13,14]. Laparoscopic cystogastrostomy has been reported in several series to be a safe and effective alternative operative technique but is only feasible once the necrosis has become walled off [16]. The major disadvantage of the laparoscopic route, however, is that infected necrotic tissue is allowed direct access into the previously sterile peritoneal cavity, thus infecting a second body compartment.

Most centers now prefer a percutaneous retroperitoneal approach, thereby restricting the spread of infection to a single body compartment. The exact technique varies between institutions, with procedures using a laparoscope, rigid nephroscope and flexible endoscope all having been reported [8,17,18] but the overall principles are similar.

For the minimal access retroperitoneal pancreatic necrosectomy (MARPN) technique, as used in Liverpool, initial access to the necrotic cavity is achieved by placement of a percutaneous drain into the necrotic collection under computed tomography (CT) guidance. This drain is normally placed through the left flank using the

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

window between the spleen, left kidney, and colon (Figs 31.1 and 31.2) [8] but alternative access routes are possible and the exact site for access is chosen individually according to the distribution of necrosis. A randomized controlled trial reported that 35% of patients could be managed with percutaneous drainage alone and did not require further procedures [5]. If there is no clinical improvement following simple radiological drainage then further debridement is indicated.

In the operating theater, under sedation or general anesthesia, the patient is positioned supine but tilted so that the drainage tract is approximately horizontal. Using a sandbag directly under the point of entry and positioning the patient close to the left hand side of the operating table facilitates access to the tract with the operating nephroscope [7,15].

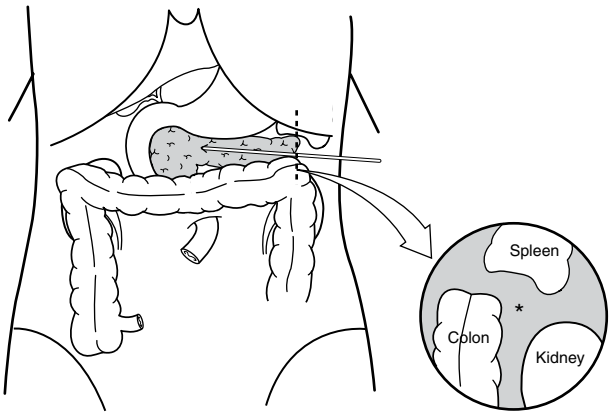

**Figure 31.1** Preferred retroperitoneal approach to infected pancreatic necrosis, avoiding the spleen, left kidney and colon. *Source:* Raraty et al. 2006 [19].

Under fluoroscopic guidance, the drainage catheter is exchanged for a guidewire and the tract dilated to 30 F using a renal dilator set or a balloon dilator [8,20]. A 2 cm skin incision allows the passage of the dilators and once they have passed the fascial and muscular layers of the retroperitoneum there should be very little resistance. Using fluoroscopy and previous CT images, care should be taken not to advance the dilators further than the extent of the necrotic cavity. Once the tract is dilated an Amplatz sheath is placed over the dilator to maintain the patency and position of the tract throughout the procedure [20]. Correct positioning is often apparent by the passage of pus and liquid debris through the Amplatz sheath.

An operating nephroscope with a wide-bore operating channel is introduced which allows visualization of the cavity as well as simultaneous irrigation and biopsy. Necrotic tissue is removed piecemeal using standard laparoscopic grasping forceps with constant irrigation of warm saline (Fig. 31.3). Samples of the removed necrotic tissue are sent to microbiology for culture and to guide antibiotic usage. Initial necrosectomy is often limited by immature necrosis which is adherent to the cavity walls; attempted removal of such adherent material can lead significant bleeding and only material which separates easily should be removed [15,21]. Repeated procedures are often required, therefore, before the cavity can be seen to be completely clean.

At the end of the procedure an irrigating drain, consisting of a 10 F or 12 F nasogastric tube sutured to a 28 F chest drain is inserted into the cavity (Fig. 31.4). The

(a) (b)

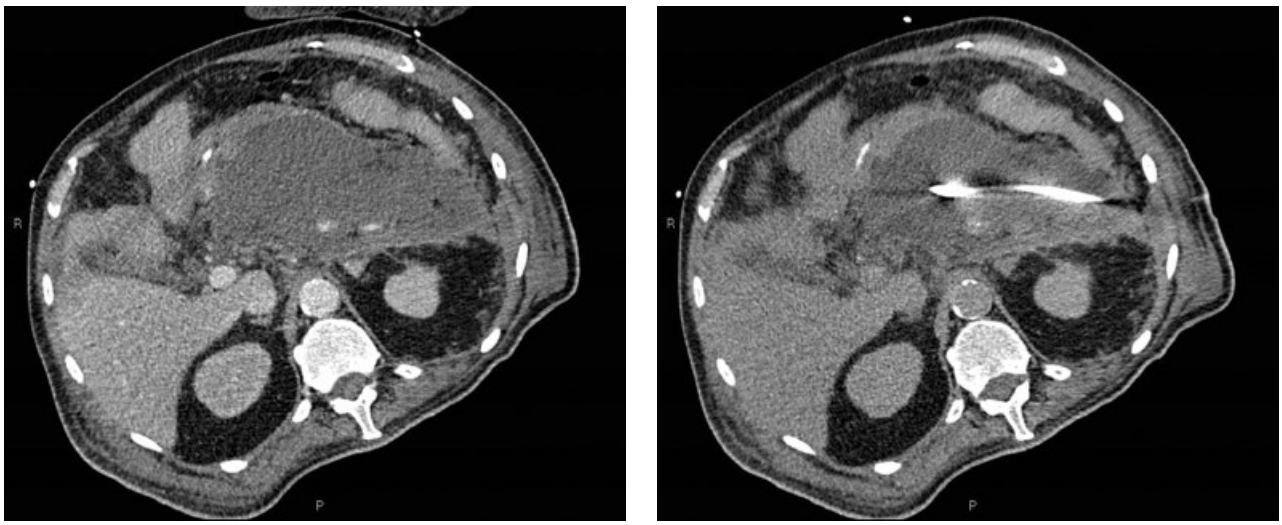

**Figure 31.2** (a,b) Radiological access to the necrotic cavity via the left flank. Tilting the patient with left side up facilitates access to the necrotic cavity.

**Figure 31.3** Debridement of necrotic pancreatic tissue under direct vision using an operating nephroscope.

**Figure 31.4** A 12 F Ryles nasogastric tube and 28 F chest drain are placed into the cavity at the end of the procedure and used as an irrigating drainage system to continuously flush the necrotic cavity with 0.9% saline solution at a rate of 125 mL/h.

cavity is continuously irrigated with 0.9% saline solution at 125 mL/h [8,15]. The procedure is repeated at 7- to 10-day intervals until necrosectomy is complete [7,8]. Taking into account the patient's condition, inflammatory markers and radiology, as well as visual inspection of residual necrosis at operation, the rate of irrigation is eventually halved to 60 mL/h, then 30 mL/h and then stopped. A CT tubogram confirms that the cavity has collapsed and that no complex tracts are present. The irrigating drainage system is then downsized to a smaller bore, single-channel drain and the patient can often be discharged at this point [8], with the drain later removed in the outpatient setting.

An alternative method of retroperitoneal necrosectomy, used frequently in the United States and the Netherlands, is the video-assisted retroperitoneal debridement (VARD) technique first described by Horvath in 2001 [5,17]. VARD was initially performed using two laparoscopic ports but the technique has been modified over the subsequent years [9]. As for MARPN, initial access to the necrotic cavity is achieved by radiological placement of a percutaneous drain.

With the patient positioned as described above for the MARPN technique, a 4–5 cm incision is made 1–2 fingers below the left costal margin over the midaxillary line close to the percutaneous drain. The abdominal wall muscles are divided and the drain is located using the surgeon's finger. The drain can then be followed to the collection and the collection opened with finger dissection. Necrosis is primarily removed with suction, blunt finger dissection and forceps. A zero degree laparoscope is then inserted through the incision along with forceps introduced parallel to the scope to perform further necrosectomy under direct vision. Laparoscopic clips can be applied in the event of bleeding. Two large-bore drains are placed into the collection, one deep and the other more superficial and continuous lavage is attached. The fascia is closed over the drains to allow postoperative lavage. The skin may be closed or left open to heal by secondary intention [9,17,20].

The aim in both procedures is to remove free and easily accessible necrosis, not to perform a complete necrosectomy in one sitting [8,9].

## Techniques for Complex Collections

As centers have become more comfortable and experienced with the procedure, developments have occurred to enable drainage and necrosectomy on more complex necrotic collections. With a retroperitoneal route, right-sided or more central collections can be difficult to access due to surrounding abdominal viscera, but access is often still possible with skilled interventional radiology. An anterior approach through the gastrocolic omentum can sometimes be used for pancreatic head collections. Collections tracking in to the right or left retroperitoneal gutters may be drained and used as accessory tracks for MARPN or VARD-type necrosectomy [8].

A combination of percutaneous as well as endoscopic techniques can be employed in complex cases or where there is suboptimal drainage or progress with the initial intervention [20].

## Early Complications

Necrotizing pancreatitis is a condition associated with a high morbidity and patients undergoing necrosectomy for infected pancreatic necrosis frequently experience a significant physiological insult. Some will develop complications related to the disease process itself and others directly from the procedure [20,22].

Our recent series of 274 patients reported an overall conversion rate from minimal access to open necrosectomy of 13.1% (36/274) [8]. The conversion rate had reduced from 17.3% in the earlier part of the study (1997–2008) to 12.1% in later years (2009–2013), suggesting a learning curve with both percutaneous drainage and operative technique [7,8]. The most common reasons for conversion are the inability to place the initial drain, difficulties dilating the tract, inaccessible collections or bleeding [7,8]. In approximately 30% of patients minimal access necrosectomy is not possible due to such difficulties [8]. Approximately one-quarter of patients will require additional percutaneous drainage following minimal access necrosectomy [5,8].

Postoperative bleeding has been shown to be an independent poor prognostic factor and is associated with a high mortality rate [22,23]. The reported incidence of significant bleeding after necrosectomy is 11–18% [5,8,22,23]. Primary hemorrhage occurs either due to avulsion of a vessel when dilating the tract or from debriding adherent or granulating tissue during the procedure [15,20]. If bleeding occurs then the cavity should be packed. If this is unsuccessful and arterial bleeding is suspected then angiography with or without embolization is required. Venous bleeding is common, and should be considered if there is no obvious bleeding point on angiogram. It will usually settle after local pressure, occluding the drain and correcting any coagulopathy [20]. If embolization is not possible or fails to stop the bleeding then a laparotomy should be performed, although this is very rarely necessary. Secondary hemorrhage may also occur, most commonly from erosion of the necrosis into a vessel or from rupture of a pseudoaneurysm. This is often preceded by a small "herald" bleed and mesenteric angiography should be arranged urgently at this point [15].

Colonic necrosis has a reported incidence of up to 17% [22] in patients undergoing open necrosectomy but data from minimal access techniques demonstrate a far lower rate of around 1.5% [8,15]. The reasons behind this discrepancy are not entirely clear, but there are likely to be some differences between the two populations. The randomized controlled trials from the Dutch Pancreatitis groups do not report ischemic bowel as a specific complication given its low incidence [5,6]. Although the incidence of colonic necrosis is low, its mortality rate is high, and has been reported at 53% [24]. Bowel ischemia may not always be apparent with a minimal access technique and there is often a delayed diagnosis which may adversely affect prognosis. A high degree of suspicion should therefore be maintained for the development of this complication [22]. A focal area of colonic necrosis can lead to enteric fistula formation which may require control in the form of a defunctioning stoma or resection as deemed clinically appropriate. Enteric fistulas are caused by the spontaneous discharge of a necrotic collection into the adjacent gastrointestinal tract [20]. Gastric and duodenal fistulas can generally be managed conservatively, giving total parenteral nutrition (TPN) if nutritional needs are not being met [15]. A physiological duodenal fistula through the ampulla is not uncommon after MARPN of extensive necrosis which involves the pancreatic head.

Pancreatic fistulas are relatively common late complications following surgery for pancreatic necrosis. They occur in 5–28% [5,8] of patients and arise from a communication with the remnant pancreatic duct. The fistula should resolve with conservative management providing there is no downstream pancreatic duct obstruction [25]. Endoscopic retrograde cholangiopancreatography (ERCP) and transpapillary pancreatic duct stent insertion may help resolution of a persistent fistula [20].

## Postoperative Course

Postoperative multiorgan failure is frequent, although less so than after an open necrosectomy, occurring in 20–50% of patients and may prove fatal following intervention for necrotizing pancreatitis [5,6,8]. Between 16% and 50% of patients will require intensive therapy unit (ITU) care postoperatively, with a median ITU stay of 9–12.5 days [5,6,8].

Multiple procedures are often required; a median of 3 (interquartile range [IQR] 2–4) procedures for techniques using sinus tract dilation are needed, therefore patients frequently have an extended length of stay [8,15]. The median total hospital stay reported is 98 days (IQR 75–128), taking into account a median stay of 29 days prior to the first procedure [8]. For centers performing VARD, patients require fewer operations with a median of 1 (range 1–2). This is reflected in a lower overall reported hospital stay of 78 days [9].

Long-term follow-up is essential given the risk of delayed complications, reported to be as high as 62% [22].

Fistulas, pseudocyst formation, new-onset diabetes, and pancreatic insufficiency are all frequently seen and may require intervention if present [5,6,22].

## Outcome

Postoperative mortality following minimal access necrosectomy is now reported to be less than 15%, however over 60% of patients experience some form of complication [5,6,8]. Reported mortality from open necrosectomy ranges from 11% to 39% [7,26], but more recent series show that the mortality rate for both open and minimal access necrosectomy techniques has fallen to 12.5% and 11.2%, respectively [8]. This can be ascribed to a general improvement across all areas of care and the management of these patients using a multidisciplinary approach in specialist centers. Patient selection may also play a role.

The incidence of both operation specific (35.4% vs. 51.7%) and nonoperation-specific (16.8% vs. 26.7%) complications is lower with a minimal access approach compared to with open necrosectomy [8]. Postoperative multiorgan failure is also significantly reduced, occurring in 12–20% of patients following a minimal access or step-up approach and 35–40% of patients following open necrosectomy. The Liverpool data show a higher rate of postoperative ITU admission after open necrosectomy, although this is not demonstrated in the Dutch PANTER trial [5,8].

Long-term complications including pancreatic fistulas, new-onset diabetes, and use of pancreatic enzymes are significantly more common following open necrosectomy compared to minimal access surgery. However, the rate of postoperative deep-vein thrombosis (6.6% vs. 1.7%) was higher in the minimal access cohort, likely influenced by the longer length of stay in this group (median 98 vs. 71 days).

# Open Surgical Debridement in Necrotizing Pancreatitis

*Lutz Schneider and Markus W. Büchler*

*Department of General, Visceral and Transplantation Surgery, University of Heidelberg, Heidelberg, Germany*

## Introduction

The management of necrotizing pancreatitis has changed over the last decades to a more conservative multidisciplinary therapeutic approach [1]. surgical debridement is needed For less than 20% of all patients with necrotizing pancreatitis [2]. Minimal invasive techniques seem to reduce the morbidity and mortality compared to open surgical debridement [3]. Open approaches are needed if minimal invasive procedures fail to achieve sufficient necrosectomy or are not available, or if complications of the pancreatic necrosis such as bleeding prohibit a minimal invasive approach.

The goals of open surgical debridement are to:

- remove all (infected) necrotic pancreatic and surrounding tissue in order to achieve local focus control and minimize inflammatory triggers leading to septic systemic inflammatory response, and
- preserve all vital pancreatic tissue to avoid long-term pancreatic exocrine and/or endocrine dysfunction.

Surgical debridement of necrotic pancreatic tissue should not be performed during the first 2 weeks after onset of the disease, but should ideally be postponed for least 4 weeks to achieve a better demarcation of devitalized pancreatic tissue and save vital pancreatic tissue [4–7]. The only prospective controlled study with focus on the ideal timing for necrosectomy was discontinued before completion because of a clear advantage in the group with a delayed surgical intervention (at least 12 days) compared to the early intervention group [5]. Surgical debridement later than 4 weeks after onset of symptoms gives no further advantage with regard to outcome and overall costs [8].

Contrast-enhanced computed tomography is the gold standard before the surgical approach and provides a roadmap for the operative strategy. Nevertheless, it has to be taken into account that the amount of necrotic pancreatic tissue can only be interpreted correctly during surgery. Pancreatic necrosis can be overestimated by preoperative imaging and an organ-sparing necrosectomy can often be performed even if the preoperative imaging suggests complete pancreatic necrosis. This is essential for morbidity, mortality, and the long-term quality of life with regard to endocrine and exocrine pancreatic function [9–13].

## General Technique of Open Surgical Debridement

The concept of necrosectomy includes surgical removal of devitalized peripancreatic and intrapancreatic tissue and evacuation of fluid collections.

The access to the lesser sac containing the pancreatic necrotic tissue can be achieved in different ways. The most commonly used routes are via diversion of the gastrocolic ligament or through the mesenterium of the transverse colon. If the access is obtained via the mesenterium of the transverse colon we recommend the left-sided route of the median colic vessels (Fig. 32.1). Other approaches to access the pancreatic necrotic tissue are left side of the ligament of Treitz (pancreatic tail) or right side of the middle colic vessels (body and part of the pancreatic head), depending on the location of the suspected necrotic tissue. If necrotic tissue is mainly present in the area of the pancreatic head, mobilization of the pancreatic head

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

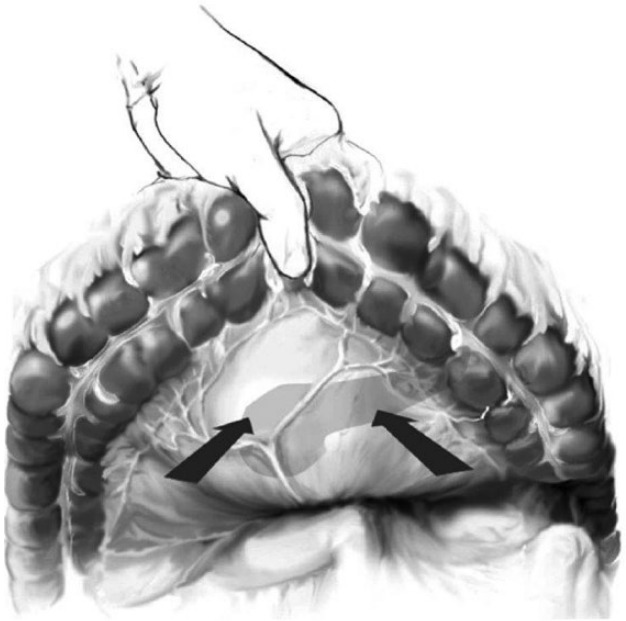

**Figure 32.1** Access to the lesser sac can be directly through the transverse mesocolon on either side of the middle colic vessel.

(Kocher maneuver) can provide adequate access for necrosectomy.

The necrotic tissue should be removed carefully by blunt digital dissection. Covering the surgeon's finger with a sponge can facilitate complete removal of the necrotic tissue. The left or right colonic flexure should be mobilized if fluid collections or necrotic tissue are present in the retroperitoneal, pararenal, or paracolic space. All necrotic tissue should be removed, remembering not to disturb friable tissue in order to minimize bleeding. An intraoperative fluid sample for bacterial culture should be taken for microbiological analysis to identify the organism(s) producing infection and guide antimicrobiological therapy.

Excessive lavage using 6–12 L of isotonic saline solution should be performed to remove infectious ascites and debris as well as to reduce the load of inflammatory mediators contained in these materials.

If possible, the lesser sac should be closed after debridement and placing of adequate drains to separate the infectious area from the rest of the abdominal cavity.

Cholecystectomy can be performed simultaneously if required.

To achieve the above-mentioned principal aims, different strategies have been developed as a one-stage procedure with initial necrosectomy and simple drainage of the pancreatic bed is often not effective and persisting or recurrent intra-abdominal sepsis can be a major problem [1,14]. This implies the need for an ongoing postoperative focus control.

## Continuous Closed Lavage

The concept of postoperative continuous closed lavage of the lesser sac was established in the early 1980s [15,16]. From several larger cohort studies, this strategy seems to have improved postoperative short- and long-term morbidity compared to other open techniques [13,17,18], although there are no prospective controlled data available.

For postoperative continuous closed lavage, large double-lumen flushing drainages (20–24F) are placed in the pancreatic bed at the end of open necrosectomy and lavage and brought out through either side of the abdominal wall. As mentioned above, the access to the lesser sac should possibly be adapted to create a closed compartment for a regionally restricted lavage. Afterwards, the abdominal wall is definitely closed as no re-exploration is planned in this surgical concept.

Postoperative initial lavage should be performed with at least 6 L/24 hours using isotonic saline solution. The amount of flushing volume can be adapted to the macroscopic aspects of the effluate, enzyme count (amylase/lipase), and the clinical condition of the patient. Lavage can be reduced and stopped when there are normal or clearly decreasing pancreatic enzymes in clear fluid produced by the drains. If none of the mentioned parameters are impaired after stopping the continuous lavage, the drains can be removed sequentially (Fig. 32.2). If the patient is in a good clinical condition a closed continuous lavage does not necessarily need to be performed on an intensive care unit. Although there are no planned re-operations required for this procedure, in some patients this may be necessary. Reasons for re-laparotomies include the development of undrained fluid collections that cannot be approached by a percutaneous drainage, intestinal fistulas, or bleeding. Table 32.1 gives an overview of data from published series on this concept with regard to mortality and morbidity, including preoperative disease severity, incidence of postoperative pancreatic fistulas, and postoperative bleeding.

## Debridement and Open Packing/ Staged Laparotomy

When a complete necrosectomy cannot be achieved by the primary operation for extended necrotic tissue in the retrocolic and/or mesenteric spaces there is a high probability of further sepsis. In this situation open packing/staged laparotomy (OP/SL) is an option for damage control. This approach was conceived 1981 to reduce the incidence of postoperative ongoing infection [19]. In patients where OP/SL is indicated, often

[a] Scores are presented as mean or median with ranges or standard deviation in parentheses.
n.r., not reported.

more than 50% of the pancreas is found to be necrotic and the disease is ramified, making an adequate retroperitoneal minimal invasive necrosectomy impossible. Another reason for OP/SL is the development of an abdominal compartment syndrome in patients with necrotizing pancreatitis. Abdominal compartment syndrome is characterized by an increase of the abdominal pressure to more than 25 mmHg. Diagnosis can be made by the clinical evaluation of the abdomen and an additional measurement of the urinary bladder. Therefore, this pressure measurement should be performed in patients with necrotizing pancreatitis since an undetected abdominal compartment syndrome is fatal; laparotomy leads to an immediate release of the pressure and avoids subsequent complications such as bowel perfusion failure or respiratory failure, which may be caused by the need for an extremely high pressure during mechanical ventilation.

In OP/SL, relaparotomy is performed every 48–72 hours to remove further demarcated necrotic tissue until granulation tissue starts to develop. After careful debridement (see earlier), soft drains should be placed a distant from the large vessels and the cavities packed with gauze. A nonadhesive organ foil is placed on the

intestinum and the abdomen is closed temporarily, either with a nonadhesive mesh or with an adhesive foil dressing after placing gauze between the foil placed on the intestinum and the outside foil layer. Evaluation of the further need for relaparotomy should be made after every operative revision. If complete necrosectomy is achieved, the concept of open treatment should be switched to continuous closed lavage and definitive closure of the abdominal wall should be applied (see earlier).

Because of the indication, the morbidity rates of this procedure in the literature are high. The reported mortality rates are 24%. The most common morbidities are fistula formation (36%) and a bleeding rate of 18%. The mean number of explorations needed to complete the therapy is approximately 6–7 per patient (Table 32.2).

These results cannot be compared to those for other necrosectomy procedures because of the underlying severity of disease, which leads to the decision to perform OP/SL. Whenever possible, necrosectomy with continuous closed lavage should be preferred. Nevertheless, OP/SP is a suitable procedure for damage control if necrosectomy cannot be achieved in a single operative intervention or an abdominal compartment syndrome requires this procedure.

## Debridement and Closed Packing

The concept of debridement and closed packing implies an open necrosectomy as described earlier. After completion of necrosectomy and lavage, stuffed Penrose drains are placed in the debrided cavity and are exteriorized via the abdominal wall. Furthermore, suction drains are placed into the debrided cavity. The stuffed Penrose drains are removed stepwise until they can be finally taken out completely, which usually requires several days. The suction drains are left in place to drain potential pancreatic fistulas. This reduces the need for re-operations in comparison to the open packing staged laparotomy procedure (Fig. 32.3).

In the primary paper describing this procedure by the Boston group, morbidity with regard to pancreatic and enteric fistulas was 42% and 15%, respectively. Furthermore, re-operations had to be performed in 12.6% and an interventional percutaneous drain placement was required in 30% of the patients. The overall mortality rate was 11.4%, which correlated with the number of organ failures during the disease course [20]. In a later series of 68 patients undergoing open necrosectomy and closed packing the Boston group achieved an in-hospital mortality rate of 8.6% [21]. In this series, 74%

of patients developed postoperative pancreatic fistula and 9% enterocutaneous fistula. All available data for this procedure are summarized in Table 32.3.

## Open Cystogastrostomy for Walled-Off Pancreatic Necrosis

If the main burden of pancreatic necrosis is located close to the posterior gastric wall, transgastric open cystogastrostomy is a further option for open necrosectomy. The prerequisite for this approach is the existence of walled-off pancreatic necrosis (WOPN). This usually occurs in the late course of necrotizing pancreatitis. Boland et al. described this procedure 2010 in a series of six patients who were successfully treated by this approach with a single laparotomy and no surgical re-explorations [22]. From the technical point of view, after laparotomy an anterior gastrostomy is performed and WOPN is identified by intraoperative ultrasound via the posterior wall of the stomach. The part of the posterior gastric wall that is attached to the WOPN is opened and an open debridement can be performed via this access. An anastomosis between the WOPN and the posterior stomach can be performed using single stich sutures or a stapler device. The rationale for this procedure is a direct drainage of the necrosis cavity into the intestinum to avoid fistulation into the abdominal cavity or the peripancreatic tissue. Based on the experience of the present publications, the time point for this procedure should be chosen between 2 and 3 months after the onset of symptoms [21–23]. The reported morbidity rates vary from 0 to 30% and mortality rates from 0–7% in series including between 6 and 46 patients [22,24,25]. As all reported patients could be sufficiently treated with only one operative debridement, this procedure seems to be effective in suitable patients. But it has to be considered that only a distinct subgroup of all patients with necrotizing pancreatitis may qualify for transgastric debridement due to the localization and extent of necrosis. Furthermore, the fact that the operative intervention needs to be postponed for 2 or 3 months may be a limitation in cases where an earlier time point of necrosectomy must be chosen due to the clinical condition. Nevertheless, reports on larger patient cohorts are awaited to re-evaluate this promising surgical approach.

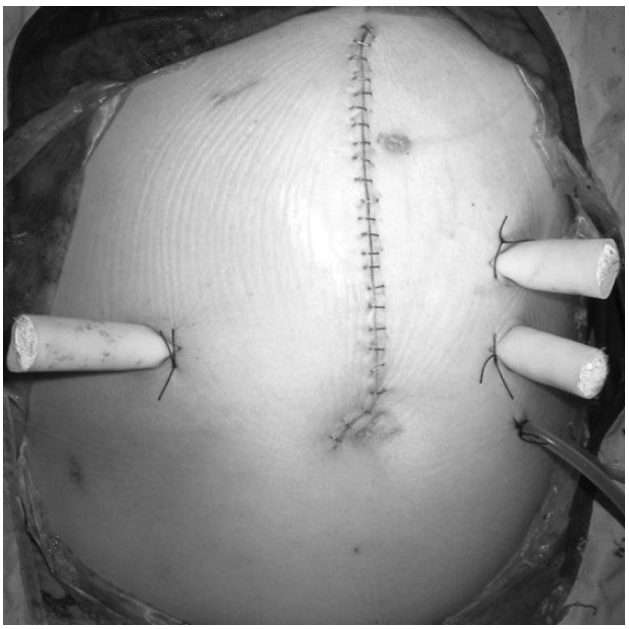

**Figure 32.3** Stuffed Penrose drains and closed suction drains are brought out through separate stab wounds and secured to the skin.

## Conclusion

Although minimally invasive approaches for necresectomy have become the primary standard of care in recent years, there is still an important role for open necrosectomy in severe necrotizing pancreatitis. The indication for open necrosectomy must be considered when minimally invasive approaches are not adequate or applicable to achieve a local focus control as well for complications including bleeding, bowel perforation, or intestinal fistulas. The standard techniques for open

necrosectomy include approaches with planned re-laparotomies (open packing, staged re-laparotomies) as well as those with a single surgical intervention (closed lavage, closed packing). In addition to these well-known techniques, transgastric debridement has been recently developed and may provide an additional possibility for a subset of patients who present with the prerequisites for this approach.

# Endoscopic Treatment of Biliary Acute Pancreatitis

*Ichiro Yasuda, Shinpei Doi, and Masatoshi Mabuchi*

*Department of Gastroenterology, Teikyo University Mizonokuchi Hospital, Kawasaki, Japan*

## Pathogenesis of Acute Biliary Pancreatitis

Acute biliary pancreatitis (ABP) is caused by pancreatic duct obstruction mainly due to bile duct stones. Once a bile duct stone is impacted at the distal end of the bile duct or at the common channel, pancreatic duct outflow is obstructed directly or by the compression of the pancreatobiliary septum. Previous reports showed that bile duct stone impaction was found in 26–72% of patients who had ABP when surgery was performed soon after the attack [1]. Spontaneous passage of bile duct stones into the duodenum has been described in up to 50% of ABP cases [2,3]. Sphincter of Oddi spasm might be another cause of ABP. Therefore, the diagnosis of ABP is not always easy at the time of diagnosis of pancreatitis.

Biliary pancreatitis, as well as alcoholic pancreatitis, is a major etiology of acute pancreatitis. ABP accounts for 20–71.4% of cases of acute pancreatitis, but the rate varies depending on the country. Biliary pancreatitis is more common than alcoholic pancreatitis in Greece, Italy, the United Kingdom, Sweden, and the United States, whereas alcoholic pancreatitis is the most major cause in Hungary, France, Taiwan, Korea, and Japan [4–9].

## Diagnosis

In addition to the increased levels of serum pancreatic enzymes, such as amylase and lipase, increased levels of hepatobiliary enzymes and bilirubin suggest the possibility of ABP. In such cases, imaging tests are strongly recommended for diagnosis. Although transabdominal ultrasound is the most convenient imaging modality, the extrahepatic bile duct is often difficult to visualize clearly due to the retention of gastrointestinal gas, especially in patients with acute pancreatitis. Abdominal computed tomography (CT) is also relatively convenient and has high sensitivity in detecting calcified stones (Fig. 33.1), but its sensitivity to detect small stones without calcification is limited. Endoscopic retrograde cholangiopancreatography (ERCP) may be indicated in highly suspected cases such as those with bile duct dilation and/or cholangitis. Magnetic resonance imaging (MRI) or endoscopic ultrasonography (EUS) can be performed before ERCP because they are safer and more convenient. In addition, magnetic resonance cholangiopancreatography (MRCP) can provide an image similar to ERCP. It has high sensitivity and specificity in detecting common bile duct stones (more than 90%) [10], but its sensitivity decreases in cases with dilated bile duct and small stones [11]. EUS is recognized as the most reliable imaging modality in detecting bile duct stones [12], has fewer complications, and shows higher sensitivity in detecting small bile duct stones than ERCP [13].

## Indication of Endoscopic Treatment

Endoscopic treatments are indicated for patients in whom a bile duct stone was confirmed on imaging tests or highly suspected from clinical or laboratory findings. In addition, patients with persistent or repeated increasing levels of biliary and pancreatic enzymes are also indicated even if the presence of biliary stone was unclear. In such cases, a dysfunction in the sphincter of Oddi might be a cause of biliary pancreatitis.

The timing of endoscopic treatments is discussed later, but urgent ERCP should be considered when there is

**Figure 33.1** Computed tomography image of an impacted stone at the duodenal papilla. White arrow indicates an impacted stone. Axial image (a) and multiplaner reconstruction image (b).

evidence of severe cholangitis and/or ongoing biliary obstruction. However, conservative treatments such as fasting, rehydration, and administration of antibiotics may be attempted first in patients with mild clinical symptoms and with mild abnormal laboratory data.

Several previous studies suggested that EUS is helpful in narrowing down subjects. They showed that a preceding EUS avoided unnecessary ERCP in 71.2–75.4% of patients without increasing the risk of adverse events [13–16].

## Techniques

The best way to treat biliary pancreatitis is the removal of the bile duct stone. Endoscopic sphincterotomy is generally performed for this. ERCP is initially attempted to confirm the stone in the bile duct, and endoscopic sphincterotomy is then performed using a sphincterotome if a stone is detected on cholangiogram. Subsequently, endoscopic stone extraction is performed using a retrieval basket or balloon. If the stone is impacted at the papilla, precut papillotomy using a needle knife would be preferred to conventional endoscopic sphincterotomy because cannulation into the bile duct is often difficult in such cases (Fig. 33.2).

Endoscopic sphincterotomy with subsequent stone extraction is currently a well-established technique with high success rate (approximately 90%) [17]. However, procedure-related adverse events, including pancreatitis, hemorrhage, perforation, and cholangitis, can occur in approximately 10% [18]. Aggravation of pancreatitis is a particularly big concern in patients with pancreatitis. Therefore, cannulation and contrast medium injection into the pancreatic duct should be avoided as much as possible; however, there is no evidence that accidental cannulation into the pancreatic duct harmfully affects the clinical course or outcome. Recently, the efficacy of pancreatic duct stenting was suggested in ABP following endoscopic sphincterotomy. In a nonrandomized study, complications were less frequent in the pancreatic duct stent group than in the control group without pancreatic duct stent (9.86% vs. 31.43%, $P < 0.002$) [19]. However, so far, there is no significant evidence to recommend pancreatic duct stenting after endoscopic treatment for ABP.

## Outcomes and Timing of Endoscopic Interventions

Endoscopic treatments for ABP were initially described in 1981 [20,21]. Since then, a number of prospective randomized controlled trials (RCTs) have compared early endoscopic treatments with conservative therapy for ABP. However, the role and timing of endoscopic intervention in ABP remain controversial. A number of clinical trials and meta-analyses have provided conflicting evidence.

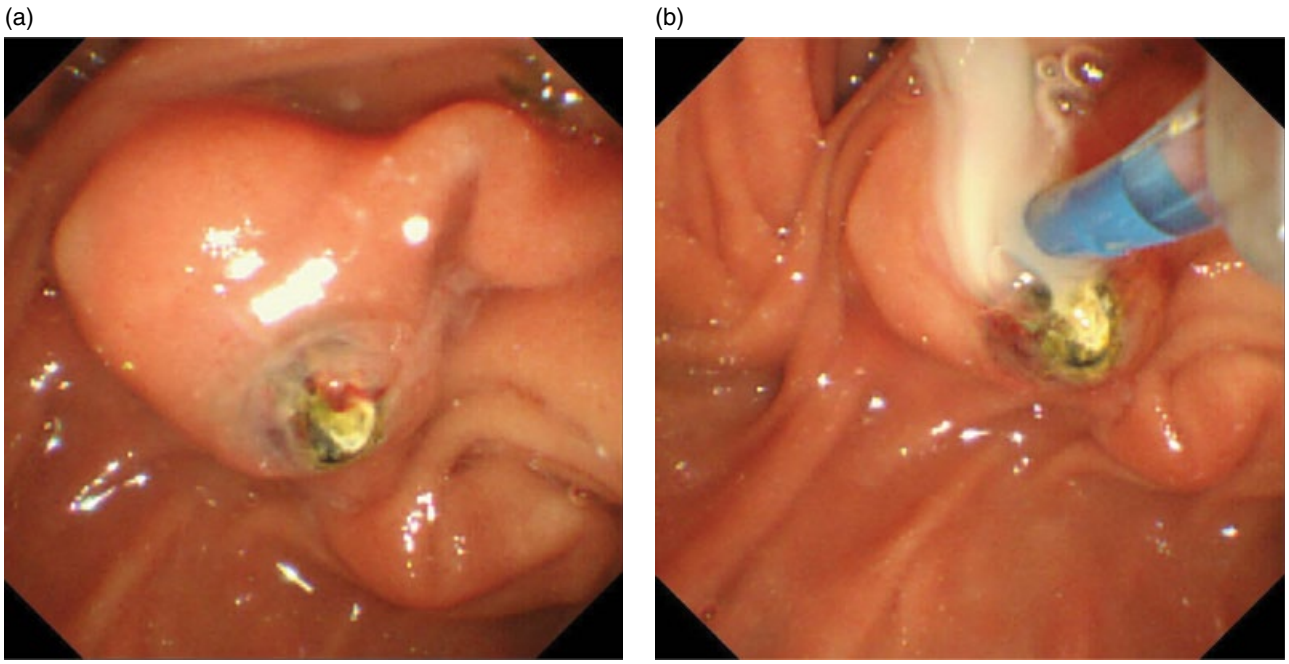

**Figure 33.2** Endoscopic view of an impacted stone at the duodenal papilla. A stone is impacting at the biliary orifice (a). Needle knife papillotomy is preferably performed in such a case. Whitish pus is discharged after cutting up the papilla from the orifice using a needle knife (b).

Two early RCTs showed lower complication rate, shorter hospital stay, and lower mortality rate in the urgent ERCP group than in the conservative group [22,23]. However, another RCT showed that the overall rate of complications was similar in the two groups, and patients in the early ERCP group had more severe complications [24]. The first meta-analysis published in 1999 showed high success rate of ERCP (92%) and concluded that early ERCP significantly reduced morbidity (25.0% vs. 38.2%, $P<0.001$) and mortality (5.2% vs. 9.1%, $P<0.05$) in ABP [25]. However, later studies suggested that early endoscopic intervention was beneficial in further limited patients.

Several studies concluded that urgent endoscopic intervention should be considered only in patients with severe biliary pancreatitis [26–28]. In a meta-analysis by Ayub et al. [27], early endoscopic intervention was associated with significant reduction in complications only in predicted severe biliary pancreatitis (odds ratio [OR] 0.27, 95% confidence interval [CI] 0.14 to 0.53), whereas reduction of mortality was not significant in both predicted mild and severe biliary pancreatitis. Later, a meta-analysis by Moretti et al. [28] also reported that a significant difference in the pooled rate for complications was found only in predicted severe pancreatitis (38.5%, 95% CI −53% to −23.9%, $P<0.0001$).

Meanwhile, several other studies suggested that the benefit of urgent endoscopic intervention was expected only in cases with cholangitis or cholestasis [29–34]. Petrov et al. [29] reviewed RCTs on early endoscopic intervention versus conservative management in patients with ABP without acute cholangitis. As a result, early endoscopic intervention in patients with predicted mild and predicted severe biliary pancreatitis did not lead to a significant reduction in the risk of overall complications and mortality. Later, van Santvoort et al. [35] conducted a prospective, observational multicenter study including patients with predicted severe ABP without cholangitis. They analyzed the outcomes in patients without and with cholestasis separately. As a result, endoscopic intervention was associated with fewer complications as compared with conservative treatment in patients with cholestasis (25% vs. 54%, $P=0.020$), whereas it was not associated with reduced complications (45% vs. 41%, $P=0.814$) in patients without cholestasis. A recent Cochrane review by Tse and Yuan [32] showed no evidence that early routine ERCP significantly affected mortality or local/systemic complications of pancreatitis, regardless of predicted severity. However, among trials that included patients with cholangitis, the early routine ERCP strategy significantly reduced mortality, local, and systemic complications. In addition, among trials that included patients with biliary obstruction, early routine ERCP strategy was associated with a significant reduction

in local and systemic complications. Finally, they concluded that early ERCP should be considered only in patients with coexisting cholangitis or biliary obstruction. From the latest systematic review [36] including 8 meta-analyses and 12 guidelines, there is consensus in guidelines and meta-analyses that early endoscopic intervention is indicated in ABP patients with coexisting cholangitis and/or persistent cholestasis. With the exception of the first meta-analysis [25], none of the included studies approved early ERCP in predicted mild ABP. Consensus is lacking on the role of routine early endoscopic intervention in patients with predicted severe ABP.

## Cholecystectomy After Endoscopic Treatment

Recurrence rates of ABP of up to 61% have been reported when definitive treatment was not provided [37,38]. Therefore, subsequent cholecystectomy after endoscopic treatment of bile duct stones has been recommended to prevent recurrent attacks of ABP [39,40], although 25–50% of patients do not undergo cholecystectomy for various reasons [41–43]. In cases of severe ABP, the current consensus is to postpone cholecystectomy until after resolution of local or systemic complications [38–40,44].

# Strategies for the Treatment of Pancreatic Pseudocysts and Walled-Off Necrosis After Acute Pancreatitis: Interventional Endoscopic Approaches

*Georg Beyer[1,2], Julia Mayerle[1], and Markus M. Lerch[2]*

[1] *Department of Medicine II, University Hospital Munich, Ludwig-Maximilians-University, Munich, Germany*
[2] *Department of Medicine A, University Medicine Greifswald, Greifswald, Germany*

## Introduction

A series of trials following improvements in intensive care medicine and endoscopic techniques has led to a paradigm shift in the management of fluid collections developing after an attack of acute pancreatitis: if undertaken at all, interventions should be delayed as much as possible and the least-invasive methods should be considered first, before escalating treatment (step-up approach) [1–4]. Intervening a post-acute pancreatic fluid collection (PFC) endoscopically is considered safe once a well-defined wall has developed, roughly 4 weeks into the disease course [5]. Whether drainage of (infected) fluid collections is beneficial before a fibrous wall has formed is being investigated by a Dutch multicenter trial (POINTER). Post-acute pancreatic pseudocysts are considered a rare complication arising from a disruption of the main pancreatic duct or major duct branches without considerable necrosis and by definition contain only fluid rich in pancreatic enzymes. In contrast, collections with a fibrous wall originating from pancreatic and/or peripancreatic necrosis are called walled-off necrosis (WON), which will contain variable amounts of solid debris and may reach into areas distant from the gland [6].

## Indications for Endoscopic Treatment

In general, only collections that cause symptoms or are at a high risk for severe complications require intervention. Indications for endoscopic intervention are features of infection on imaging or a high suspicion for infection with persistent signs of sepsis that do not improve under adequate intravenous antibiotics. Less common indications are pain, persistent unwellness, jaundice caused by the collection compressing the bile duct, bleeding, disconnected duct syndrome, gastric outlet obstruction, or pancreatic fistulas.

## Endoscopic Drainage vs. Necrosectomy: Choosing the Right Patient

It is currently unclear which collections will improve with drainage alone, which ones need irrigation, and for which ones a patient should undergo advanced endoscopic necrosectomy, as reflected by discordant results of a recent international expert survey [5]. In many cases, patients will initially improve after a drainage procedure and optional nasocystic lavage with few plastic pigtail stents in place to ensure the patency of the tract. A systematic review and meta-analysis comparing 324 patients who underwent conservative management of infected pancreatic necrosis to 157 who underwent necrosectomy concluded that the conservative management was successful in 64% and that mortality was lower than in patients who underwent percutaneous treatment [7] although this result is fraught by significant selection bias. Multiple early case series which included pancreatic necrosis and pancreatic abscesses even reported full resolution of these collections without

Companion website: www.wiley.com/go/beger/thepancreas

further necrosectomy in over 80% of cases [8–11]. Unfortunately a nonuniform nomenclature impairs the comparability of these observations. A Swedish trial comparing drainage of pseudocysts to pancreatic abscesses with variable amounts of debris showed that the rate of successful drainage was lower in abscesses (94% vs. 80%; $P = 0.04$) and the risk for complications five times higher ($P = 0.02$). Of note, all abscesses underwent necrosectomy and lavage later [12]. This suggests that in patients with a higher burden of necrotic material and/or infected collections a more invasive approach may be warranted. Transmural endoscopic necrosectomy has been shown to be a safe and efficient way to deal with necrotic collections accessible to endoscopy. It remains burdened, however, with serious complications even in the hands of experienced investigators [13–17]. In a retrospective comparison of conventional transmural drainage versus necrosectomy in patients with evidence of WON on contrast-enhanced computed tomography (CT), Gardner et al. showed superiority of direct necrosectomy in terms of treatment success, need for surgery or additional percutaneous drainage, and recurrence [18]. Another registry-based, matched cohort study comparing direct necrosectomy to initial percutaneous access as suggested by the original "step-up approach" in 12 patients showed favorable outcomes for the direct endoscopic approach [19]. Taken together, the current data suggest that mere endoscopic drainage is reasonable and often sufficient in defined collections with minimal amounts of solid material, whereas patients with WON and more extensive necrotic material will most likely profit from a more aggressive approach with sometimes repeated sessions of endoscopic removal of necrotic tissue [20]. In unstable patients who developed sepsis due to infected WON requiring ventilator support and vasopressors an initial endoscopic or even percutaneous drainage to achieve sepsis control and delayed more advanced endoscopic necrosectomy may be more appropriate. Endoscopic drainage is generally preferred over percutaneous drainage for infected fluid collections, not because it is more effective but because the latter very often leads to persistent fistulas [21]. If, however, drainage is required before a fibrous wall has formed (generally 4 weeks) percutaneous drainage is still a valid and frequently used alternative.

## Preventing Recurrence by Treating Disconnected Duct Syndrome

A disconnected pancreatic duct with pancreatic juice leaking into the connected PFC is a major complication of acute pancreatitis and a well-known risk factor for persistence or recurrence of PFC. This includes pseudocysts and WON, even after initially successful endoscopic treatment [22–24]. The integrity of the pancreatic duct should therefore be confirmed whenever pancreatic necrosis requiring an intervention is present and preferably by noninvasive methods such as magnetic resonance cholangiopancreatography (MRCP). Although found in up to 50% of patients with acute necrotizing pancreatitis, studies on the optimal management of PFC associated with disconnected pancreatic duct syndrome are scarce. A small randomized controlled trial ($n = 28$) recruiting patients with and without disconnected pancreatic duct showed a significant reduction of recurrence (0 vs. 5, $P = 0.013$) when stents were not removed [25]. The approach of long-term indwelling plastic stents has been adopted for the treatment of WON with disconnected pancreatic duct syndrome as reported in two retrospective series including 26 and 33 patients respectively, in which it appears to have led to a satisfactory outcome with regard to resolution of the collection [26,27]. Another approach involves stenting the pancreatic duct after transmural access and cavity stenting is established. This allows transpapillary drainage of both the content of the connected collection and, more importantly, pancreatic juice away from vital pancreatic tissue distal to the duct disruption [28]. ERCP should be performed with caution in these patients as it is associated with considerable rates of adverse events [29]. Recently a group from Mumbai, India described a promising strategy in 42 patients with symptomatic post-acute pancreatic pseudocysts. Three weeks after initially successful drainage using an expandable covered nitinol stent, the patients underwent MRCP. A pancreatic duct leak was detected in three patients and treated successfully by stenting the pancreatic duct with consecutive retrieval of the transmural stent [30]. Although only preliminary, these data suggests that a consecutively deferred combination of transmural and transpapillary stenting could be an alternative to long-term transmural stents.

# Strategies for the Treatment of Pancreatic Pseudocysts and Walled-Off Necrosis After Acute Pancreatitis: Surgical Treatment

*Naohiro Sata, Masaru Koizumi, and Alan K. Lefor*

*Department of Surgery, Jichi Medical University, School of Medicine, Tochigi, Japan*

## Introduction

The strategy for surgical intervention in patients with pancreatic pseudocysts (PPC) and walled-off necrosis (WON) has dramatically changed in recent decades and the optimal approach is still controversial. In the early 1980s, open drainage and closed lavage were the most common surgical procedures performed for "pancreatic abscess." A more aggressive approach resulting in earlier surgical intervention, with more extensive drainage and debridement of associated necrotic tissue has been recommended [1]. However, early intervention including open necrosectomy is associated with poor outcomes and the latest guidelines suggest that surgical intervention should be delayed as long as possible, until at least 4 weeks after the onset of the illness [2,3].

Peripancreatic fluid collections are frequently seen in the management of patients with acute pancreatitis. Acute pancreatitis is divided into interstitial edematous pancreatitis and necrotizing pancreatitis [4]. In interstitial edematous pancreatitis, fluid collections are usually resorbed spontaneously and clinical symptoms are improved after a week. However, remnant localized fluid collections sometimes require intervention in patients with necrotizing pancreatitis. The terminology for these remnant localized fluid collections was completely changed in 2012 by the revised Atlanta classification [4]. This chapter will focus on surgical strategies for the treatment of patients with PPC and WON after episodes of acute pancreatitis.

## Definition of Pancreatic Pseudocyst and Walled-Off Necrosis

In the Atlanta classification, advocated at the International Symposium on Acute Pancreatitis in Atlanta in 1992, acute fluid collections and pancreatic necrosis/infected necrosis were defined as local complications in the early stage of acute pancreatitis [5]. In addition, PPC and pancreatic abscess are also defined as local complications in the late stage. The term "pancreatic pseudocyst" had been used to describe a wide spectrum of fluid collections derived from necrotizing pancreatitis, interstitial edematous pancreatitis, and acute exacerbations of chronic pancreatitis. Capsulized liquefied necrotic pancreatic and/or peripancreatic tissue after necrotizing pancreatitis should be considered different from a capsulized collection of pure pancreatic exocrine secretions. If the same treatment had been performed, the outcome would be different [6,7]. In fact, pancreatic abscess was seldom encountered in either Western countries or East Asia. Based on this background, the concept of "walled-off pancreatic necrosis" was proposed for an encapsulated fluid collection derived from necrotic pancreatic and/or peripancreatic tissue in patients with necrotizing pancreatitis [8]. The term was changed to "walled-off necrosis (WON)" and the concept of this condition was then established by the revised Atlanta classification in 2012 [4] (Fig. 35.1). WON is defined as a mature, encapsulated collection of pancreatic and/or peripancreatic necrosis that has developed a well-defined inflammatory wall and usually occurs more than 4 weeks after the onset of necrotizing pancreatitis [4].

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

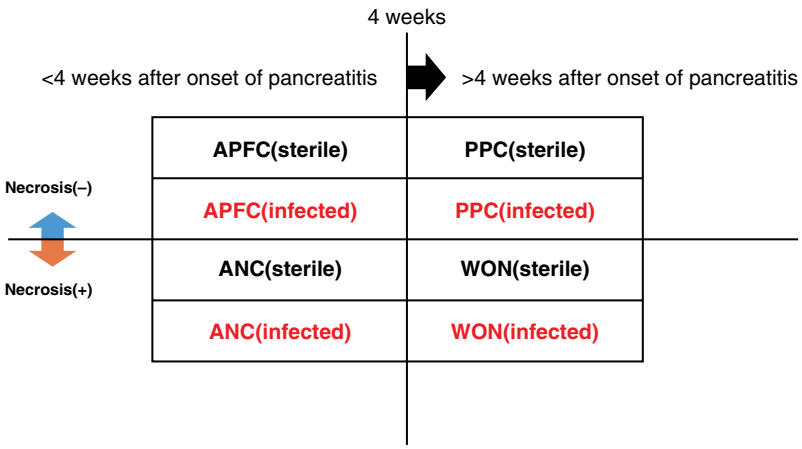

**Figure 35.1** Eight categories of local complications of acute pancreatitis defined by the revised Atlanta classification of 2012. APFC, acute peripancreatic fluid collection; ANC, acute necrotic collection; PPC, pancreatic pseudocyst; WON, walled-off necrosis.

A fluid collection originating from necrosis less than 4 weeks after the onset of necrotizing pancreatitis is referred to as an acute necrotic collection (ANC). The concept of a PPC was proposed to be limited to an encapsulated collection of fluid with a well-defined inflammatory wall, usually outside the pancreas, with minimal or no necrosis that occurs more than 4 weeks after the onset of interstitial edematous pancreatitis [4,9]. As the concept of PPC changed and the new concept of WON was developed in 2012, care must be taken to avoid confusion regarding the terms PPC and WON, especially when reviewing clinical studies reported before 2012.

The International Association of Pancreatology and the American Pancreatic Association (IAP/APA) guidelines were revised according to the revised Atlanta classification of 2012, and the IAP/APA evidence-based guidelines for the management of acute pancreatitis were published in 2013 [2]. At the same time, Japanese guidelines for the management of acute pancreatitis were revised and the fourth edition was published in 2015 [3]. The diagnosis and treatment of acute pancreatitis should be based on these guidelines.

## Indications for Surgical Intervention

Previously, surgical intervention with drainage and necrosectomy was the gold standard for treatment of the infectious complications of acute pancreatitis. In the early 2000s, minimally invasive interventions were developed and have been replacing highly invasive surgical procedures such as open drainage. Minimally invasive interventions include procedures such as endoscopic and laparoscopic drainage and necrosectomy. Both the IAP/APA guideline 2013 and the Japanese guideline 2015 recommend that interventions should be performed in patients with infections or other persistent symptoms, such as ongoing gastric outlet, intestinal, or biliary obstruction, pain, or complications due to a mass effect secondary to WON or PPC. Most patients with infected localized fluid collections that cannot be managed by the administration of wide-spectrum antibiotics will require some therapeutic intervention.

The terminology for drainage and necrosectomy should be appropriately used. Drainage is a procedure to drain fluid by percutaneous, transgastric, enteral, or transpapillary routes, or by open surgery. Necrosectomy is a procedure to remove necrotic tissue aggressively, using percutaneous, transgastric, or enteral approaches, or by open surgery. Confusion regarding the terminology for drainage and necrosectomy procedures must be considered when evaluating clinical studies reported before 2012.

## Timing of Interventions and Optimal Interventional Strategy for Walled-Off Necrosis

In the past, outcomes following early invasive surgical interventions were very poor [10–12]. In a prospective study of 629 patients, late intervention significantly decreased mortality and morbidity [13]. Both the IAP/APA guideline 2013 and the Japanese guideline 2015 refute the beneficial therapeutic effect of early intervention, and recommend that intervention should be delayed as much as possible, until at least 4 weeks after the onset of pancreatitis [2,3]. Interventions should be performed when fluid collections are encapsulated and the capsule wall is thickened.

The optimal interventional strategy is still controversial. Open surgery was the only choice for intervention before 2000. Minimally invasive interventions, including endoscopic drainage and necrosectomy, and laparoscopic necrosectomy, were introduced in the late 1990s and early 2000s. Though the use of these novel interventions has been increasing, they require advanced technical skills and should be done only in high-volume

centers. Some centers reported good results, although there is a large variance in the expertise in performing these novel interventions among centers. Further assessment is necessary for these interventions to become standard approaches.

The Dutch Pancreatitis Study Group proposed a step-up approach for the treatment of patients with suspected or confirmed infected necrotizing pancreatitis [14]. The step-up approach is composed of two parts, including initial image-guided percutaneous (retroperitoneal) catheter drainage or endoscopic transluminal drainage followed by endoscopic or surgical necrosectomy. Percutaneous catheter drainage alone is reported to reduce the necessity for necrosectomy in 23–50% of patients with infected necrotizing pancreatitis [2,14–19]. Additionally, the step-up approach is reported to decrease major short-term and long-term complications and reduce overall costs compared to conventional surgical necrosectomy [14]. At present, the step-up approach is thought to be the most effective approach and both the IAP/APA guideline 2013 and the Japanese guideline 2015 clearly recommend it as the optimal interventional strategy [2,3]. The IAP/APA guideline 2013 also states that no subgroup of patients requiring a different strategy can be defined, and the optimal method of necrosectomy (i.e., surgical or endoscopic necrosectomy) is unclear if catheter drainage fails [2].

Catheter drainage is always the first step for intervention in patients with local infectious complications of necrotizing pancreatitis. Less-invasive procedures, such as percutaneous drainage by ultrasonography or computed tomography, and endoscopic transluminal drainage are the primary recommendations [13–16] (Fig. 35.2).

**Figure 35.2** Computed tomography scan findings of infected walled-off necrosis on the 170th day after the onset of necrotizing pancreatitis. Air bubbles were observed in the area of walled-off necrosis located in the lesser omentum, which strongly suggests the presence of infection.

Surgical drainage with a small incision is indicated in patients for whom percutaneous or endoscopic approaches are contraindicated or fail. Multiloculated cysts, multiple cysts, presence of significant necrotic debris, cysts in the pancreatic tail, and uncontrolled hemorrhage are also indications for surgical drainage. If catheter drainage fails to control infection, minimally invasive or open surgery or endoscopic transluminal necrosectomy are the next steps.

Laparoscopic and video-assisted retroperitoneal debridement (VARD) have become new choices for a second step intervention [14]. The results from 13 recent series of percutaneous drainage for necrotizing pancreatitis indicate a 26.4% conversion rate from percutaneous drainage to surgical drainage, with a 15.2% mortality rate [14,20–31]. The results from 17 recent series of surgical necrosectomy indicate the need for additional necrosectomy in 16.5%, additional drainage in 13.8%, and an overall 25.8% mortality rate [32–48]. However, the step-up approach has better outcomes. The results from nine recent series report a 17.4% conversion rate to the surgical approach with a 14.9% mortality rate [14,33,49–54]. Bleeding, pancreatic fistula, and gastrointestinal fistula are frequent complications of these interventions.

## Surgical Intervention for PPC

Since acute exacerbations of chronic pancreatitis are a leading cause of PPC, the strategy for the treatment of PPC should be different from that used for WON. Most small PPC spontaneously regress without specific interventions. Evidence of infection or persistent symptoms are a common indication for intervention in patients with PPC (Fig. 35.3). External or internal drainage is the first

**Figure 35.3** Computed tomography scan findings of a pancreatic pseudocyst. The pancreatic pseudocyst resulted from an acute exacerbation of chronic pancreatitis, and is located in the left subphrenic space.

choice for infected PPC, and other novel interventions have been developed and evaluated clinically. Open cyst-enterostomy (i.e., cyst-gastrostomy or cyst-jejunostomy) is often used with a reported 25.4% morbidity and 0.2% mortality in five recent retrospective series [55–59]. Laparoscopic cyst-enterostomy, a minimally invasive approach, is becoming more common and performed by various methods, including a Roux-en-Y anastomosis and intragastric procedures [60–65]. The laparoscopic procedure has good outcomes, with 9.5% morbidity, 3.6% PPC recurrence, and 0% mortality in seven recent series [60–66]. Percutaneous cyst-gastrostomy, draining the PPC via both percutaneous and transgastric routes with a gastroscopic procedure, is feasible with 11.3% morbidity and 9.4% requiring an additional surgical cyst-gastrostomy [14,67–69]. Bleeding, abdominal abscess including cyst infection, pancreatic fistulas, and surgical site infections are common complications of surgical procedures for PPC [55–66]. Pancreatectomy, distal pancreatectomy, pancreaticoduodenectomy, or duodenum-preserving pancreas head resection are indicated in some patients with a PPC and persistent chronic pain [59].

# Management of Fluid Collection in Acute Pancreatitis

*Felix Lämmerhirt, Frank Ulrich Weiss, and Markus M. Lerch*

*Department of Medicine A, University Medicine Greifswald, Greifswald, Germany*

## Introduction

Acute pancreatitis is the most common cause for hospitalization in gastroenterology and has an incidence of 13–45/100 000 with regional variations [1]. Alcohol and gallstones are the main risk factors (30–50%) with alcohol as an etiology being more common in men [2,3].

Considering the variety of different courses of pancreatitis, ranging from mild abdominal pain to death, it is important to predict the likely severity of the disease early in the clinical course.

The current definition of acute pancreatitis, the grades of severity (mild, moderately severe, and severe) [4], and the detailed description of the systemic and local complications based on the revised Atlanta classification from 2013 [5] are discussed in Chapter 20.

## Definitions

The way acute fluid collections are classified depends on the timeframe of their development as well as some morphological imaging features. The acute peripancreatic fluid collection (APFC) is a typical complication of the interstitial and edematous subtype and often develops during the first 7 days of pancreatitis. It has no wall and a homogenous internal structure. The spread of an APFC is orientated along the fascial anatomy. Occasionally, APFC are found in multiple locations and they tend to regress spontaneously. If an APFC persists for longer than 4 weeks there is a high probability that a pseudocyst will develop.

A pseudocyst is defined as a fluid-filled space, similar to a real cyst, with a fibrotic wall. In contrast to real cysts, pseudocysts have no internal epithelial cell lining. Pseudocysts are considered complications of chronic pancreatitis and occasionally of acute pancreatitis. Following the latter they evolve from APFC usually later than 4 weeks after the onset of symptoms. The treatment strategies of pancreatic pseudocysts are described in Chapter 34.

Regions of nonvital tissue damaged by extravasated pancreatic juice or immune cells are defined as necrosis. It represents a form of tissue injury resulting in premature nonapoptotic cell death. The morphological characteristics of necrosis caused by acute pancreatitis are highly variable. The necrotic tissue may appear as solid in a fluid structure on imaging, although the sensitivity for detecting the solid component varies greatly between computed tomography (CT), magnetic resonance imaging (MRI), and endoscopic ultrasound (EUS).

An acute necrotic collection (ANC) arises within the first 4 weeks of the disease in the pancreatic parenchyma as well as the extrapancreatic tissue. It contains varying amounts of fluid or solid material. The solid parts are the crucial feature to distinguish an ANC from an APFC or a pseudocyst.

If a necrotic area is enclosed by a radiologically distinguishable capsule it is called walled-off necrosis (WON). The difference between WON and a pseudocyst is the presence of variable amounts of solid content in the cystic cavity. Usually it arises from an ANC later than 4 weeks from the onset of pancreatitis.

An originally sterile necrosis can maintain its status or become infected over the course of the disease. The diagnosis of infected necrosis is based on the patient's clinical presentation and the presence of gas in the necrotic cavity on radiological imaging. It is of note that an asymptomatic fistula from the necrotic cavern to the gastrointestinal tract also leads to the presence of gas within the necrosis but can be without any signs of infection. Fine-needle aspiration followed by microbiological

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

analysis of the content can confirm the presence of infected necrosis but is not needed in most cases and has a high false negative rate. Moreover, microorganisms isolated from the blood of patients with the clinical presentation of an infection or signs of an infected necrosis on imaging are of greater relevance for choosing appropriate antibiosis than those isolated from cultured content of the necrotic cavity. Other than the extent, there are currently no features by which to predict whether necrosis will persist or regress over weeks and months.

## Imaging of Acute Fluid Collections

### Transabdominal Ultrasound

Transabdominal ultrasound is an inexpensive, immediately available technique to allow a first imaging impression of a patient with an acute abdomen. The imaging of the pancreatic gland is often impaired by abdominal pain and an atonic gut. Edematous pancreas is characterized by an inhomogeneous, hypoechoic structure with poorly defined boundaries [6]. The pancreatic main duct is often not visualized inside the edema. Necrotic and hemorrhagic tissue appears more hypoechoic than the inflamed parenchyma. The echo contrast gain or use of ultrasound contrast agent permits a somewhat better distinction between vital or nonperfused tissue. For the detection of small amounts of free fluids in the abdominal or pleural cavity ultrasound remains the undisputed gold standard. The presence of ascites or the mostly left-sided pleural effusions are predictors for a more severe course of acute pancreatitis. Another domain of sonography is the fast and reliable imaging of the gallbladder and, if present, gallstones, which can confirm or rule out a biliary pathogenesis.

### Computed Tomography, Endoscopic Ultrasound, and Magnetic Resonance Imaging

Contrast-enhanced CT scan is the fastest and most accurate method for the differential diagnosis of an acute abdomen. At hospital admission CT scan is not recommended for patients with clinical confirmed acute pancreatitis unless other differential diagnosis cannot be ruled out. Imaging via CT should not be performed to assess the severity of pancreatitis on admission [7], because the extent of necrosis can still evolve until up to 72 hours after the disease onset. Therefore, a CT scan should be delayed, if required at all, for 4 days after symptom onset [8].

Contrast-enhanced CT can confirm the size, shape, and volume of fluid collections or necrosis and is a valuable tool to identify extrapancreatic complications including hemorrhage or pseudoaneurisms.

Two alternative methods are EUS and MRI. Despite having cost and procedural disadvantages, both methods are more sensitive in detecting solid content within a fluid collection and thus in distinguishing between plain fluid collections and pseudocysts on the one hand and areas of necrosis and WON on the other. For more details Chapters 25 and 34 are recommended.

## Conservative Treatment of Pancreatitis and Pancreatic Fluid Collections

### Basic Support

All patients with acute pancreatitis should be monitored regularly within the first 48 hours after admission [4]. Important parameters include:

- heart frequency, 3 (or 6)-lead ECG, blood pressure, oxygenation (to detect circulatory respiratory failure and shock);
- blood gas analysis (in case of oxygenation <90%) (to detect respiratory failure);
- hourly urinary excretion measurements for the management of fluid resuscitation (for fluid management and to detect renal failure);
- abdominal pressure measurement via bladder pressure measurement (to detect compartment syndrome);
- blood electrolytes;
- blood glucose levels (to detect endocrine failure).

### Fluid and Electrolyte Management

Due to retroperitoneal edema and increased vessel permeability a massive fluid shift is typical for acute pancreatitis leading to APFC. Fluid resuscitation is currently the most important intervention for reducing patient mortality. Mortality can increase to 61% if less than 3.5 L of fluid are transfused in the first day [9,10]. An increase of blood urea nitrogen (BUN) of 5 mg/dL within 48 hours is a sign of prerenal kidney failure and increases mortality by a factor of 2.2 [11]. The recommended amount of fluid is 5–10 mL/kg bodyweight/h. Greater therapeutic fluid volumes lead to a mortality increase partially due to abdominal compartment syndrome (intra-abdominal pressure >20 mmHg), sepsis, or a prolonged stay in the intensive care unit (ICU) [12]. The monitoring of fluid resuscitation should use either invasive thermodilution techniques or, if unavailable, the following parameters:

- heart frequency <120 bpm;
- mean arterial pressure between 65 and 85 mmHg;

- urinary excretion >0.5–1 mL/kg per hour;
- hematocrit between 35 and 45%.

Another important point is the composition of administered fluid. Crystalline solutions are superior to colloids. Colloidal infusions are suspected of being associated with a higher incidence of renal insufficiency and should be avoided. The advantage of Ringer's solution is its similar composition to blood as well as the nonimpairment of electroneutrality by compensating the anion gap with lactate or acetate [13]. Moreover, the incidence of systemic inflammatory response syndrome (SIRS) is reduced within the first 24 hours if Ringer's solution is used rather than saline [4]. Ringer's solution is inappropriate for patients with hypercalcemia.

## Nutrition

Complete fasting has no positive influence on the outcome and course of pancreatitis [4]. In fact, fasting leads to atrophy of gut villi resulting in a more rapid translocation of intraluminal bacteria, facilitating the infection of necrotic areas. Starting enteral nutrition early is recommended [14]. If enteral nutrition is not advised because of paralytic ileus, parenteral nutrition is required until enteral nutrition can be administered [15]. If the patients are not able to take oral food, feeding by tube is the most effective method. Nasogastric and nasojejunal tubes have been shown to be equally effective and safe, although nasojejunal feeding tubes tend to dislocate more often. The best and most natural form of nutrition remains eating by mouth. Once patients are pain-free (with pain medication if required) and can tolerate food they should take oral food. If not, enteral nutrition is less expensive and more physiologic than parenteral nutrition. Starting enteral nutrition immediately after admission was not found to lead to better outcomes than withholding food for 72 hours [16]. The current approach to nutrition has become much more pragmatic than in the past when all patients were put on nil-by-mouth for long periods.

## Antibiotics

Prophylactic application of antibiotics is not necessary for patients with acute pancreatitis, regardless of its predicted severity, and could contribute to the rise of multiresistant bacteria. Neither the mortality nor the rate of infected necrosis is positively influenced by prophylactic antibiotics [17]. If, on the other hand, infected necrosis is suspected, antibiotic therapy must be initialized immediately. Antibiotics with appropriate pancreatic tissue levels are carbapenems, gyrase inhibitors, or metronidazole. If the response to the administered antibiotics is insufficient, fine-needle aspiration followed by microbiological testing allows switching to antibiotics based on resistograms. In patients with sepsis other infectious foci must be considered, such as peritonitis, cholangitis, or pneumonia. In general, microbes sampled from blood cultures of pancreatitis are often more informative than those from necrotic fluid collection because of the high rate of false negatives among the latter.

## Management of Edematous Fluid Collections

An APFC tends to regress spontaneously. If it persists longer than 4 weeks under conservative treatment it may develop into a pseudocyst or WON (see Chapter 34). Simple intra- or extrapancreatic fluid collections, the focus of this chapter, generally do not require interventional treatment unless they give rise to compartment syndrome as characterized by fluid overload and elevated urinary bladder pressure. An abdominal compartment syndrome is defined as an increased abdominal pressure (>20 mmHg) for longer than 12 hours and simultaneous organ failure.

## Minimally Invasive Treatment of Acute Fluid Collections in Acute Pancreatitis

When conservative management is unsuccessful, minimally invasive treatment is recommended. The following sections give an overview about the different modalities.

### Imaging-Guided Percutaneous Drainage

This is a technically easy and well-established method to treat pseudocysts or fluid collections. Ultrasound, CT, or MRI can be used for imaging. Although single-step needle aspiration is associated with a high relapse rate, continuous catheter-drainage systems are recommended based on their high success rate (70–100%) and a low recurrence rate [18,19]. The risk of fistula formation must be considered.

### Endoscopic Drainage

This method provides a minimal invasive access for draining a pseudocyst. Transpapillary and transmural approaches from the stomach or duodenum are available. The aim is to create an artificial connection between the cyst cavity and the gastrointestinal tract. For pseudocysts communicating with the pancreatic main or branch duct transpapillary techniques are preferable [20]. Transpapillary drainage has a success rate of 85% and a low morbidity of 6% in some studies. The authors' personal experience is much less optimistic. Endoscopic transmural drainage is recommended

for cysts that do not communicate with the pancreatic ductal system. Based on a better visualization of vessels, EUS-guided drainage is associated with a lower complication rate than the endoscopic technique without EUS visualization [21–23] and the latter should be abandoned.

For the treatment of pseudocysts with a location distant to gastric lumen and with a thick fibrotic capsule a laparoscopic approach should be favored. In Chapter 34 the strategies for surgical and endoscopic interventions for pancreatic pseudocysts, infected necrosis, and WON are outlined and discussed in detail.

## Conclusion

Fluid collections that arise in the context of acute pancreatitis generally regress under conservative treatment and do not require interventional treatment in most cases. They may require endoscopic or surgical treatment when they fulfil the morphological criteria of infected (walled-off) necrosis, when they represent complication-causing or complication-prone pseudocysts, or when they precipitate abdominal compartment syndrome. How early in the course of the disease a drainage procedure may be beneficial is currently being investigated in the multicenter POINTER trial.

# Management of Pancreatic Fistula in Acute Pancreatitis

*Jörg Kaiser, Thilo Hackert, and Markus W. Büchler*

*Department of General, Visceral and Transplantation Surgery, University of Heidelberg, Heidelberg, Germany*

## Introduction

A pancreatic fistula is defined as a leakage of pancreatic juice as a result of disruption of pancreatic ducts or parenchyma. During severe acute necrotizing pancreatitis, local complications—besides the systemic inflammatory response syndrome (SIRS) or sepsis-associated consequences—play a major role in the management of patients. Local complications include infected necrosis and pancreatic abscesses which cause destruction of the pancreatic parenchyma and eventually small or larger ducts leading to a leakage of pancreatic enzyme-rich fluid. This can either lead to the formation of pseudocysts or, in the case of erosion of surrounding structures, to fistulas. In most cases, parenchyma or duct leakages are self-limiting and can be covered by the surrounding organs, reabsorbed by the serosa, or encapsulated by a fibrous pseudowall followed by pseudocyst formation [1,2].

In the case of acute fistula-associated complications, including erosional bleeding or bowel perforation, immediate intervention and surgical treatment are required, which includes angiographic bleeding localization and management (i.e., stent placement in the eroded vessel) as well as emergency surgery [3]. However, if the pancreatic fistula does not cause acute complications, a continous leakage may occur and require therapy which needs to be adapted to the site and clinical symptomatology of the fistula. In this context, internal fistulas to the gastrointestinal tract, bronchi, pleural, mediastinal space, pericardium, and other organs [4,5] have to be differentiated from external—cutaneous—fistulas [6,7]. As internal fistulas are often clinically asymptomatic, they are more difficult to diagnose and may not immediately be detected [6]. In contrast, external fistulas are observed more often and can be easily diagnosed by analyzing the pancreatic enzyme content of the respective fluid [6,7].

## Pathogenesis and Classification

### Pathogenesis

The pathogenesis of pancreatic fistulas is multifactorial and seems to differ according to the site of origin of the fistula and the time at which the fistula occurs. On the basis of the necrotizing process in the pancreas, the peripancreatic fat and soft tissue, and the retroperitoneal space during severe acute pancreatitis, a widespread induction of autodigestion with a complex interaction between liberated pancreatic exocrine enzymes and local and systemic inflammatory mediators occurs [8]. Pancreatic parenchyma necrosis is understood to be a consequence of oxidative stress and potential calcium overload, leading to a combination of necrosis, apoptosis, pyroptosis, and autophagy, in which damage-associated molecular pattern molecules (DAMP) play a central role [9]. In addition, microcirculatory perfusion failure due to local thrombotic and inflammatory alterations of the microvascular architecture contributes to necrosis formation. Following parenchyma necrosis, proteases and the entire spectrum of all other activated pancreatic enzymes are released into the retroperitoneum and an autodigestive process is initiated. Local leukocyte recruitment and further activation of the inflammatory cascade helps to extend the necrotizing process throughout the peripancreatic region and the retroperitoneum, toward the mesocolon, small bowel mesentery, and paracolic retroperitonal gutters. The autodigestive process may extend to the skin, bowel, or any other organ to form fistulas.

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.
 Published 2018 by John Wiley & Sons Ltd.
Companion website: www.wiley.com/go/beger/thepancreas

In addition, the development of colonic fistulas during acute pancreatitis may also be a consequence of colonic wall necrosis secondary to mesenteric thrombosis, which is quite frequently observed in the transverse mesocolon because of its close proximity to the pancreas. All ischemic complications can furthermore be a consequence of systemic hemodynamic instability due to a septic shock during the systemic inflammatory response in severe acute pancreatitis.

Besides spontaneous fistula formation, endoscopic, interventional, or surgical therapeutic measures play an important role in fistula formation. Intraoperative manipulation during exploration of the abdomen or during necrosectomy in particular may lead to unintended injury by surgeons. Consequently, open surgery in acute pancreatitis is no longer regarded as a standard but should be evaluated critically and reserved for patients in whom other treatment options have failed [10].

The incidence of fistula formation and other local postoperative injuries after necrosectomy differs significantly depending on the operative techniques used [3]. Four principal methods have been established, namely necrosectomy combined with open packing [11], planned staged relaparotomies with repeated lavage [12], closed continuous lavage of the lesser sac and retroperitoneum [13,14], and closed packing [15]. In the hands of experienced surgeons, mortality rates below 15% have been described for all four techniques [11,16–18]. To achieve sufficient debridement, blunt necrosectomy is performed in a more or less identical fashion in all approaches, but management after the initial necrosectomy differs significantly [12–21]. The first two methods—open packing [11,16,17] and planned staged relaparotomies [12,19]—require several relaparotomies before final closure of the abdomen. Since there is a positive correlation between repeated surgical interventions and morbidity, including gastrointestinal fistula, stomach outlet stenosis, incisional hernia, and local bleeding, these two procedures should only be considered when very early debridement is indicated and a single operation does not seem to sufficiently guarantee further postoperative exit of remaining debris and infected fluid.

The other two techniques—necrosectomy and subsequent closed continuous lavage of the lesser sac [20,21] and closed packing [15]—imply a postoperative method to continuously remove residual pancreatic necrosis. Consequently, relaparotomies are usually not necessary. The most commonly adopted approach is that of closed lavage, first described by Beger in 1982 [14]. This leads to a reduction of postoperative morbidity, especially pancreatic and gastrointestinal fistulas as well as hemorrhage and incisional hernias. The results of the latter two surgical strategies with regard to morbidity, relaparotomies, and mortality are comparable and thus dependent on the preference of the surgeon.

## Classification

In contrast to postoperative pancreatic fistulas, which are the most common major complications after pancreatic resections and have been classified (postoperative day 3 with an amylase level greater than three times the upper limit of the normal serum value) and graded (severity grade B–C) by the International Study Group of Pancreatic Fistula (ISGPS) in 2016, there is no comparable grading system for fistulas in acute pancreatitis [22]. Pancreatitis-associated fistulas can be basically divided into internal and external fistulas. If their orifice is located intracorporally—regardless of the organ or structure affected—they are classified as internal fistulas; if there is a connection to the skin, the fistula is defined as external. In addition, low- or high-flow fistulas are differentiated, but this is only applicable for external fistulas. A daily output cut-off of 200 mL/day discrimiates low- from high-flow fistulas [23].

Further characterization of fistulas includes description as simple (straight channel from the pancreas toward the skin or another organ) or complex (multiple channels and tracts to different organs or structures). Moreover, the fluid can be characterized as clear pure pancreatic juice (due to external drainage of a pseudocyst communicating with the pancreatic duct) or mixed (consisting of pancreatic juice in combination with gastrointestinal secretions or bile). In the latter case, the pancreatic juice might be activated by enterokinase, leading to proteolytic effects of the fluid and a more severe injury. The amount and duration of the drainage are closely related to the size of the involved duct (main duct or branches of first, second, or third order), localization of duct rupture (head, body, or tail of the pancreas), and functionality of the sphincter of Oddi. In the acute phase of the disease, edema or spasm of the sphincter of the papilla may impair outflow, leading to increased pressure within the ductal system and subsequent rupture of the duct or maintenance of the outlet via the fistula. Once outflow via the papilla is restored, secondary to resolution of either the edema or spasm, spontaneous healing of the fistula can be observed in most cases. This is also consistent with the observation that spontaneous healing is less frequent in chronic pancreatitis, since both fibrosis and calcification as the cause of outflow reduction in chronic pancreatitis do not resolve. Main pancreatic duct disruption with leakage of pancreatic juice is a complication resulting from necrotizing pancreatitis with or without surgical intervention. If the main pancreatic duct shows a complete

loss of continuity a disconnected pancreatic duct syndrome (DPDS) occurs, which is either characterized by a high-volume fistula or development of a pseudocyst, which may become evident even months after the initial episode of pancreatitis [24].

## Diagnosis

### External Fistulas

The vast majority of external fistulas form along the tract of interventional or surgical drainages that are inserted to treat pancreatic abscesses, pseudocysts, and infected necrosis. They can easily be recognized by their typical secretions, with a large amount of amylase and lipase. As mentioned above, in terms of pancreatitis-associated fistula, there is no clearly defined cut-off for the increase in amylase, amount of fluid, or duration of secretion. To differentiate between simple and complex fistulas, radiological imaging should be performed. Conventional fistulography, computed tomography (CT), magnetic resonance cholangiopancreatography (MRCP) and endoscopic retrograde cholangiopancreatography (ERCP) can be used for this purpose [25–27]. Comparing these methods, CT scan is the gold standard in the diagnosis of acute pancreatitis and may also show the extent of necrosis as well as any complications including pancreatic abscesses, pseudocysts, and infected necrosis, but has a lower accuracy in fistula detection than MRI/MRCP imaging [28]. Conventional fistulography is useful to determine additional connection of an external fistula to other organs (i.e., colon) and ERCP has additional therapeutic value in that a stent is placed to bridge the leak site, which may contribute to the definitive resolution of partial pancreatic duct disruption [24,29].

### Internal Fistulas

The presence of fluid within in the peritoneal cavity is a common event in severe pancreatitis and can be caused by either inflammatory exudation alone or by additional leakage of pancreatic ducts. Internal pancreatic fistulas, which are mostly clinically asymptomatic, are often difficult to recognize and diagnose, especially as peripancreatic fluid in severe acute pancreatitis may contain high enzyme levels even if no clinically relevant fistula is present. In the case of persistent pancreatic ascites and/or a pleural effusions, an internal fistula should be considered; in rare cases acute mediastinitis arising from pancreato-mediastinal fistula can also be observed [30]. Apart from this rather rare complication, unrecognized internal fistulas can lead to other life-threatening medical conditions in terms of erosional bleeding or abdominal sepsis on the basis of bowel erosion. Therefore, suspicion of an internal fistula should be raised if abdominal fluid collections are associated with sepsis or bleeding [31].

If an internal fistula is suspected, further work-up needs to be done quickly, including ultrasonography and CT scan with the option for an interventional drain placement. Drained pleural or ascitic fluid shows highly elevated amylase and lipase levels and contrast vizualization after drain placement may confirm the suspected fistula [32,33]. Additional modalities suitable for visualizing the complete extent of the defect include oral contrast radiography for fistulas involving the upper gastrointestinal tract, and MRCP or ERCP for those involving the bile duct [34] (Figs 37.1 and 37.2).

## Management of External Fistulas

The management of pancreatic fistulas depends on the presence of symptoms, the characteristics and location of the fluid collection on imaging and the presence of associated complications. External pancreatic fistulas are usually managed conservatively in the beginning using supportive and specific treatment regimens [7,35–37]. In general, these fistulas tend to close spontaneously within 2–3 months. Failure to heal is mainly due to larger defects of the pancreatic duct, resulting in high-volume output and fistulas with complications of necrotizing pancreatitis, especially infection. Although almost all peripheral leaks will seal in time, central defects will not resolve easily, especially if there is no internal drainage via the pancreatic duct system into the duodenum. If leaks do not resolve, the anatomy should be diagnosed by ERCP, CT, and fistulography.

Endoscopic stenting or percutaneous drainage is recommended in the majority of cases [38–40]. However, if all consevative and interventional treatment options fail, persistent fistulas require surgery as an alternative treatment option. Supportive management includes adequate fluid drainage, antibiotic treatment if infectious complications occur, as well as balancing the nutritional and electrolyte state. The first and most important treatment is to ensure adequate drainage of the fistula to avoid enzyme-rich fluid collections and infected cavities [7,41]. Furthermore, a fistula tract should be established to facilitate long-term drainage.

Pancreatic fluid should be sent for microbiological examination to rule out an infection or allow a specific anti-infectious treatment when indicated. Prophylactic antibiotics should not be given to patients with noninfected external pancreatic fistula when there is complete remission of the pancreatitis and especially if the fistula

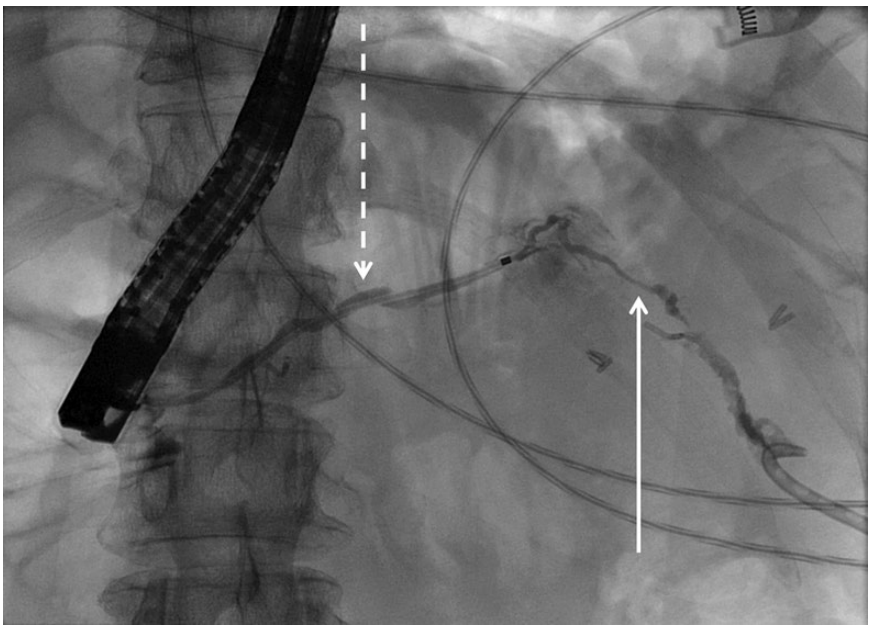

**Figure 37.1** Internal pancreatic fistula to the retroperitoneal space after severe necrotizing pancreatitis. Endoscopic retrograde cholangiopancreatography (ERCP) showing the pancreatic duct (broken white arrow) and the leakage with contrast medium extravasation (white arrow).

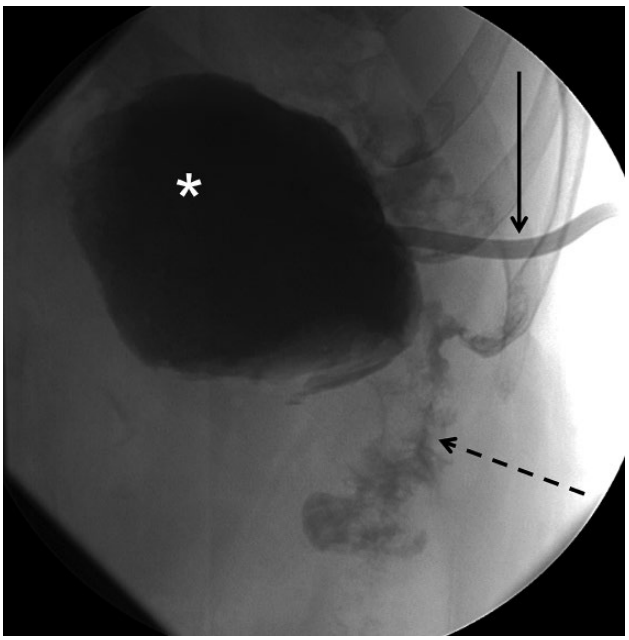

**Figure 37.2** Internal pancreatic fistula during severe necrotizing pancreatitis. X-ray after percutaneous catheter drainage (black arrow) of a large fluid collection (white star). Transition of contrast medium to the descending colon (broken black arrow).

is stabilized and well drained. However, in most cases, the focus of infection is still present by the time of fistula diagnosis and consequently antibiotic treatment is needed.

Supportive early enteral feeding and electrolyte balancing should follow the standards of acute pancreatitis care [42]. However, parenteral nutrition should be considered if enteral feeding is not sufficient to counteract the loss of electrolytes, proteins, and calories associated with acute pancreatitis itself.

In conjunction with parenteral and enteral nutrition, several drugs have been used to inhibit the secretory function of the pancreas. The use of somatostatin and its analogs has been studied extensively. Somatostatin preparations may be effective in the reduction of fistula output but do not affect the likelihood of fistula closure or the time to fistula closure [43]. Based on these results, the use of somatostatin should be limited to patients with high-output fistulas [44]. Endoscopic sphincterotomy with or without stenting facilitates drainage of pancreatic juice into the duodenum and can consequently release pressure from the disruption site. This accelerates healing and may even allow closure of partially disrupted pancreatic ducts within a median interval of 10 days [45–47]. This therapy is highly effective, especially if a bridging of the leakage site can be achieved.

In the case of complete disruption, such as a disconnected duct, pancreatic duct stenting may be technically difficult and even impossible as the distal part of the duct may not be reached after insertion of the guidewire [44,48]. After successful interventional and endoscopic management, gradual withdrawal and downsizing of drainage catheters allows the closure of persistent fistulas as long as they are low-flow fistulas [7].

Surgery is reserved for patients in whom the fistula persists for a prolonged period despite all nonsurgical interventions, which especially occurs in the case of

larger defects of the main pancreatic duct with anatomic discontinuity, persistence of the fistula due to an endoscopically untreatable obstruction of the pancreatic duct, and pancreatic infection. The aim of surgical therapy of external pancreatic fistulas is to redirect the drainage into the intestinal tract [37]. Surgical options available include fistulojejunostomy, distal pancreatectomy, or lateral pancreaticojejunostomy [40]. The surgical procedure chosen is based on the site of the fistula (proximal or distal), the thickness and nature of the fistula tract as well as the texture of the pancreatic tissue. If the fistula tract is located on the right side of the body of the pancreas or even in the head, resection should be avoided and internal drainage into a Roux-en-Y jejunal loop is preferred [7,49]. For persisting fistulas located in the tail of the pancreas distal pancreatetomies are suitable procedures to remove the fistula-bearing part of the pancreas [24]. If communication with the ductal system is present, internal drainage is more effective; if communication is not present, percutaneous drainage is indicated [49–52].

Crucial for surgical treatment of pancreatic fistula is the timing of the procedure as formal pancreatic resections are not possible in the early phase of fistula occurrence. The risk of developing complications during the further course of the disease and the chance of spontaneous closure need to be estimated. Fistulas in severe necrotizing pancreatitis may close even 6 months after the initial episode, since the underlying disease and especially the infection need to heal first. In addition to the patient's condition, it is important to consider the type of fistula before surgery is considered. Simple fistulas do not lead to complications and thus conservative management can be performed for much longer than is recommended for complex fistulas, which tend to develop potentially dangerous complications. These are due to the activated and contaminated intestinal secretions, which can further digest the surrounding tissue and thus induce penetration, hemorrhage, and sepsis.

## Management of Internal Fistulas

Internal fistulas are usually managed by conservative treatment in the beginning using supportive treatment regimens. With supportive care, case series have reported spontanous fistula closure in approximately 50–65% of internal fistulas over 4–6 weeks [53]. Internal pancreatic fistulas, either with pancreatic ascites or with pleural or mediastinal collections, respond well to interventional and endoscopic therapy. The pleural space or peritoneal cavity can be drained, although there is no secure way to place the drain close to the fistula itself in order to produce a controlled tract. The fistula tract will close spontaneously as soon as the sphincter pressure and the obstruction are relieved by papillotomy and/or stenting [54]. However, if all conservative and interventional therapies fail, complex internal fistulas require surgical treatment. This is required not only because of the existence of the fistula itself, but also because of the concomitant presence of complications of necrotizing pancreatitis, especially infected necrosis and abscesses. Thus, the surgical approach to internal fistulas focuses mainly on treatment of the underlying disease. Once infected necrosis is treated adequately, internal fistulas will close rapidly [55,56]. Bowel resections may be necessary in the case of ischemia-associated bowel necrosis and if fistula-associated perforations lead to septic complications, which are mainly observed in colonic involvement. In these situations, colon resections may require a diverting colostomy as there is a high risk of anastomotic leakage due to the intraperitoneal environment of activated pancreatic enzymes and infected fluid.

## Conclusions

External pancreatic fistulas are common sequelae of infected necrosis and interventions required to manage infected severe necrotizing pancreatitis. The majority of fistulas are low output and close spontaneously, which justifies an initial conservative management approach. If this is not successful, there are a wide range of therapeutic options available, including additional percutaneous drainage, endoscopic management, and surgical procedures. Endoscopic or surgical interventions should be considered if a fistula persists beyond 12 weeks or if local complications develop. Endoscopic treatment can aim at an improvement of pancreatic duct drainage via the sphincter of Oddi or a direct closure of the fistula if a bridging stent placement is possible. Surgery usually requires a resection of the fistula-bearing pancreatic region (i.e., distal pancreatectomy) and should be postponed as long as possible. Internal fistulas, which are rarely diagnosed, are usually managed by conservative treatment in the beginning.

If all conservative and interventional therapies fail, surgical treatment of the underlying disease is required. Once the underlying disease, such as infected pancreatic necrosis, is treated adequately, internal fistulas will generally close rapidly. Gastrointestinal fistulas often develop after surgical necrosectomy and can be managed conservatively in most cases. Bowel resection is needed in cases of ischemia-induced bowel necrosis or septic complications and often implies diverting procedures if colonic fistulas are present.

# Long-Term Outcome After Treatment of Acute Pancreatitis

## 38

## Long-Term Outcome After Acute Pancreatitis

*Christin Tjaden and Thilo Hackert*

*Department of General, Visceral and Transplantation Surgery, University of Heidelberg, Heidelberg, Germany*

### Introduction

Most patients with acute pancreatitis recover completely without any further symptoms or morphological alterations within days or weeks after discharge. This observation was described in the original definition of acute pancreatitis by the Consensus Symposium 1963 in Marseille [1]. However, recent reports on long-term outcome after acute pancreatitis show growing evidence that there is a certain risk for late pancreatitis-associated complications even after mild clinical courses [2–5].

Functional impairments can occur immediately or even years after sustaining acute pancreatitis [2,4–6], specifically loss of endocrine function resulting in diabetes mellitus type 3 or exocrine insufficiency with the need for pancreatic enzymes substitution, have been described in numerous studies [2,7–9]. Etiology or severity of the index episode are not clearly associated with the overall risk for an impairment of pancreatic function. In addition, episodes of pain with a considerable impact on quality of life can occur at any point of time after the initial event of acute pancreatitis. These possibly recurrent pain sensations bear a high risk for chronification and may be associated with recurrent pancreatitis; there is also a certain overlap with clinical courses of chronic pancreatitis [2,4,10,11]. This latter correlation has been examined in several recent publications [2–4,12–17]. It is sometimes difficult to distinguish between the primary episode of acute pancreatitis as a symptom of a chronic disease and chronic pancreatitis developing as a long-term consequence of pancreatitis. Morphological characteristics (i.e., those found in cross-sectional imaging at the initial episode of pancreatitis) can be useful for this differentiation as preexisting signs of subclinical chronic pancreatitis may be found in terms of fibrosis or calcifications and can be clearly distinguished from typical signs of new-onset acute pancreatitis.

In contrast to chronic pancreatitis, little is known about histomorphologic pathways and alterations of recurrent acute pancreatitis. One hypothesis is the so-called necrosis–fibrosis sequence [18], which suggests that acute inflammatory changes after an initial and acute damage of the pancreas result in mesenchymal cell activation with various patterns of subsequent fibrosis development and obstruction of pancreatic ducts. Another model is based on a "sentinel acute pancreatitis event (SAPE)," postulating a long-lasting intrapancreatic activation of immunomodulatory and stellate cells during the index episode. These alterations lead to hypersensitivity of the pancreas when responding to potential stimuli, resulting in recurrent attacks of acute and eventually chronic pancreatitis [19]. Despite these hypotheses, the possible pathophysiologic link between acute and chronic pancreatitis remains controversial and is not well understood [20].

Because there are no follow-up guidelines for clinical examinations and imaging after acute pancreatitis and histopathologic findings for such patients are rare due to the infrequent need for operations with respective tissue harvesting, the frequency of such alterations is unknown. In available cross-sectional imaging, alterations of the pancreatic duct, parenchyma, or surrounding areas (i.e., formation of pseudocysts or fluid collections) can be observed during both short- and long-term courses. These morphological findings may be correlated with the severity of the first attack and the type of treatment, in particular interventional or surgical necrosectomy. Their extent and the underlying initial etiology of the primary acute pancreatitis

episode determine clinical outcome patterns. In alcohol-related acute pancreatitis a recurrent and eventually chronic course is observed more often than it is in a biliary genesis of the disease [11,13,16,17]. This fact underlines the importance of avoiding further exposure to risk factors such as alcohol and nicotine as a basic precaution following a first pancreatitis episode [12,21]. Furthermore, patient education can be regarded as a simple method to reduce the lifelong risk of recurrence and associated healthcare costs [17,21]. Follow-up examinations should therefore address the above-mentioned topics and should include clinical and laboratory as well as imaging examinations, when necessary. This chapter gives an overview of the long-term sequelae of acute pancreatitis with regard to risk factors, diagnosis, and management.

## Risk Factors

Risk factors for long-term complications of acute pancreatitis have been examined in several cohort studies in recent years [3,4,6,12]. With regard to recurrent episodes of acute pancreatitis, a recent meta-analysis including nearly 8500 patients showed an overall risk of 22% with a nearly twofold increase in alcoholic etiology (38%) and a lower risk for biliary etiology (17%) [3]. With regard to biliary etiology, early removal of the gallbladder after the index episode of pancreatitis reduces the risk of recurrence [4,12]. In nonbiliary etiology, persistence of smoking and alcohol consumption are well-documented risk factors for both recurrent acute episodes as well as progression of primary acute to chronic pancreatitis in the long term [4,6,12]. Nevertheless, some authors report experience with patients who show a progression to chronic pancreatitis despite stopping consumption of alcohol and nicotine [12,13]. In addition, male patients seem to have a higher risk of progression to chronic pancreatitis, even when lifestyle-associated risk factors are excluded [3]. Risk factors for functional failure after acute pancreatitis include preceding necrosectomy, which leads to both exocrine and endocrine insufficiency due to the procedure-associated loss of tissue itself and the disease-specific damage to the remaining tissue [4,22]. Again, the risk for developing progressive pancreatic dysfunction and diabetes mellitus or exocrine dysfunction is increased in men [3,5]. Moreover, a subset of patients may also have unrecognized genetic risk alterations leading to increased risk of progressive pancreatic failure and chronic pancreatitis through an effect on trypsinogen activation [23]. Tables 38.1 and 38.2 summarize studies on patterns and risk factors for long-term sequelae after acute pancreatitis.

## Endocrine Pancreatic Dysfunction

Hyperglycemia, impaired glucose tolerance, and diabetes mellitus occur frequently as a consequence of acute pancreatitis and have therefore been investigated as primary or secondary endpoints of several large studies on the loss of pancreatic function on long-term follow-up. A recent meta-analysis of 24 prospective studies published between 1968 and 2009 revealed that nearly 40% of patients showed a prediabetic metabolic situation or a full clinical manifestation of diabetes mellitus [2]. Within 12 months after the index episode of acute pancreatitis the prevalences of hyperglycemia and diabetes mellitus were 19% and 15%, respectively. After a 5-year observation period, the risk for diabetes mellitus showed a twofold increase compared with the prevalence after 12 months. A Dutch cohort study on 669 patients described a new onset of diabetes mellitus in 20% of the patients during a median follow-up time of 57 months [6]. These data are consistent with findings of a Taiwanese study, which showed a comparable twofold increase of diabetes risk after 10 years in nearly 3000 acute pancreatitis patients, regardless of the severity of the initial course of the disease [5].

In severe courses characterized by extensive parenchyma necrosis and the need for necrosectomy, the correlation between loss of tissue and function seems to provide an explanation for these observations, especially when the body and tail of the pancreas are affected. Decay of a considerable amount of islets predisposes for functional deterioration and 15–30% of patients undergoing extensive necrosectomy show insulin-dependency soon after recovery [4]. This is comparable to outcomes following distal pancreatectomy for other indications, with a rate of postoperative diabetes mellitus of approximately 10% [25–27], and underlines the relevance of the pancreatic body and tail for the endocrine function of the gland due to the pronounced location of islet cells in these segments of the pancreas. In contrast, the pathophysiologic explanation for mild episodes of acute pancreatitis resulting in endocrine insufficiency and an increased risk of diabetes mellitus remains unclear.

## Exocrine Dysfunction

In the early phase after acute pancreatitis, exocrine function is often compromised and is easily diagnosed by clinical symptoms of diarrhea, steatorrhea, and maldigestion. In the long term, the reported prevalence rates of exocrine dysfunction differ considerably in the available studies [4,6,22,28]. A study by Sand and Nordback

**Table 38.1** Patterns of long-term sequelae after acute pancreatitis.

| Author, year, country, observation period | Patients (*n*) etiology | Diabetes mellitus *n* (%) | Exocrine dysfunction *n* (%) | Recurrent pancreatitis *n* (%) | Chronic pancreatitis *n* (%) | Median follow-up |
|---|---|---|---|---|---|---|
| Pelli [13], 2000, Finland, 1972–1991 | 562 alcoholic | nm | nm | 260 (46%) | nm | 38 months |
| Lund [16], 2006, Sweden, 1995–1998 | 138 alcoholic: 61 biliary: 48 | nm | nm | 41% nonbiliary vs. 10% biliary | nm | 6 years |

nm, not mentioned.

reports 25% of patients having exocrine failure after necrosectomy in a follow-up period of 2–5 years [4], whereas other studies with comparable observation times reported much higher rates of 55% after mild and up to 83% after severe courses, independent of the etiology of acute pancreatitis [28–30].

Symptoms of exocrine failure can be controlled very well in most patients by oral enzyme replacement to prevent maldigestion, malabsorption, and consecutive malnutrition. Supplementation of the diet with fat-soluble vitamins in the follow-up period should also be considered [31]. A discontinuation of enzyme supplementation may be possible as several studies have reported a potential for long-term recovery of exocrine function within 12–24 months after acute pancreatitis [4,29], which is comparable to the functional recovery often observed after pancreatic resections for other indications.

## Recurrent Pancreatitis and Chronic Pancreatitis

Regarding the frequency and timeline of progressive pancreatic disease after acute pancreatitis, about 20% of all patients and 50% of patients with an alcoholic etiology show recurrent episodes within 10–20 years, but most recurrences occur during the first years after the initial attack [3,4,6]. Overall, one out of ten patients will suffer from a progression to chronic pancreatitis [3], which may be associated with few symptoms for a long period but may finally result in end-stage findings of chronic pancreatitis despite a subclinical course (Fig. 38.1). In the case of recurrent acute episodes, the risk of progression to chronic pancreatitis shows a 3- to 4-fold increase which is, again, pronounced in patients with an underlying alcoholic etiology [6].

**Table 38.2** Risk factors for long-term complications of acute pancreatitis.

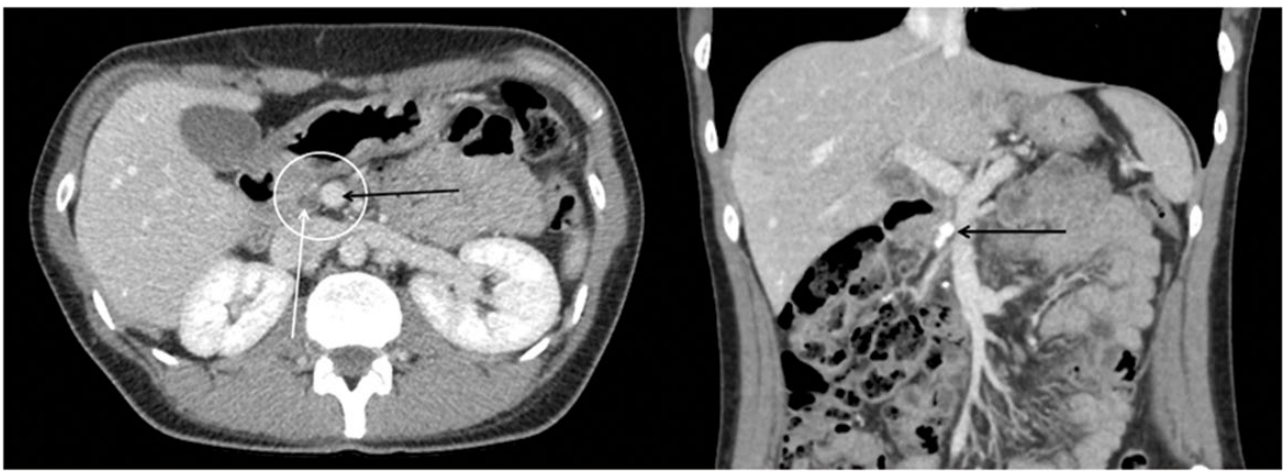

**Figure 38.1** A 39-year-old female patient 9 years after a solitary episode of severe acute pancreatitis following hemorrhagic shock and acute respiratory distress syndrome (ARDS) due to atonic bleeding after cesarean section. This was followed by complete recovery and primary discharge from hospital after 5 weeks and complete remission of residual pseudocysts over a 6-month period. Afterwards, the patient had no clinical symptoms for 8 years before recurrent abdominal pain attacks irradiating to the back occurred. CT scan revealed nearly complete atrophy of the pancreatic parenchyma (left side, white circle; black arrow: portal vein, white arrow: bile duct) and a calcification in the pancreatic head (right side, black arrow). As no signs of inflammation, tumor suspicion, or endocrine insufficiency were present, symptomatic treatment was successful (oral enzyme replacement and analgesia).

## Quality of Life and Pain

Several outcome studies report on the occurrence of pain and the quality of life after acute pancreatitis [4,6,10,11]. An observational study on 145 patients from Finland showed no impairment of quality of life, regardless of pancreatitis etiology, compared to the general population [10]. Similar results are shown in several smaller observational studies, even after necrosectomy [4]. In contrast, in a Polish study patients suffering from severe alcohol-induced acute pancreatitis showed a reduced quality of life in comparison to those with

a biliary origin of the disease with regard to social and family life as well as emotional well-being [11]. How far persisting alcohol consumption after the index episode of pancreatitis contributes to these findings, however, remains unclear from the study data. With regard to chronic pain, a large Dutch cohort study including 669 patients found that 13% had recurrent episodes of pain related to acute pancreatitis [6].

## Incisional Hernia

With the implementation of minimally invasive management of infected pancreatic necrosis during the initial episode of acute pancreatitis, open surgical interventions have considerably decreased and are regarded as the last resort in modern treatment concepts [32,33]. Less than 5% of patients with acute pancreatitis need to be treated by open surgery (e.g., in case of unsuccessful minimally invasive necrosectomy, for bleeding control, or due to organ perforation). These patients show a high rate of surgical site infections (80%) [34] and a correlating high risk of developing an incisional hernia (40%) [35]; surgical re-intervention is often required for symptomatic, functional, and cosmetic aspects of these, often large, hernias.

## Pancreatic Cancer and Pancreas-Related Death

In general, death related to acute pancreatitis, besides short-term mortality during a severe necrotizing course, seems to be rare and not related to progression to chronic pancreatitis and finally pancreatic cancer. A German study reported on four deaths of pancreatic cancer in 532 patients (0.8%) observed after acute pancreatitis during an average follow-up of 7.8 years, which occurred 9–56 months after acute pancreatitis, none of them with a diagnosis of chronic pancreatitis [12]. In an Italian study, three of 631 patients (0.5%) died of pancreatic cancer 5, 6, and 19.9 months after acute pancreatitis with unknown etiology in the first case and biliary etiology in the others [14]. These data support the conclusion that the initial pancreatitis event may be a symptom of an already existing tumor rather than pancreatic cancer and the related mortality is a long-term consequence of acute pancreatitis.

## Imaging Findings

Most episodes of mild acute pancreatitis do not result in any morphologic changes and, after restitution, ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI) scans show a normal pancreas without any damage to the gland or the duct system. Even when functional impairment occurs, this is not necessarily associated with any pathological imaging findings. This is also observed in most cases of diabetes mellitus of other genesis and in many patients with endocrine dysfunction without underlying chronic pancreatitis. In contrast, severe episodes of acute pancreatitis with or without the need for interventional or surgical treatment often result in morphologic pancreatic alterations of varying extent.

Common reversible or irreversible findings on CT or MRI imaging include:

- inhomogeneity of the parenchyma;
- atrophy of the parenchyma;
- duct alteration (strictures/dilation);
- residual peripancreatic fluid collections;
- pseudocysts.

Diagnosis of the above-mentioned alterations alone does not require any measures, unless accompanying symptoms are present. Further follow-up examinations should be performed to evaluate a potential dynamic of these changes and recognize potential need for any interventional or surgical therapy early to prevent ongoing destruction of the pancreatic parenchyma in the case of recurrent pancreatitis episodes or development of chronic pancreatitis or chronic pain. The management of pseudocysts and persisting postpancreatitis fistulas is described in Chapters 34 and 35.

Another important aspect is the recognition of cystic lesions as the cause of acute pancreatitis and their differentiation from residual pseudocysts. It has been reported that 13–67% of all patients with intraductal papillary mucinous neoplasia (IPMN) show an episode of acute pancreatitis as their initial symptom [36–38]. However, this is frequently misdiagnosed and studies in the past report on a delay in diagnosis of a cystic neoplasm as the trigger of acute pancreatitis of several years or even more than two decades [36–38]. With growing awareness of cystic neoplasms in recent years this may be avoided in the future as distinguishing postinflammatory duct dilatation and pseudocysts from IPMN is of high importance because of the malignant potential of IPMN.

## Postpancreatitis Care and Follow-Up Visits

Six to eight weeks after hospital discharge due to an episode of acute pancreatitis, a clinical control examination can be recommended to document the status, including symptoms and nutritional status with regard to pancreatic function, blood tests, and imaging in cases of severe acute pancreatitis. In case of biliary

acute pancreatitis, cholecystectomy (preferably by a laparoscopic approach) must be scheduled if it has not been performed during the initial hospital stay. There is good evidence concerning the indication and timing of cholecystectomy which shows that a delay of this operation results in an increased risk of recurrent biliary pancreatitis [3,4,39]. For mild biliary pancreatitis cholecystectomy should be performed during index admission. In contrast, in patients with severe pancreatitis, cholecystectomy can safely be performed after resolution of symptoms (4–6 weeks). A similar timeframe should be chosen for patients who undergo sphincterotomy during biliary pancreatitis [39]. Besides biliary pancreatitis, a Finnish study suggested that recurrence of idiopathic acute pancreatitis can also be prevented effectively by laparoscopic cholecystectomy, which should be evaluated for the respective patients [40].

No general guideline or consensus recommendations for long-term follow-up visits after acute pancreatitis exist to date. From the clinical point of view, follow-up at 6-monthly intervals during the first 2 years seems to be reasonable, followed by yearly examinations thereafter [41]. A possible scheme for follow-up could include:

- documentation of abdominal and unspecific symptoms;
- clinical examination;
- blood samples for the determination of routine parameters (including $HbA_{1c}$, electrolytes, creatinine, urea, liver enzymes, amylase, lipase, white and red blood cell counts, and C-reactive protein) as well as the serum tumor markers CEA and CA19–9;
- analyses of genetic factors (*PRSS1*, *SPINK1*, *CFTR*) in the case of unclear etiology of the underlying acute pancreatitis [3,23];
- cross-sectional imaging with abdominal CT or MRI scan.

## Conclusions

Overall, the majority of patients show a good long-term outcome after acute pancreatitis. However, one out of four patients will develop some kind of problem in the long run, including endocrine or exocrine dysfunction, recurrent acute pancreatitis, or transition to chronic pancreatitis even many years after the initial event. Risk factors for clinical deterioration are incompletely examined and understood at present. Lifestyle habits, such as ongoing consumption of alcohol and nicotine, have been shown to increase this risk, especially for patients with alcohol-induced first attack of acute pancreatitis. Following biliary pancreatitis, removal of the gallbladder is an essential measure for prevention of future relapses and should preferably be performed during the initial hospital stay in mild pancreatitis and 6–8 weeks after recovery from a severe episode. To detect long-term loss of function before progression to an irreversible stage, regular follow-up is recommended, including clinical examination and blood tests at 6- to 12-month intervals to check for new onset of diabetes mellitus as well as maldigestion due to pancreatic exocrine dysfunction even when patients are asymptomatic. In the case of abdominal complaints, cross-sectional imaging should be considered. Pathologic findings alone (i.e., atrophy of the pancreatic parenchyma) do not require immediate intervention but should be further monitored during regular follow-up. In the case of transition to chronic pancreatitis with fibrosis and calcifications of the pancreas or dilatation of the pancreatic duct in combination with episodes of pain, a tailored approach including timely surgery should be considered to prevent ongoing deterioration of function and symptoms.

Recommendations for follow-up schemes after acute pancreatitis have not yet been standardized by international guidelines. The number of recent studies shows that heterogeneous protocols are being used in clinical practice and underlines the need for better and evidence-based recommendations to examine the long-term outcome of patients after acute pancreatitis as it is one of the most frequent gastrointestinal indications for inpatient treatment. The rising interest in this area and the results themselves underline the need for implementation of regular follow-up. This would allow a systematic evaluation of the risk of diabetes mellitus, pancreatitis relapse, and development of chronic pancreatitis, all of which exert an immense impact on healthcare costs. The possibility of earlier recognition and prevention of these complications on a risk-stratified basis could offer significant benefits.

## Introduction

Chronic pancreatitis is a pathologic pancreatic process containing both fibrotic and immunologic responses to injury that result in destruction and replacement of the exocrine and endocrine features of glandular function. It is primarily a clinically described syndrome characterized by consistent cellular stress or repeated bouts of pancreatic injury, resulting in pancreatic atrophy, fibrosis, and duct distortion, a chronic pain syndrome (suggesting neural injury and responses), and, eventually, loss of both exocrine and endocrine function. Depending on the proposed etiology of the disease, there can be other secondary characteristics, including calcifications, duct centric inflammation with either lymphocytes or neutrophils, or primarily an obstructive phenotype. Focusing on the etiology of the injury and the subsequent pathologic response is important to direct our understanding of the molecular mechanisms of chronic pancreatitis. Importantly, chronic pancreatitis is currently described by specific features seen at the end stage of the disease; however, the molecular path taken to achieve these features can be drastically different. Therefore, although there are likely multiple distinct molecular mechanisms that initiate the pathologic process, the responses of the organ to recovery converge on overlapping immunologic and fibrogenic responses, resulting in a histologically similar result. This convergence of responses by the pancreas suggests that understanding both recovery and regenerative mechanisms resident within the pancreas are of equal importance.

## Risk Factors in Chronic Pancreatitis

The challenge to understanding the molecular mechanisms of chronic pancreatitis is determining the etiologic risk factors. There are several recognized etiologic factors thought to confer risk and allow progression to chronic pancreatitis (Fig. 39.1). These risk factors have been described by the TIGAR-O (toxic–metabolic inflammatory genetic autoimmune recurrent and severe replace with: obstructive pancreatitis) classification [1], which include genetic and environmental factors, obstructive etiologies such as anatomical or traumatic features, and immune-mediated etiologies. The typical organ response to injury and cellular stress promotes recovery and regeneration of the pancreas following injury. However, with repeated injury or prolonged cellular stress, the organ response may become pathologic and drive cellular loss and fibrotic replacement of exocrine and endocrine cells. A proper understanding of the molecular mechanisms leading to chronic pancreatitis requires that we address both the specific etiology, with its associated genetic and epigenetic modifiers, as well as the organ's pathologic response mediated through immune and stellate cells. Therefore, chronic pancreatitis describes a complex disorder. Each patient has a different panel of risk factors, a distinct progression of their clinical course, and will endure different complications, even though the final pathologic appearance of the gland may be indistinct [2].

The current attempts to define chronic pancreatitis focus on a clinical description of the end histologic appearance of the pancreas, which is a result of an immune-mediated response to stress or injury coupled

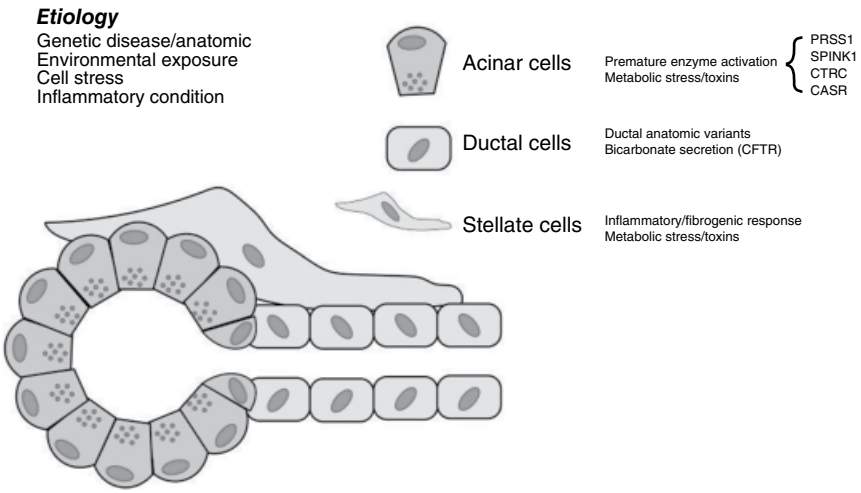

**Figure 39.1** Several etiologies exist for chronic pancreatitis. Specific etiologies affect unique cell types within the pancreatic parenchyma, leading to repetitive injury.

to a fibrogenic wound response. There are inherent challenges to the attempt to define this process. The definition of chronic pancreatitis starts by describing a syndrome that has already progressed to the end stages of the pathologic response. Syndromes describe characteristics rather than defining molecular mechanisms driven by etiologic factors. This attempt to define chronic pancreatitis is not without merit, as it has allowed the identification of the two main pathologic responses that drive the end stage of the disease, namely the immune and fibrotic responses.

Pancreatitis is an inflammatory disorder involving a complex immunologic cascade of events that drives the pathologic result. Environmental cues shape the initiation and progression of the immune system to accelerate or limit the immune response. This immunologic response can be modulated by epigenetic and genetic factors that alter the progression of the disease. The inflammatory response is modulated by the cytokines and chemokines produced by injured acinar cells that act as recruiting and signaling molecules. The etiology of initial and subsequent pancreatic injury or stress will drive or alter the immune response based on the molecular drivers associated with a particular etiology. There are likely multiple modifying factors and intervening steps that impact an individual patient's clinical course but at some point progression becomes similar because the end result of this process is a similar histological pattern.

In this chapter, we will focus on the current understanding of these two distinct stages of disease development, specific etiologies, and the immune-activated fibrogenic response. The first stage relates to specific etiologies and is especially challenging because the risk factor may only be realized after permanent damage has occurred. The second stage of chronic pancreatitis development—the fibrogenic response—is the organ response to injury, and it appears to be similar whatever the specific etiology of the repeated injury.

## Sentinel Acute Pancreatic Event Model

Recently, a disease model hypothesis was promoted to help provide a framework for understanding how different risk factors, including environmental, genetic, and toxin-mediated injury, could impact and allow progression towards chronic pancreatitis. The model, the sentinel acute pancreatitis event hypothesis (SAPE hypothesis) uses the TIGAR-O risk classification system to allow the organization of multiple possible risk factors in promoting the progression of chronic pancreatitis. In this model, a stressor (environmental exposure or toxin) or risk factor (genetic susceptibility factor) is present and impacts the pancreas through alterations in stress responses by parenchymal cells (acinar and duct cells). Once the stress reaches a particular threshold and overcomes the adaptive mechanisms within the pancreas, injury overwhelms the protective regenerative mechanisms, and clinical pancreatitis ensues. This leads to wound-healing responses within the pancreas, including the activation of the inflammatory (neutrophils and lymphocytes) and matrix remodeling systems (macrophages and stellate cells) to stop the injury and allow regeneration to occur. If the inciting factor is removed, healing can occur. However, if the inciting factor is only reduced or removed but then recurs, repeated injury can occur, leading to an injury–wound response cycle that over time leads to parenchymal loss and fibrotic matrix replacement of acinar cells.

Following an isolated episode of pancreatitis, the organ can appear normal histologically. If no other exposures occur then chronic pancreatitis does not develop. However, if the injury–wound cycle continues, the organ suffers loss of normal pancreatic cells and replacement of these cells with fibrosis promoted by macrophages and stellate cells, indicative of the progression towards chronic pancreatitis (Fig. 39.2). In addition to the ideas

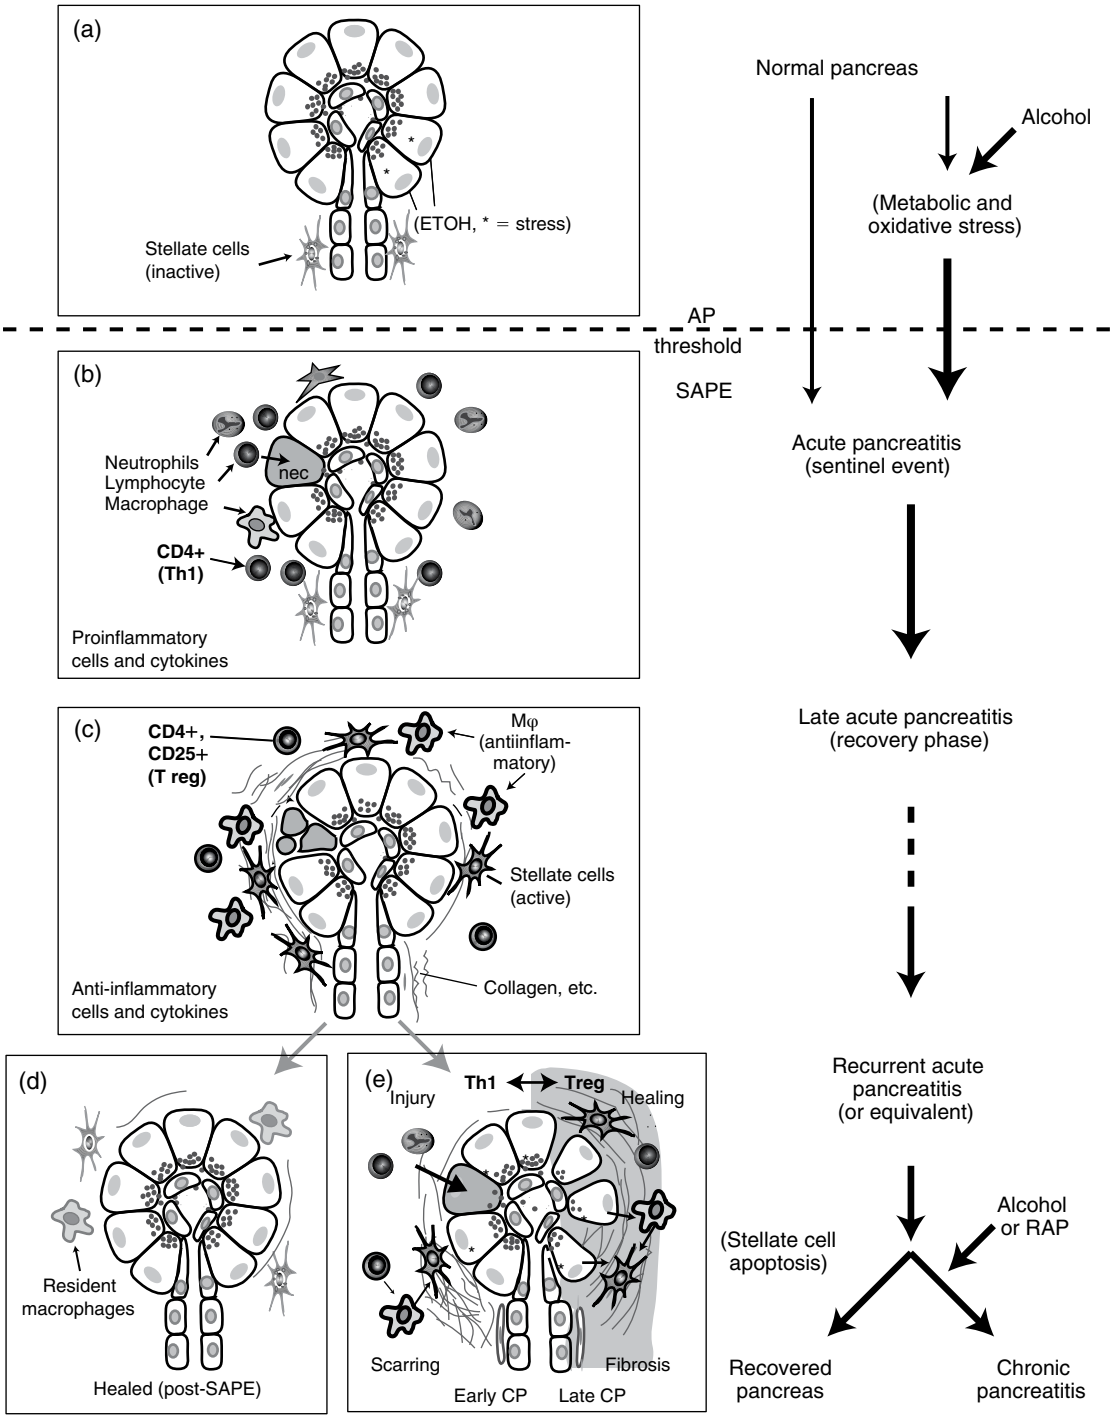

**Figure 39.2** Sentinel acute pancreatitis event (SAPE) hypothesis model. (a) Normal pancreas. If the subject is a heavy alcohol user, the acinar cells are under metabolic and oxidative stress (indicated by asterisks) but histology remains relatively normal. Alcohol increases the risk of crossing the acute pancreatitis (AP) threshold (bold line crossing the dashed line). (b) Acute pancreatitis with pancreatic injury and infiltration of proinflammatory cells. (c) Late acute pancreatitis is dominated by anti-inflammatory cells that limit further injury by proinflammatory cells and products, and promote healing. This includes activation of stellate cells, which produce collagen etc. (d) Recurrent acute pancreatitis (RAP): acinar cell injury or other factors that activate an acute inflammatory response (Th1) are immediately countered by an anti-inflammatory counterresponse (Treg) which, among other things, drives fibrosis. This vicious cycle results in both continued injury (top) and further fibrosis (bottom) leading to (e) extensive acinar cell loss and sclerosis (right) characteristic of chronic pancreatitis (CP). Both genetic factors and environmental factors play a role in this process by increasing susceptibility to acute pancreatitis, altering the severity and duration of acute pancreatitis and altering the healing processes that drive fibrosis. *Source:* Adapted from Whitcomb 2004 [3].

presented within this SAPE model, epigenetic mechanisms also likely occur following an environmental exposure or injury event that changes the organ response to subsequent stimuli.

## Epigenetics as a Modifying Factor in Chronic Pancreatitis

Epigenetics is the control of gene expression that does not involve a change in the primary DNA sequence. In other words, epigenetics refers to modifications of DNA by methylation or of chromatin structure through the posttranslational modification of histone proteins. The posttranslational modification of histones can alter chromatin structure or may alter the affinity of transcription factors to promoter regions. The epigenome can have significant effects on human health as well as disease susceptibility, and epigenetic alterations can be induced through environmental and prenatal exposures to toxins or stressors. Epigenetic changes can be stable and allow "memory" of past stresses to impact future exposures. Epigenetic alterations may be the result of "subclinical" stresses on the pancreas that over time allow molecular remodeling of stress responses to other stimuli. These "subclinical" stresses may alter the epigenetic pattern of genes with little or no immediate effect on gene expression; however, the gene may have an altered response in gene expression when exposed to a new specific environmental cues, which may activate the fibrogenic response and lead to chronic pancreatitis.

In experimental models of pancreatitis, chronically stressed animals (e.g., by ethanol exposure [4], fatty diet [5], or genetic mutation [6]) have an altered response to acute injury compared to animals that have no chronic stress. Ethanol has been shown to affect the action of several epigenetic proteins, including the histone acetylases CREB and CBP [7], as well as the histone deacetylases [8,9]. Recently an epigenetic acetylation mechanism was implicated in the control of acute pancreatitis [10]. Delayed recovery was demonstrated in mice treated with the antiepileptic drug and histone deacetylase inhibitor valproic acid (VPA). VPA is thought to be a definite cause of pancreatitis, especially in pediatric patients [11–13], but the mechanism by which VPA induces pancreatitis was unknown. In fact, chronically treating experimental animals with VPA does not induce pancreatitis but will cause pancreatic atrophy over time [14]. However, animals treated with VPA that are then subjected to a new injury-provoking stimulus develop pancreatitis that is severe and is delayed in its recovery. VPA does not induce pancreatitis but predisposes individuals to severe pancreatitis by altering the epigenetic landscape and thereby inhibiting the recovery mechanisms that allow regeneration to occur.

## Environmental Exposures as Modifying Factors in Chronic Pancreatitis

Chronic pancreatitis is thought to be initiated by several different but interacting mechanisms. A mechanism thought to initiate pancreatic injury is environmental exposure to substances that either sensitize or stress the parenchymal cells of the pancreas. These substances can include alcohol, byproducts of smoking, and other drugs or toxins [15]. They do not by themselves induce pancreatitis but alter the acinar cell's response to other stressors, leading to adaptations that compensate for the exposure. This adaptation by parenchymal cells allows homeostasis to be maintained; however if a second insult or exposure is presented, the cells are more susceptible to injury and have a clinically pathologic response. The response may be actualized by increased injury or conversely may be realized as a delay in regeneration by the pancreas.

Alcohol as disease modifier is a good example of this concept. Ethanol has long been accepted as a major contributor to disease progression in chronic pancreatitis [16,17]. However the number of heavy alcohol drinkers that develop acute or chronic pancreatitis are a minority. This has led many to suggest that there are usually concomitant risk factors necessary to tip the balance towards the development of pancreatitis. Ethanol has been shown to directly affect pancreatic cell types either through direct effects on specific cells or through the metabolism of the drug to toxic metabolites. Ethanol has many effects on the pancreatic acinar cell. These include the emergence of aberrant acinar cell calcium signaling [18], mitochondrial dysfunction [19,20], impairment of autophagic or lysosomal responses [21], and the induction of the unfolded protein response (UPR) with increased expression of x-box binding protein 1 (XBP1), a key regulator of endoplasmic reticulum (ER) function [22,23]. Ethanol appears to increase ER stress, as visualized by ER swelling and UPR induction, but also impacts protein trafficking and alters structural components of zymogen granules [24]. It has also been shown to alter the pathologic intra-acinar activation of digestive enzymes [25,26]. This effect may be due to increased expression of digestive enzymes such as trypsinogen, chymotrypsinogen, or lysosomal cathepsin B [27]. It is postulated that increased protein expression may allow early activation of these digestive enzymes or may cause organelle fragility, allowing early activation of digestive enzymes through inappropriate interaction between lysosomal and digestive enzymes.

## Genetic Influences in Chronic Pancreatitis

A second mechanism shown to mediate the pathologic response in the pancreas occurs through repeated injury by specific insults in a person who is susceptible due to genetic risk factors. Genetic or epigenetic alterations may allow subclinical or clinical repeated injury to occur, which over time results in the destruction of the pancreatic parenchyma and replacement by fibrosis through repeated activation of immune and fibrotic responses. This replacement results in loss of exocrine and endocrine pancreatic function. Hereditary pancreatitis is an example of this mechanism. This condition is caused by a mutation within the cationic trypsinogen gene (*PRSS1*), the primary proteolytic enzyme responsible for activating pancreatic digestive enzymes or zymogens. These gain-of-function mutations lead to premature trypsinogen activation. Several mutations have been identified, but the most common are R122H and N29I. Interestingly, although these mutations place an individual at higher risk of developing chronic pancreatitis, the disease course and ultimate outcome is dependent on other factors, including environmental and metabolic stressors. These additional modifiers are thought to mediate the differences among patients with identical mutations.

In the case of hereditary pancreatitis, the penetrance of the disease is only 80%. Environmental exposures or other genetic modifiers are thought to alter the disease course as individuals with the same genetic mutation can have significantly different disease courses despite having similar histopathology [28]. An extreme example of this was a case where identical twins had the same genetic defect but had different disease progressions, including one twin having no pancreatic disease [29]. This suggests that a single mutation or defect does not lead to chronic pancreatitis but rather a set of factors are required to allow progression from an isolated event to a chronic condition.

In addition to *PRSS1* mutations, there are other genetic mutations associated with increased risk for chronic pancreatitis; these include mutations within the *CFTR* (cystic fibrosis transmembrane conductance regulator) and *SPINK1* (serine protease inhibitor Kazal type 1) genes. As with *PRSS1* mutations, identical mutations within these genes do not predict a similar disease course for affected individuals. Overall, these observations suggest a complex disease process that requires careful analysis of multiple factors that impact and allow the disease to progress.

## Inflammatory Response in Chronic Pancreatitis

The secondary phase of progression to chronic pancreatitis involves the inflammatory and fibrotic responses to chronic stress or repeated injury (Fig. 39.3). Recently, progress has been made in

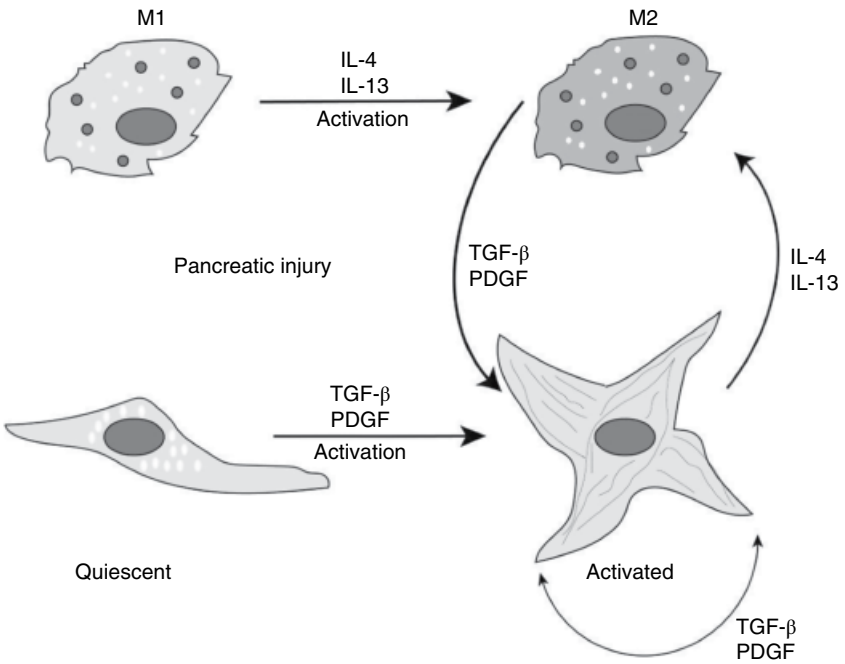

**Figure 39.3** Pancreatic injury activates resident immune cells as well as pancreatic stellate cells to promote pancreatic recovery. However, persistent injury or pathologic signaling between macrophages and stellate cells leads to persistent activation and fibrogenic replacement of the pancreatic parenchyma.

understanding this aspect of chronic pancreatitis. Injury within the pancreas results in damaged acinar cells that will either repair or undergo cell death through necrosis or apoptosis. The damaged cells promote a sterile inflammatory response to mediate the recovery and regeneration process [30]. The inflammatory response is signaled by cytokines released from injured acinar cells and mediated by neutrophils, monocytes, lymphocytes, and macrophages which mediate the resolution of the damaged cells and promote the regeneration of the pancreas [31]. During progression of chronic pancreatitis, inflammation appears to be mediated by different immune cells depending on the experimental model used [32–34]. These cells produce additional inflammatory mediators such as tumor necrosis factor α (TNF-α), interleukin 1β (IL-1β), IL-6, IL-10, and monocyte chemoattractant protein-1 (MCP-1). Initially, these signals are produced by damaged acinar cells but with repeated injury and activation of other resident pancreatic cells, such as macrophages and stellate cells, there appears to be a shift towards cytokine production from activated immune and stellate cells that promotes and allows progression towards chronic pancreatitis. Neutrophils are thought to activate trypsinogen and allow progression towards severe injury in acute pancreatitis, but in chronic pancreatitis T cells and macrophages are the predominant immune cell infiltrates [35–37].

Neutrophils and macrophages can play a dual role during inflammation, either releasing cytokines such as interferon γ (IFN-γ), leading to a proinflammatory phenotype repressing regeneration, or repairing signals necessary for regeneration to occur [38]. T cells are thought to help control the immune-mediated destruction initiated in chronic pancreatitis by secreting IL-10 [34]. Macrophages can promote healing and regeneration, depending upon macrophage polarity [39]. Activated M2 macrophages have been shown to play a pathogenic role in chronic pancreatitis in both rodents and humans [40]. These studies underscore the importance of the immune response as well as the specific microenvironment that exists in chronic pancreatitis. It is important to understand the course of injury that produces the chronic pathologic response in order to promote healing rather than perpetuating injury.

## Fibrogenesis in Chronic Pancreatitis

The immune system regulates and is regulated by cells within the pancreas, including the mesenchymal cells known as pancreatic stellate cells (PSC). PSC have emerged as critical players in mediating pancreatic recovery after injury [41–43]. They are localized in the periacinar region and are characterized at baseline (i.e., in the quiescent state) by vitamin A droplets [44]. In response to injury, PSC undergo transient activation and take on a fibroblast-like role, secreting extracellular matrix (ECM), particularly collagen [45,46], which is a necessary substrate scaffold for proper regeneration and recovery. The hallmarks of pancreatic injury and recovery are regenerative structures called acinar-to-ductal metaplasia (ADM) [47,48]. The stroma surrounding ADM is composed of activated PSC (aPSC) that function to remodel ECM and are thought to coax ADM to redifferentiate into new acinar cells.

Aberrant regulation of PSC has been implicated in the pathogenesis of chronic pancreatitis and pancreatic cancer [45,49–52]. PSC are not only activated by acinar cell injury but can be activated by cellular stress and ethanol byproducts. Transforming growth factor β (TGF-β) appears to be a major contributor to the fibrotic properties of PSC by increasing collagen and fibronectin expression but also by inhibiting metalloproteinases (MMPs). Once activated, PSC initially help to remodel the parenchyma through the removal of matrix proteins by MMP. Interestingly, PSC not only produce MMP but also the inhibitors of MMP, called tissue inhibitor of metalloproteinases (TIMP). A balance of these two factors likely affects the progression towards fibrosis. The destruction of matrix releases growth factors and cytokines that signal adjacent cells and stimulate parenchymal healing through interactions between the immune and exocrine and endocrine pancreatic cells. PSC not only orchestrate the destruction of matrix but also help orchestrate the regeneration of the framework to allow regenerating acinar and duct cells to proliferate and repopulate the parenchyma. However, if PSC remain activated through repeated injury to the pancreas or aberrant cell signaling from adjacent cells such as macrophages, a pathogenic response can exist that perpetuates the remodeling of the ECM and replaces acinar tissue with fibrosis, leading to the loss of pancreatic exocrine function.

Recently, PSC in chronic pancreatitis models have been shown to respond to adjacent macrophages that produce higher levels of TGF-β and platelet-derived growth factor β, suggesting that the macrophage–PSC interaction may be important in regulating pancreatic regeneration [40] and that when a pathologic state is present, PSC may be a target for therapy.

## Conclusions

Two general mechanisms are thought to result in chronic pancreatitis. These include a sentinel pancreatic event in a susceptible host that perpetuates a progressive

low-grade injury, resulting in fibrosis and loss of physiologic function. Alternatively, several repeated injury events of acute pancreatitis may lead to chronic injury and fibrotic replacement of parenchymal tissue. In light of these two proposed mechanisms for chronic pancreatitis, several animal models have been developed to help target specific aspects of injury and disease progression for the study of chronic pancreatitis. One must be careful when using animal models to mimic disease states in humans. However, with careful attention to the limitations of the experimental model, it is possible to begin to understand aspects of this complex, multifaceted disease. There are likely multiple risk factors and progressive steps that lead to the histopathologic disease known as chronic pancreatitis. The animal model systems used most frequently are rodent models due to cost and the ease of genetic manipulation. However, for certain etiologies, such as CFTR disease, the rodent models do not mimic the human condition, and other models (such as the porcine or ferret model for CFTR) must be used.

Models focused on mechanical injury have been used to study chronic pancreatitis. These models use a partial or complete ligation of the pancreatic duct to induce and allow progression of the disease. This model is species-specific as duct obstruction in rats only induces a mild pancreatitis injury pattern. With the use of a secondary injury stimulus or sensitizing factor, progressive and severe injury can be induced which leads to a histopathologic tissue similar to that seen in the pancreas from humans with chronic pancreatitis. These models have been used to study the fibrogenic response. Chronic inflammation and fibrosis, with increases in collagen and fibronectin, have been observed in rats following chronic duct obstruction [53].

# Epidemiology and Pathophysiology of Alcoholic Chronic Pancreatitis

*Atsushi Masamune and Tooru Shimosegawa*

*Division of Gastroenterology, Tohoku University Graduate School of Medicine, Sendai, Japan*

## Introduction

The association between alcohol misuse and chronic pancreatitis has been recognized for a long time. As early as 1878, Friedrich [1] described "drunkard's pancreas" as chronic interstitial inflammation in the pancreas, which might result from alcohol misuse. In 1946, Comfort et al. [2] described the clinical presentation of chronic relapsing pancreatitis in subjects with alcohol misuse. Many studies thereafter established that alcohol misuse is a risk factor for the development of chronic pancreatitis [3–7]. However, unlike alcohol-induced liver injury, chronic pancreatitis develops in only a small portion of heavy drinkers and ethanol feeding alone does not cause pronounced pancreatic injury in animals [8]. It is therefore clear that additional genetic and/or environmental predisposing factors are required for the development of clinical chronic pancreatitis [9,10]. In this chapter we review the epidemiology and pathophysiology of alcoholic chronic pancreatitis.

## Epidemiology of Alcoholic Chronic Pancreatitis

Historically, alcohol misuse was considered the leading cause of chronic pancreatitis and it still accounts for approximately 60–90% of cases in industrialized nations worldwide [11]. An epidemiologic study in France in 2006 showed that 84% of chronic pancreatitis cases could be attributed to alcohol misuse [12]. However, in recent years, it is reported that the proportion of cases attributable to alcohol misuse may be smaller than expected. The North American Pancreatitis Study 2 (NAPS2) showed that the frequency of alcoholic chronic pancreatitis at tertiary referral centers in the United States was 44.5% [11]. A report from Italy showed a shift in the etiologic profile of chronic pancreatitis [13]. Alcoholic chronic pancreatitis was the leading cause of chronic pancreatitis (74%) between 1971 and 1995, but the proportion decreased to 43% in patients evaluated between 2000 and 2006 [13]. These findings suggest that the contribution of alcohol misuse to the pathogenesis of chronic pancreatitis might have been overestimated [11]. Referral bias might exist in tertiary referral centers and accurate assessment of alcohol exposure to determine the association with chronic pancreatitis is challenging because self-reports about alcohol consumption are usually unreliable [14]. On the other hand, in Asia, alcohol misuse accounted for 69.7% of chronic pancreatitis cases in Japan in 2011 [15]. Idiopathic pancreatitis was the most common type in India (tropical pancreatitis) and accounted for approximately 70% of the chronic pancreatitis cases [16]. In China, 35% of the chronic pancreatitis cases were alcoholic [17]. Importantly, alcohol consumption has been stable or decreasing in many North American and European countries as well as in Japan, whereas it has been increasing in India and China [16,17]. It would be of interest to see whether the trends in alcohol consumption affect the burden of alcoholic chronic pancreatitis in India and China in the future.

Many studies have attempted to clarify the dose–response relationship between alcohol consumption and pancreatitis [4–6,18]. The first study on this topic was published by Durbec and Sarles in 1978 [4]. They reported that the logarithm of the relative risk of chronic pancreatitis increased linearly as a function of the quantity of alcohol and protein consumed. In the NAPS2, the association between alcohol consumption and pancreatitis was evaluated in 540 cases and 695 controls [6]. Logistic regression analyses revealed a significant

Companion website: www.wiley.com/go/beger/thepancreas

association between alcohol and chronic pancreatitis only in the very heavy drinkers who consumed ≥5 alcoholic drinks per day (odds ratio 3.1). In another case–control study [19], among patients with onset of chronic pancreatitis after the age of 35, alcohol intake, even less than 50 g/day, induced earlier disease characterized by more frequent severe pain, calcification, and complications such as pseudocysts. In a Japanese case–control study [18], compared with nondrinkers, the odds ratios (95% confidence interval [CI]) for alcohol consumption of ≤20 ~ <40 g/day, ≤40 ~ <60 g/day, ≤60 ~ <80 g/day, ≤80 ~ <100 g/day, and ≥100 g/day were 2.6 (95% CI: 1.2–5.5), 3.2 (95% CI: 1.5–7.1), 9.2 (95% CI: 4.1–20.3), 13.0 (95% CI: 5.3–31.6), and 19.6 (95% CI: 8.2–46.8), respectively.

In 2015, Samokhvalov et al. [20] reported a systematic review and meta-analysis of four studies (three case–control and one cohort studies) including the NAPS2 [6] and the Japanese case–control study [18] to assess the risk of pancreatitis and alcohol consumption. They showed that the risk of chronic pancreatitis increased monotonically according to the average alcohol consumption with no identifiable threshold in men (relative risks (95% CI) at 25 g/day = 1.58 (95% CI: 1.32–1.90); 50 g/day = 2.51 (95% CI: 1.74–3.61); 75 g/day = 3.97 (95% CI: 2.30–6.85); 100 g/day = 6.29 (95% CI: 3.04–13.02)) (Fig. 40.1). The risks calculated in the meta-analysis might be somewhat lower than those in the Japanese study [18]. One explanation may be related to genetic differences: a high proportion of Japanese individuals have a relative deficiency of alcohol dehydrogenase (ADH) and/or aldehyde dehydrogenase, resulting in higher blood levels of alcohol and/or acetaldehyde [21]. Another explanation may be the difference in body size between Japanese individuals and those from Western countries.

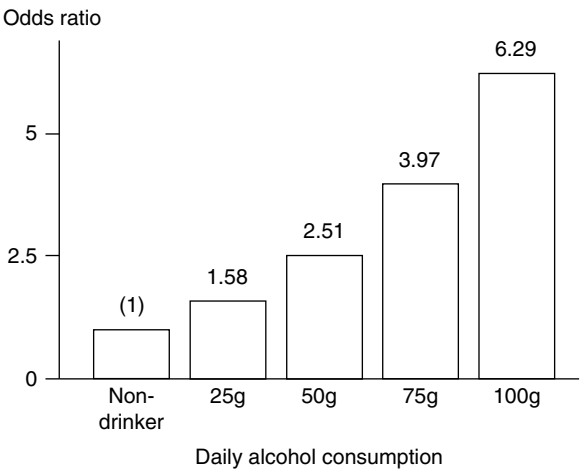

**Figure 40.1** Amounts of daily alcohol consumption and risk of chronic pancreatitis. *Source:* Based on data from [20].

It is well known that alcoholic chronic pancreatitis is predominantly a disease of men; 90–95% of the patients diagnosed with alcoholic chronic pancreatitis are male [22]. However, alcohol misuse is also an important health problem in women. Because of the increase in alcohol consumption by women in recent years the incidence of alcoholic chronic pancreatitis in women has been increasing in some countries, as reported for the Netherlands [23]. Importantly, it has been shown that susceptible women might develop alcoholic chronic pancreatitis with shorter duration of alcohol consumption and lower cumulative amounts of alcohol consumption than men [24].

## Pathophysiology

To date, several pathophysiologic mechanisms linking alcohol consumption and pancreatic injury have been suggested. These are described in the following sections [25–28].

### Ethanol Metabolism in the Pancreas

Pancreatic acinar cells are the main source of ethanol metabolism. Two pathways of ethanol metabolism have been described in pancreatic acinar cells: oxidative and nonoxidative pathways [29,30]. Ethanol oxidation involves the conversion of ethanol to acetaldehyde and acetate, a reaction catalyzed by ADH and cytochrome P450 2E1. The nonoxidative pathway of ethanol metabolism involves the esterification of ethanol with fatty acids to form fatty acid ethyl esters (FAEE) such as palmitic acid ethyl ester. This reaction is catalyzed by FAEE synthases. FAEE synthase activity in the pancreas is much greater than that in the liver, whereas pancreatic ADH and cytochrome P450 2E1 activities are low [29]. Therefore, the dominant nonoxidative metabolism is a characteristic feature of ethanol metabolism in the pancreas. It has been shown that ethanol intake results in the accumulation of FAEE in the blood and in several organs, with the highest concentrations in the pancreas [31]. FAEE synthases in the pancreas have not yet been fully characterized, but possible candidates include pancreatic triglyceride lipase and carboxyl ester lipase [32]. Patients with pancreatic diseases released FAEE synthase into their plasma in amounts proportional to those of amylase and lipase [33].

### Effects of Ethanol and its Metabolites on the Pancreas

Major targets of ethanol's actions in the pancreas include the sphincter of Oddi, pancreatic ductal cells, pancreatic acinar cells and pancreatic stellate cells (PSC) [25–28].

Animal studies showed an ethanol-induced spasmogenic effect on the sphincter of Oddi leading to occlusion of the main pancreatic duct (large duct), but both ethanol-induced decreased and increased Oddi activities have been reported in humans [25]. In the 1970s, the protein plug theory was proposed: alcoholic pancreatitis was thought to be caused by the blockade of small pancreatic ducts by protein plugs which were formed by the precipitation of secreted pancreatic proteins [34]. Thereafter, the focus of research has shifted to pancreatic acinar cells *in vitro* and *ex vivo*.

### *In Vitro* and *ex vivo* Studies

Ethanol might affect several aspects of homeostasis in pancreatic acinar cells. It induces a sustained elevation of the intracellular calcium levels [35] and increases the synthesis of digestive enzymes [36] (Box 40.1). It also increases the fragility of zymogen granules [37] and lysosomes [38], which sequester lysosomal enzymes such as cathepsin B within the cells. Mitochondrial dysfunction might play a role in ethanol-induced necrosis of the pancreatic acinar cells [39]. Some of these effects are mediated by metabolites of ethanol such as acetaldehyde and FAEE rather than ethanol itself. Gukovskaya et al. [29] showed that ethanol might regulate nuclear factor-κB (NFκB) and activator protein-1 (AP-1), the key transcription factors regulating the gene expression of inflammatory responses and cell survival. FAEE activate NFκB and AP-1, whereas ethanol and acetaldehyde inhibit NFκB activation. Thus, ethanol may regulate the activation of NFκB and AP-1 positively or negatively, depending on which metabolic pathway predominates. These effects may play a role in the ethanol-induced toxicity in the pancreas. Interestingly, ethanol and its metabolites altered the cholecystokinin 8-induced activation of these transcription factors [40]. As we will describe later, this may be a mechanism by which ethanol sensitizes pancreatic acinar cells to pancreatitis.

Recently, the pathophysiologic roles of autophagy have attracted the attention of researchers. Autophagy comprises several intracellular pathways of lysosome-mediated degradation and recycling of organelles, long-lived proteins, and lipids [41]. Evidence from animal models showed that autophagy is impaired in pancreatitis and lysosome dysfunction might be involved [42]. Fortunato et al. [43] reported that the combination of ethanol exposure and endotoxemia resulted in the depletion of several lysosomal proteins, including lysosomal-associated membrane protein-2 (LAMP-2), a protein required for the proper fusion of autophagosomes with lysosomes. LAMP-2 depletion was correlated with a switch from apoptotic to necrotic cell death. Importantly, human patients with ethanolic pancreatitis also exhibited local LAMP-2 depletion, indicating the crucial roles of LAMP-2 and autophagy in acinar cell death in humans.

A major breakthrough in this research field was the identification and characterization of PSC, a major effector cell type in pancreatic fibrosis, in 1998 [44]. *In vitro* culture of PSC provides a useful and unique platform to investigate the molecular mechanisms of alcohol-induced pancreatic fibrosis. Ethanol and its metabolites induced the activation, extracellular matrix production, and chemokine expression in PSC, leading to the perpetuated activation of PSC and pancreatic fibrosis [45,46].

**Box 40.1 Effects of ethanol and its metabolites on pancreatic cells**

**Pancreatic acinar cells**

- Sustained elevation of intracellular calcium level [35]
- Increased synthesis of digestive enzymes [36]
- Increased fragility of zymogen granules and lysosomes [37,38]
- Mitochondrial dysfunction [39]
- Activation of transcription factors NFκB and AP-1 [29]
- Impaired autophagy through depletion of LAMP-2 [43]
- Impaired regeneration [55]

**Pancreatic ductal cells**

- Protein plug formation [34]
- CFTR dysfunction [56]

**Pancreatic stellate cells**

- Activation (as assessed by increased α-smooth muscle actin expression) [46]
- Extracellular matrix synthesis (type I collagen) [45]
- Interleukin-8 production [46]

### *In vivo* Studies

Although a number of *in vitro* and *ex vivo* studies have shown the effects of ethanol and its metabolites on pancreatic cells, *in vivo* studies have shown that feeding ethanol to rats and mice even for a long time, with either liquid diet or continuous intragastric infusion, did not cause prominent injury to the pancreas [8,47,48]. Chronic ethanol feeding by the Lieber–DeCarli pair-feeding model [47] induces a number of metabolic changes in acinar cells, including an increase in the content of digestive enzymes and lysosomal enzymes and in the fragility of zymogen granules and lysosomes. However, chronic pathologic changes resembling chronic pancreatitis did not develop. On the other hand,

chronic ethanol exposure sensitizes the pancreas to other insults. Pancreatitis developed in rats that had received an ethanol-containing diet in response to low doses of cholecystokinin octapeptide or its analog caerulein, which do not cause pancreatitis by themselves [40]. The sensitization was accompanied by increased NFκB activation and the upregulation of proinflammatory cytokines and chemokines in the pancreas [40]. A combination of short-term administration of caerulein and long-term intraperitoneal administration of ethanol led to the activation of PSC and fibroinflammatory responses in the pancreas [49]. Chronic ethanol consumption accelerated pancreatic fibrosis in response to caerulein-induced pancreatitis in rats [50].

The findings in animal studies support the concept that, in humans, ethanol misuse alone does not cause chronic pancreatitis and additional cofactors such as smoking and genetic factors are required for the development of chronic pancreatitis in susceptible humans [9,10]. Animal studies have suggested that endotoxin in the microbiota might be such a cofactor. Gut permeability is increased in alcoholics, allowing translocation of Gram-negative bacteria across the mucosal barrier and allowing bacterial endotoxins to enter the circulation. A combination of Lieber–DeCarli ethanol-enriched diet and repeated injection of lipopolysaccharide (LPS) developed acute acinar cell injury, activation of PSC, and fibrosis [51]. Repeated LPS injection caused pancreatic fibrosis in ethanol-fed rats, but not in rats fed the control diet. When ethanol administration was continued, the activation of PSC and fibrosis persisted, but resolved soon after ethanol was discontinued [52]. Conversely, continued alcohol intake perpetuates pancreatic injury by inhibiting apoptosis and promoting the activation of PSC. These findings indicate the importance of abstinence to prevent the progression of acute pancreatitis to chronic pancreatitis [53].

Gukovsky et al. [8] reported that ethanol dramatically aggravated the pathologic effects of the combination of cyclosporine A and caerulein. In ethanol-fed, but not control diet-fed, animals, the combined treatment of cyclosporine A and caerulein resulted in severe pancreatic injury that displayed three key responses of human alcoholic chronic pancreatitis: loss of parenchyma, sustained inflammation, and fibrosis. On the other hand, for the repair of the exocrine pancreas, acinar cells could act as progenitor cells; mature acinar cells undergo dedifferentiation and redifferentiation back to the differentiated phenotype [54]. Clemens and Jerrells [55] reported that chronic ethanol administration delayed the structural and functional regeneration of the pancreas in mice. The delayed regeneration was associated with the decreased expression of pancreatic developmental factors including PDX-1. These findings suggest that ethanol might impair the recovery from acute pancreatic injury, thus facilitating the progression from acute pancreatic injury to chronic pancreatitis.

Recent studies have highlighted again the role of the pancreatic duct in the pathogenesis of alcohol-induced pancreatitis. Maléth et al. [56] showed that alcohol disrupted the expression, folding at the endoplasmic reticulum, and function of the cystic fibrosis transmembrane conductance regulator (CFTR) in pancreatic ductal cells. CFTR knockout mice given ethanol or fatty acids developed more severe pancreatitis than mice not given ethanol or fatty acids.

## Co-Predisposing Factors for the Development of Alcoholic Chronic Pancreatitis

The fact that only 1–5% of heavy drinkers develop pancreatitis [57] indicates that alcoholic pancreatitis is not caused by chronic alcohol misuse alone [9,10]. Some individuals may develop alcoholic pancreatitis with alcohol intake as low as 20 g/day, whereas most individuals do not develop pancreatitis no matter how much they drink or how long. Therefore, additional genetic and/or environmental factors such as cigarette smoking, high lipid diet, and gut microbiota [9,10,51] are required for the development of clinical chronic pancreatitis.

Most of the patients with alcoholic chronic pancreatitis are smokers and smoking has been established as an independent risk factor for the development of chronic pancreatitis [9,10,58]. Attention has been paid to identifying individuals at high risk of pancreatitis, and genetic studies might be useful to identify such individuals. The association between alcoholic chronic pancreatitis and pancreatitis susceptibility genes such as *PRSS1*, *SPINK1*, and *CTRC* has been shown in some studies, but the association exists primarily with nonalcoholic chronic pancreatitis [59]. Polymorphisms in the alcohol-metabolizing enzymes have been studied in patients with alcoholic chronic pancreatitis [60,61]. The frequency of the *ADH1B*2* allele was significantly higher in patients with alcoholic chronic pancreatitis compared with alcoholic subjects. The frequency of the *ALDH2*2* allele was significantly lower in patients with alcoholic chronic pancreatitis and in alcoholic subjects compared with healthy controls [60,61]. However, most of the studies have come from East Asia, and the data in Caucasians is very limited.

Genome-wide or exome-wide approaches overcome the limitations of a candidate gene approach, enabling the discovery of new and unsuspected pancreatitis susceptibility genes. A genome-wide study from North America has shown that the polymorphisms in the trypsin locus

(*PRSS1* rs10273639) and the claudin 2 locus (*CLDN2-RIPPLY1-MORC4* locus rs7057398 and rs12688220) conferred an increased risk of alcoholic chronic pancreatitis, but not with alcohol-associated cirrhosis or alcohol dependence [62]. The association of alcoholic chronic pancreatitis with polymorphisms in these loci has been replicated in Europe, Japan, and India [63–65], indicating that these polymorphisms are susceptible to alcoholic chronic pancreatitis worldwide. In such individuals at risk, lower levels of alcohol consumption might not be safe. Very recently, another genome-wide association study showed a novel association between alcoholic chronic pancreatitis and polymorphisms in the genes encoding fucosyltransferase 2 nonsecretor status (*FUT2* locus rs632111 and rs601338) and blood group B (*ABO* locus rs8176693) [66]. Obviously, further studies are required to clarify the underlying cellular events in the presence of these susceptibility polymorphisms.

# Pain Mechanisms in Chronic Pancreatitis

*Pierluigi di Sebastiano, Tommaso Grottola, and Francesco F. di Mola*

*Surgical Oncology, ASL-2 Abruzzo, "SS Annunziata" Hospital, Chieti, Italy*

## Introduction

Chronic pancreatitis used to be defined as a continuing inflammatory disease of the pancreas, characterized by irreversible morphological change, and typically causing pain and/or permanent loss of function. Recently, however, a new mechanistic definition has been proposed: "Chronic pancreatitis is a pathologic fibro-inflammatory syndrome of the pancreas in individuals with genetic, environmental and/or other risk factors who develop persistent pathologic responses to parenchymal injury or stress" [1]. This definition recognizes the complex nature of chronic pancreatitis, separates risk factors from disease activity markers and disease endpoints, and allows for a rational approach to early diagnosis, classification, and prognosis. About 65–70% of chronic pancreatitis cases are attributed to alcohol abuse. The remaining cases are classified as idiopathic chronic pancreatitis (ICP; 20–25%) and include tropical pancreatitis, which is a major cause of childhood chronic pancreatitis in tropical regions, or unusual causes such as hereditary pancreatitis, cystic fibrosis, and chronic pancreatitis-associated metabolic and congenital factors or autoimmune disorders [2,3]. Chronic pancreatitis is characterized by progressive remodeling processes leading to the replacement of the exocrine parenchyma by extensive fibrosis. However, the most clinically relevant feature is recurrent upper abdominal pain. Pain can be so intense and long-lasting that the follow-up care of patients is difficult and frustrating [3] and many patients become addicted to narcotics.

Three different typical pain profiles during the evolution of chronic pancreatitis have been described: (i) acute intense pain associated with repeated episodes of acute pancreatitis (acinar necrosis) in early stages, (ii) spontaneous lasting pain relief in association with severe pancreatic dysfunction in late stage of uncomplicated chronic pancreatitis, and (iii) persistent severe pain (or frequent recurrent episodes of pain) usually in association with local complications such as pseudocysts, ductal hypertension, or extrapancreatic complications such as partial obstruction of the common bile duct, peptic ulcer, and opiate addiction [4]. Several hypotheses have been advanced to explain pain genesis in chronic pancreatitis, including pancreatic and extrapancreatic causes. Today we have evidence for peripheral and central nervous system (CNS) involvement during chronic pancreatitis. It is believed that following injury, rapid and long-term changes occur in parts of the CNS that are involved in the transmission and modulation of pain (nociceptive information). A central mechanism in the spinal cord called "wind-up," also referred to as hypersensitivity or hyperexcitability, may occur. Wind-up occurs when repeated, prolonged, noxious stimulation causes the dorsal horn nerves to transmit progressively increasing numbers of pain impulses. This abnormal processing of pain within the peripheral nervous system and CNS may become independent of the original painful event in chronic pancreatitis [5].

## Extrapancreatic Pain

Bile duct stenosis and duodenal stenosis due to extensive pancreatic fibrosis and inflammation have been considered extrapancreatic causes of pain [6]. Becker and Mischke described a pathologic condition named "groove pancreatitis" in 19.5% of 600 patients with chronic pancreatitis [7]. This is characterized by the formation of a scar plate between the head of the pancreas and the duodenum. A scar in the groove is said to lead to complications that are determined by the topography: disturbance in the motility of the duodenum, stenosis of

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

the duodenum, and tubular stenosis of the common bile duct, occasionally leading to obstructive jaundice. These alterations are suggested to be responsible for several symptoms present in chronic pancreatitis and for postprandial pain due to the compression of nerves and ganglia located between the pancreatic head and the duodenum [8].

## Pancreatic Pain

Many investigators have related the origin of pain to increased pressure in pancreatic ducts and tissue [9–12]. The "ductal hypertension hypothesis" as an explanation for pain in chronic pancreatitis is supported by observations that decompression of a dilated pancreatic duct or pseudocyst frequently relieves pain [13]. According to this hypothesis, administration of pancreatic enzymes reduces pancreas juice production in patients with chronic pancreatitis, producing lower intraductal pressure and thereby reducing pain. Interestingly, pancreatic insufficiency appearing in the late stage of the disease may be accompanied by reduction or complete relief of pain, thus suggesting that the disease can burn itself out [8]. However, the "burn-out theory" in chronic pancreatitis has been questioned by epidemiologic data which show that pain in many patients with chronic pancreatitis continues despite pancreatic insufficiency, the appearance of calcifications, alcohol withdrawal, or pancreatic surgery. In fact, it has been estimated that around 30% of the patients treated with decompressive surgery exhibit recurrent attacks of pain [14].

In addition, octreotide, a somatostatin analog which strongly inhibits pancreatic secretion and therefore should interrupt the postulated pain cycle described, failed to significantly reduce the pain syndrome in many patients with chronic pancreatitis [15]. In addition, Manes et al. found no relationship between pain score and pancreatic pressure, although the intrapancreatic pressure was positively correlated with ductal changes, and they concluded that pancreatic parenchymal pressure is not closely related to pain in chronic pancreatitis [12]. Another hypothesis suggests that pain is induced when increased pancreatic ductal and parenchymal pressure produce a compartment syndrome that causes ischemia [16]. This hypothesis is supported by experimental studies [17] that show increased interstitial pressure correlates with decreased blood flow in a feline model of chronic pancreatitis. These abnormalities were reversed by surgical incision of the gland and draining the pancreatic duct, but were affected minimally by stenting the pancreatic duct. This would suggest that incision of the gland may be more important in relieving pain than ductal drainage. In addition, different studies [18,19] revealed that the degree of pancreatic fibrosis has no significant influence on pain generation since no correlation between the degree of fibrosis and intensity of pain could be demonstrated. Pseudocysts of the pancreas can cause intense pain in patients with chronic pancreatitis. In the majority of cases (60%) treatment with octreotide results in a reduction in size and in the eventual disappearance of the pseudocysts together with reduction of pain [20]. Enlargement of pseudocysts, causing compression of adjacent structures, might be a mechanism for pain generation.

Several authors have described patients with chronic pancreatitis associated with autoimmune diseases. Sarles et al. [21] described a type of chronic pancreatitis that might be caused by an autoimmune mechanism and termed it "primary inflammatory sclerosis of the pancreas." Yoshida and colleagues [22] reported a similar case and proposed that pancreatitis with these characteristics has to be considered as autoimmune pancreatitis. Current accepted terminology for this condition is lymphoplasmacytic sclerosing pancreatitis or autoimmune pancreatitis [22,23]. Pain is often associated with this type of inflammation although the genesis of this clinical symptom has not yet been investigated.

## Neural Remodeling

Neurogenic inflammation as a result of pancreatic inflammation and neural remodeling has recently been linked to both acute and chronic pathological conditions of the pancreas. Neurogenic inflammation encompasses a series of vascular and nonvascular inflammatory responses, triggered by the activation of primary sensory neurons (C- or Aδ-type nerve fibers) and the subsequent release of inflammatory neuropeptides, including substance P (SP) and calcitonin gene-related peptide (CGRP), and has been validated in human as well as in animal models of acute and chronic pancreatic damage [24,25]. Pancreatic and central changes can be distinguished.

### Pancreatic Changes

Keith et al. suggested initially that neural and perineural alterations might be important in pain pathogenesis in chronic pancreatitis [26]. They concluded that pain severity correlated with the duration of alcohol consumption, pancreatic calcification, and the percentage of eosinophils in perineural inflammatory cell infiltrates, but not with duct dilatation.

A subsequent study demonstrated an increase in both number and diameter of pancreatic nerve fibers in the course of chronic pancreatitis [27]. In tissue specimens

from patients with chronic pancreatitis, foci of chronic inflammatory cells were often found surrounding pancreatic nerves (called pancreatic neuritis), which by electron microscopic analysis exhibit a damaged perineurium and invasion by lymphocytes. The changed pattern of intrinsic and possibly extrinsic innervation of the pancreas in chronic pancreatitis suggested that there could be an upregulation of neuropeptides that usually populate those enlarged nerves. In fact, a further study [28] showed that there were striking changes in peptidergic nerves in chronic pancreatitis. The changes consisted of an intensification of immunostaining for CGRP and SP in numerous nerve fibers. Because both of these peptides are generally regarded as pain neurotransmitters, these findings provided evidence for direct involvement of pancreatic nerves in the long-lasting pain syndrome in chronic pancreatitis.

Later reports [23,29] revealed that the presence of growth-associated protein-43 (GAP-43), an established marker of neuronal plasticity, directly correlated with the pain scores in patients with chronic pancreatitis. GAP-43 is a neuronal protein known to be involved in the development of axonal growth cones and presynaptic terminals, and mRNA and protein levels of GAP-43 are increased after neuronal lesions. In the chronically inflamed human pancreas, enzymatic and double fluorescence immunohistochemistry reveals a significant expression of GAP-43 in the majority of pancreatic nerve fibers. These immunohistochemical findings correlated with clinical and pathological findings in patients with chronic pancreatitis, including the parenchyma–fibrosis ratio and the degree of perineural immune cell infiltration. Furthermore, a strong relationship with individual pain scores was present. The infiltration of pancreatic nerves by immune cells is significantly related to pain intensity, whereas pain scores do not correlate with the degree of pancreatic fibrosis or with the duration of the disease.

The demonstration of a direct relationship between the degree of perineural inflammation and the clinical pain syndrome strongly supports the hypothesis of "neuroimmune interaction" as an important, if not predominant, factor in pain generation in patients with chronic pancreatitis.

An interesting question concerns the mechanisms that contribute to the enlargement of pancreatic nerves. A recent study analyzed the expression of nerve growth factor (NGF) and one of its receptors (TrkA) in patients with chronic pancreatitis [25]. NGF belongs to the neurotrophin family and plays a role in neuroblast proliferation and neuronal maturation, affecting neuronal phenotype and maintaining neuronal survival. NGF signaling is mediated via binding high- and low-affinity receptors. TrkA is present in dorsal root and peripheral ganglia cells of primary sensory nerves, and is involved in signal transduction of noxious stimuli and tissue injury. Inflammation results in an elevation of NGF levels in different diseases. Interestingly, NGF may itself have cytokine-like functions; it can modify mast cell, macrophage, and B-cell functions, but may also activate TrkA located on sensory and sympathetic nerve fibers innervating the site of inflammation, thus modulating neuroimmune interactions. In chronic pancreatitis tissue samples NGF and TrkA mRNA expressions are markedly increased and enhanced in pancreatic nerves and ganglia. Comparison of the molecular findings with clinical parameters revealed a significant relationship between NGF mRNA levels and pancreatic fibrosis and acinar cell damage and between TrkA mRNA levels and pain intensity. These findings indicate that the NGF/TrkA pathway is activated in chronic pancreatitis and that this activation might influence nerve growth and the pain syndrome, most probably by modulating the sensitivity of NGF-independent primary sensory neurons through increasing channel and receptor expression [25].

Similar results showing positive correlation with pain intensity and frequency in patients with chronic pancreatitis were reported for brain-derived neurotrophic factor gene expression, a member of the neurotrophin family [30]. In addition, upregulated NGF might influence the pain syndrome in chronic pancreatitis patients by regulating transcription and synthesis of SP and CGRP, as well as through the release of histamine. The neuropeptide SP is the main tachykinin involved in neural transmission of sensory information, smooth muscle contraction, nociception, sexual behavior, and possibly wound healing and tissue regeneration [31,32]. SP has wide-ranging functional effects, including the crosstalk between nervous and immune systems by acting through its specific receptor neurokinin 1 (NK-1R). A recent report by Shrikande et al. [33] demonstrated a significant correlation between NK-1R and clinical–pathologic findings in patients with chronic pancreatitis. In chronic pancreatitis samples, NK-1R mRNA expression and protein were localized mainly in nerves, ganglia, blood vessels, inflammatory cells, and occasionally in fibroblasts. A significant relationship between NK-1R mRNA levels and intensity, frequency, and duration of pain in chronic pancreatitis patients was reported. The expression of NK-1R in inflammatory cells and blood vessels also points to crosstalk between immunoreactive SP nerves and inflammatory cells and blood vessels, and further supports the existence of a neuroimmune interaction that probably influences the pain syndrome and chronic inflammatory changes in chronic pancreatitis.

In addition, a recent study demonstrated that SP mRNA expression levels were higher in chronic pancreatitis tissues compared to controls, whereas neprilysin (NEP) mRNA levels showed no significant

differences between chronic pancreatitis patients and healthy subjects. In chronic pancreatitis patients, SP serum levels correlated with those in tissue, and after surgical resection SP serum levels were reduced compared to preoperative values. Failure of NEP to overexpress in chronic pancreatitis tissues was associated with significant miR-128a overexpression, suggesting that in an SP/NEP-mediated pathway NEP fails to provide adequate surveillance of SP levels and this failure of NEP might be microRNA associated [34].

The exact mechanisms involved in the interaction between inflammatory cells and nerves and ganglia—neuroimmune crosstalk—are not yet fully clarified. Different cytokines have been shown to interact with SP in various paradigms for pain and inflammation. SP directly stimulates the release of interleukin 8 (IL-8) from macrophages. IL-8 release generates hyperalgesia by stimulation of postganglionic sympathetic neurons. A significant increase of IL-8 mRNA was reported in chronic pancreatitis tissue samples [35]. IL-8 was present mainly in macrophages surrounding the enlarged pancreatic nerves, in remaining acinar cells, and often in ductal cells. IL-8 mRNA expression was positively correlated with the inflammatory score and the presence of ductal metaplasia in chronic pancreatitis tissue samples.

The reported findings in the literature on the interaction of SP and IL-8, in combination with what was reported in chronic pancreatitis, suggests that the increased mRNA expression of IL-8 in chronic pancreatitis could in part be mediated by SP released from sensory pancreatic nerves. In addition, the release of IL-8 from the remaining exocrine pancreatic parenchyma suggests the fascinating hypothesis of an intrinsic maintenance of the inflammatory response after the initial damage to the pancreatic gland, thus sustaining progression and evolution of the disease. In addition, in a rat model it was found that repeated caerulein stimulation causes experimental pancreatitis that is mediated in part by stimulation of vanilloid receptor type 1 (VR1) on primary sensory neurons, resulting in endogenous SP release [36]. These results were confirmed in human pancreas [37]. In fact, an activation of the VR1 in pancreatic tissues from patients with pancreatic cancer and chronic pancreatitis is known. This increase was correlated with pain score in those patients. The release of SP and NKA from primary afferent (sensory) nerve endings to various stimuli is now considered to be induced by activation of the capsaicin (vanilloid) receptor (VR1).

### Central Involvement

Considering the noxious input described above from these pancreatic changes, it is not surprising that evidence for central sensitization is found in patients with chronic pancreatitis. In fact, patients with chronic pancreatitis have lower thresholds to pain in response to deep abdominal palpation than healthy individuals (reflecting secondary referred hyperalgesia in the musculature) [38]. Furthermore, the area of referred pain is expanded in patients with chronic pancreatitis who are subject to experimental electrical stimulation of viscera with changes in evoked potentials in the brain [39–41]; these data have also been confirmed by magnetic resonance imaging. In constrast, hyposensitivity to cutaneous stimulation has also been reported in these patients, probably as a result of altered descending inhibitory influences on spinal nociceptive neurons [42]. Patients with chronic pancreatitis have also been shown to have hyperalgesia to rectosigmoid stimulation, accompanied by impairment in diffuse noxious inhibitory control, a phenomenon that reflects descending central inhibition of pain, thought to be a countermeasure to noxious stimulation [43].

However, it is difficult to determine the importance of central sensitization in the pathogenesis of pain in humans with chronic pancreatitis with constant abnormal input into the CNS [44]. Central sensitization could simply reflect the expected response to an ongoing barrage of impulses from the periphery [45,46]. If so, then suppression or interruption of afferent signaling from the pancreas should also attenuate central sensitization, as has been suggested by the results of small studies on the effects of thoracic splanchnectomy/denervation on hyperalgesia in patients with chronic pancreatitis [47,48], as well as by the response to a peripherally acting κ-opioid antagonist.

## Conclusions

Clarifying the pathophysiologic mechanism for pain generation in chronic pancreatitis remains a major clinical problem. The recent concept of neuropeptides released from enteric and afferent neurons and their functional interactions with inflammatory cells might play a key role. An interesting recent finding is the presence of a spatial relationship between peptidergic neurons and inflammatory cells in chronic pancreatitis. Furthermore, there is the intriguing possibility of a functional interaction among neuropeptides, immune cells, cytokines, and NGF. A correlation between those molecules and pain has been demonstrated and the present information provides evidence for neuroimmune crosstalk in the pathogenesis of pain and inflammation in chronic pancreatitis.

# Natural History of Recurrent Acute and Chronic Pancreatitis

*Rohit Das and Dhiraj Yadav*

*Division of Gastroenterology & Hepatology, Department of Medicine, University of Pittsburgh Medical Center, Pittsburgh, PA, USA*

## Introduction

Pancreatitis, especially chronic, is a disease of low prevalence. Consequently, the epidemiologic focus has primarily been to define the disease at the level of individual patients. In the past two decades, the importance of understanding the distribution of risk factors and disease at the population level has been recognized. This has enabled determination of disease estimates and increased our understanding of the relationship between acute pancreatitis and chronic pancreatitis at the population level. The recognition that subsets of patients with acute pancreatitis develop recurrent acute pancreatitis (RAP) and/or progress to chronic pancreatitis provides empiric evidence that these conditions represent stages of a disease continuum. Knowledge of the risks and factors associated with disease progression will help in risk stratification, prediction, and developing strategies for altering the natural history of disease.

This chapter focuses on the burden of disease, natural course, and survival of acute, recurrent acute, and chronic pancreatitis. For acute pancreatitis, the emphasis will not be on the severity and outcome of the initial attack, but rather the risk of readmissions, recurrences, and progression to chronic pancreatitis. In chronic pancreatitis, the prevalence and natural history of clinical features (i.e., pain, endocrine and exocrine insufficiency) and the risk of pancreatic cancer will be discussed. Finally, we will summarize available data on quality of life.

## Natural History After First Attack of Acute Pancreatitis

### Disease Burden, Etiology, and Severity

Acute pancreatitis is one of the leading gastrointestinal causes of hospitalization in the United States [1]. The estimated incidence of acute pancreatitis in recent studies is between 30 and 50 per 100,000 population. Acute pancreatitis affects all age groups, but is most frequent in middle-aged and older individuals [2]. Gallstones and excessive alcohol consumption account for about 60–70% of all cases, the latter being more common in men than in women. Other etiologies include metabolic factors (hypertriglyceridemia, hypercalcemia), endoscopic retrograde cholangiopancreatography (ERCP), medications, genetic mutations (*PRSS1*, *SPINK1*, *CFTR*, *CTRC*), obstructive causes (such as pancreatic duct stricture etc.), and trauma. In 10–25% patients no identifiable etiology is found on evaluation [2]. The two main determinants of mortality in acute pancreatitis are the presence of organ failure and infected necrosis [3]. The risk of death increases with age and comorbidities [4]. Increased morbidity is seen in patients with local complications who do not have organ failure [5].

### Readmissions

After the first attack of acute pancreatitis, about 20–30% patients are readmitted to the hospital (Table 42.1). The reasons for readmission differ based on time since

CP, chronic pancreatitis.

discharge from the hospital. Vipperla et al. [6] differentiated between early (<30 days after index acute pancreatitis) and late (>30 days after index acute pancreatitis) readmissions and found that early readmissions were more likely due to smoldering symptoms from acute pancreatitis and/or local complications, whereas late admissions were more likely to be due from recurrent episodes of acute pancreatitis. Whitlock et al. [7] identified five factors at the time of discharge that independently predicted the risk of early readmission (<30 days after discharge): tolerance of less than a solid diet, gastrointestinal symptoms (nausea, vomiting, diarrhea), pain, pancreatic necrosis, and use of antibiotics and/or opiates. Using these parameters (one point each), they developed a scoring system to predict the risk of early readmissions (low risk 0–1 points; moderate risk 2–3 points; high risk 4–5 points) and tested this in a validation cohort. The risk of readmissions was approximately 5%, 15%, and over 65% in the low-, moderate-, and high-risk groups, respectively [8]. Younger age and concurrent alcohol use and/or alcohol-related etiology have also been identified to predict readmissions [6,7,9,10].

These data suggest that focused discharge planning may reduce the risk of early admissions (i.e., ensuring that the patients' symptoms are well controlled and they have received counseling for behavior modification). In patients with severe acute pancreatitis, close follow-up with relevant specialists (e.g., nutrition, gastroenterologist, surgeon) is helpful to determine the need and timing of cross-sectional imaging, duration of enteral feeds, and "step-up" therapy. Many patients with severe acute pancreatitis need short-term stay at a transitional care facility or rehabilitation unit prior to safe discharge home.

## First Recurrence

The risk of RAP after the first attack has been evaluated in several, mostly retrospective, population- and non-population-based studies (Table 42.2). The overall risk of a subsequent attack of acute pancreatitis is ~20% during a median follow-up period ranging from 4 to 8 years. Similar to the first attack, among patients with a second attack of acute pancreatitis, alcohol, gallstones, and idiopathic causes are the most common etiologies [11–14]. When compared with the first attack of acute pancreatitis, subsequent recurrence is generally milder, with an overall lower mortality [15].

The risk of recurrent attack is highest among patients with alcohol etiology (35–40%) followed by idiopathic and biliary acute pancreatitis (both 10–20%) [11–14]. Takeyama et al. noted that the risk of subsequent recurrence was directly related to continued alcohol consumption: the risk was highest in patients who continued drinking at the same level and lowest among patients who stopped drinking completely [17]. Contrary to what many physicians may believe, counseling against alcohol consumption has a significant impact on patient behavior. This was tested empirically in a randomized controlled trial, where repeated counseling of patients led to a significant decrease in the risk of abdominal pain attacks, acute pancreatitis episodes, and hospitalizations [18].

After an attack of biliary pancreatitis, the risk of recurrence can be dramatically reduced by early cholecystectomy. This has been demonstrated in randomized clinical trials, as well as in a meta-analysis of published data [19,20]. In patients with mild biliary pancreatitis, cholecystectomy should be considered as soon as possible following the attack of acute pancreatitis, preferably during the same admission. In patients with severe acute pancreatitis, cholecystectomy should be delayed until resolution of inflammatory changes in the pancreas/peripancreatic area. In patients with pancreatic/peripancreatic collections that need drainage, a surgical approach (preferably laparoscopic or minimally invasive) to address this along with a cholecystectomy should be considered [21]. In patients with another known etiology (i.e., medications, hypertriglyceridemia, hypercalcemia, etc.), addressing the inciting cause will decrease the risk of recurrence [22,23].

Because tobacco abuse is consistently associated with an increased risk of recurrent acute pancreatitis (odds ratio 1.5–2) [11,12,14,16], after an attack of acute pancreatitis, patients should be informed about this risk and counseled for tobacco cessation. This will be especially relevant in patients in whom the cause was related to alcohol, hypertriglyceridemia, genetic factors, or idiopathic, or if the acute pancreatitis attack was moderate to severe. Individual studies have also shown that age and severity of initial attack may also play a role in recurrence [11,13,14,16].

The burden of RAP at a population level is not well defined. Using information on the total number of admissions for acute pancreatitis in the United States and applying the incident acute pancreatitis rates from California, the approximate number of recurrent attacks can be estimated [1,24]. Among the 275,000 annual admissions for acute pancreatitis, approximately 150,000–160,000 would be incident attacks, while the remaining 115,000–125,000 would represent RAP (first or subsequent recurrences), readmissions for ongoing symptoms or complications of acute pancreatitis, or acute on chronic pancreatitis.

## Quality of Life After Acute Pancreatitis

Severe acute pancreatitis, with or without necrosis, results in worsened quality of life when compared with control populations [25–27]. A recent meta-analysis

**Table 42.2** Summary of recent studies examining the rate and risk factors for development of recurrent acute pancreatitis (RAP) after a first attack of acute pancreatitis.

| Author, year | Cohort size | Follow-up time (years) | RAP rate (%) | | | | Time to recurrence (months) | Risk factors for RAP |
|---|---|---|---|---|---|---|---|---|

analyzed 267 acute pancreatitis patients, accumulated from four prospective cohort studies. Overall, when compared with controls, the general health domain (which measures patients' abilities to conduct daily activities) and vitality domain (which measures patients' energy levels) were significantly impaired [28]. Subgroup analysis based on severity or types of intervention were not statistically feasible, and further studies are required to clarify the determinants of poor quality of life after acute pancreatitis more precisely.

### Subsequent Recurrences

As for the initial recurrence, alcohol is the most common etiology for subsequent recurrences, followed by idiopathic pancreatitis, genetic causes, hypertriglyceridemia, and underlying chronic pancreatitis as other important causes. The role of pancreas divisum and sphincter of Oddi dysfunction in causing initial or recurrent acute pancreatitis attacks is controversial [29,30].

Approximately one-third of patients who have a recurrence after the first attack of acute pancreatitis will have one or more subsequent recurrences. Burden of RAP was further quantified in two studies. Among 562 patients with first attack of alcoholic acute pancreatitis who survived the index admission, Pelli et al. reported at least one recurrence in 260 (46%) patients. Among these patients, 133 (51%) had only one recurrence, 49 (19%) had two recurrences, 39 (15%) had three recurrences, and 39 (15%) had four or more recurrences [31]. Among patients who underwent a cholecystectomy for presumed biliary pancreatitis, Trna et al noted the risk of subsequent attacks to be related to the presence of abnormal liver function tests and documentation of gallbladder stones or sludge. Among patients who did not have either, 26% had a second attack, and 9% had a third attack of acute pancreatitis [32]. Although few empiric data are available, the risk of multiple attacks of acute pancreatitis seems high in patients with certain genetic mutations (e.g. *PRSS1*, *CFTR*) [33]. The risk of recurrences would also appear to be higher in patients with uncommon causes of acute pancreatitis, such as hypertriglyceridemia, hypercalcemia, etc., especially if the underlying cause is not corrected, but definitive data on the burden of attacks in these patients are also lacking [23].

### Progression to Chronic Pancreatitis

Many recent studies evaluating the natural history after first attack of acute pancreatitis have determined the risk of progression to chronic pancreatitis (Table 42.3) [11–14,16,34]. Overall, the risk of progression to chronic pancreatitis varied from 5% to 25% during a follow-up period ranging from 4 to 8 years. The three factors consistently shown to have an independent effect on disease progression are alcohol etiology, tobacco abuse, and RAP. The association with severity of acute pancreatitis is less consistent and has been noted in some but not all studies.

Lankisch et al. noted that progression to chronic pancreatitis occurred almost exclusively in patients with alcohol etiology [13]. However, in other studies progression was also noted in patients with nonalcoholic or idiopathic chronic pancreatitis, albeit at a lower rate. The role of tobacco, especially in combination with alcohol in disease progression is important. Ahmed Ali et al. reported that while the cumulative risk of progression to chronic pancreatitis overall was 7.6%, it was 18% among current smokers, and increased to 30% in current smokers who also had alcohol etiology [16]. Therefore, including the counseling of tobacco cessation along with alcohol abstinence should be emphasized. Genetic factors also seem to play a role in the development of chronic pancreatitis, but outside of hereditary pancreatitis, few empiric data are available [33].

Perhaps the strongest risk factor for disease progression is RAP, and the risk of progression in these patients is ~30–40%. Bertilsson et al. noted that among patients who transitioned to chronic pancreatitis, 74% had at least two attacks of acute pancreatitis, and 54% had more than two attacks. When compared with alcohol or tobacco (hazard ratio 2–3), the risk of progression to chronic pancreatitis is much higher (hazard ratio ~6) [11].

Because the evolution to chronic pancreatitis may occur over several years, the duration of follow-up is also an important determinant of a study's ability to accurately characterize the risk of progression to chronic pancreatitis. Indeed, the study with the longest follow-up period observed the highest incidence of progression to chronic pancreatitis [34].

In a recent meta-analysis of 14 studies consisting of 8492 patients, Sankaran et al. summarized the natural history of progression from acute pancreatitis to chronic pancreatitis [35]. The pooled prevalence of RAP was 22% (38% for alcohol etiology, 17% for biliary etiology), and of chronic pancreatitis was 10%. As stated previously, the major risk factors were RAP, alcohol use, and tobacco smoking.

## Natural History of Chronic Pancreatitis

### Disease Burden, Demographics, and Etiology

The population distribution for chronic pancreatitis is becoming clearer. Annual incidence data have been reported from many populations and range from 4 to 14 per 100,000 population, with an estimated prevalence of ~50 per 100,000 population [2]. Alcohol continues to be the predominant cause of chronic pancreatitis worldwide,

CP, chronic pancreatitis; RAP, recurrent acute pancreatitis.

followed by idiopathic chronic pancreatitis. The role of genetic factors is increasingly recognized and mutations in four susceptibility genes (*PRSS1*, *SPINK1*, *CFTR*, and *CTRC*) are now routinely tested in clinical practice in patients with unexplained chronic pancreatitis [33]. Alcoholic chronic pancreatitis is seen more commonly in men, whereas the other etiologies are more evenly distributed in both sexes. The median time to diagnosis of chronic pancreatitis is typically 5–10 years after that of acute pancreatitis [36].

## Natural Course of Clinical Symptoms

### Abdominal Pain

Abdominal pain is the most common symptom which prompts patients with chronic pancreatitis to seek medical attention. Approximately 85–90% patients with alcoholic chronic pancreatitis have pain at some point of time during their clinical course [37–40]. Differences have been described in the pain experience based on disease etiology: patients with alcoholic chronic pancreatitis and early-onset idiopathic chronic pancreatitis are more likely to have any or severe pain when compared with patients who have the onset of disease later in life [39–42]. Pain can be related to a multitude of factors, including mechanical (pancreatic or biliary duct obstruction), inflammatory (episodes of acute pancreatitis, peripancreatic collections), neuropathic, and visceral hyperalgesia.

In a study of 206 patients with alcoholic chronic pancreatitis, 56% of whom needed at least one surgical intervention, Ammann et al. described two main patterns of pain. Type A pain was defined by intermittent episodes of pain, sometimes severe needing hospitalization, lasting up to a few days at a time and could be managed medically. Type B pain was characterized by constant pain with exacerbations, often related to local complications, needing frequent hospitalization and surgical intervention for pain relief (most frequently for pseudocysts, less often for symptomatic large duct disease or cholestasis) [42]. Using a questionnaire modeled to mimic Ammann's pain categories, a recent multicenter cross-sectional study of 518 chronic pancreatitis patients of all etiologies from the United States assessed the pain pattern in the year preceding the enrollment. Overall, 84% patients reported having pain—described as intermittent by 32% and constant by 53%; mild-moderate by 18%, and severe by 67% [43]. Due to the cross-sectional design, the study could not examine the relationship between interventions (medical, endoscopic, surgical) and pain relief.

In most large series of patients with chronic pancreatitis, approximately 40–50% undergo some form of intervention (endoscopic, surgical) for pain relief [38–40,42]. There is controversy as to whether all chronic pancreatitis patients will achieve pain relief or "burnout" during the course; Ammann et al. proposed this based on their observation that >80% patients become pain free approximately 5–10 years after onset of symptoms, usually in parallel with the development of exocrine and endocrine insufficiency [37]. However, others argue that pain relief may not be universal, and that a significant proportion of patients continue to have pain even after developing pancreatic insufficiency [44].

Due to persistent and severe pain, there is a risk of narcotic dependence. As a consequence, management of pain related to chronic pancreatitis requires a multidisciplinary approach [45]. In recent years, increasing numbers of patients are undergoing total pancreatectomy with islet autotransplantation (TPIAT). Guidelines have been proposed on the selection of patients, timing of procedure, and pre- and postoperative follow-up of patients who are being considered for TPIAT [46].

### Endocrine and Exocrine Insufficiency

Chronic pancreatitis leads to progressive loss of functioning pancreatic tissue, and consequently can lead to "pancreatogenic or type 3c" diabetes and fat malabsorption. Diabetes in the setting of chronic pancreatitis has distinct characteristics from type 1 and 2 diabetes, which may have clinical and prognostic implications [47]. Both of these complications require lifelong therapy.

The incidence of diabetes and exocrine insufficiency in chronic pancreatitis ranges between 40% and 80% [37–40]. In the largest prospective study addressing this question (431 patients, 51% with surgical intervention), Malka et al. reported a cumulative risk of 50% at 10 years and 83% at 25 years after diagnosis of chronic pancreatitis, with a median time to diagnosis of 4.5 years [48]. Independent variables were pancreatic calcification, distal pancreatectomy, and alcohol etiology.

Subclinical exocrine insufficiency is more frequent in chronic pancreatitis, since clinical symptoms of steatorrhea develop only after significant destruction of the exocrine pancreas [49]. Patients with exocrine insufficiency develop fat-soluble vitamin deficiencies and osteopenia/osteoporosis with associated complications such as bone fractures [50]. Fortunately, exocrine insufficiency is easily addressed with the initiation of pancreas enzyme supplementation, which has been shown to improve symptoms, nutritional status, and quality of life [51,52].

### Pancreatic Cancer

Chronic pancreatitis is an established risk factor for pancreatic cancer. The risk increases with the duration of disease, and is similar for alcohol and nonalcoholic etiologies. In a meta-analysis of 22 published studies, the relative risk of pancreatic cancer was increased 5.1-fold for unspecified pancreatitis, 13.3-fold for chronic pancreatitis, and 69-fold for hereditary pancreatitis [53]. The

absolute risk of developing pancreatic cancer in a patient with chronic pancreatitis is low (5%), except for tropical pancreatitis and hereditary pancreatitis, where the risk can be as high as 25% and 40–50%, respectively [53].

### Quality of Life and Survival

Chronic pancreatitis negatively impacts quality of life independent of demographic factors, risk factors, and coexistent medical problems [54]. Among chronic pancreatitis patients, pain is one of the primary determinants of poor quality of life [55]. Patients frequently use healthcare services with significant associated cost [56,57]. The overall survival and the standardized mortality ratio in chronic pancreatitis patients are 2- to 4-fold higher than in the general population [34,58]. Most patients die from nonpancreatic causes.

## Conclusion

Studies in the past two decades have provided an insight into the population distributions and natural histories of different stages of pancreatitis. Readmission to hospital is frequent after acute pancreatitis. After the first episode of acute pancreatitis, about one in five patients develop a recurrence and one in ten progress to chronic pancreatitis. Alcohol and tobacco abuse are the main predictors of recurrence, and these, along with RAP, are the main predictors of progression to chronic pancreatitis. Abdominal pain is the main symptom of chronic pancreatitis, and a significant fraction of these patients develop exocrine and/or endocrine insufficiency during the disease course. Chronic pancreatitis is an established risk factor for pancreatic cancer, although the absolute risk of this is low.

# Chronic Pancreatitis with Inflammatory Mass of the Pancreatic Head

*Ulrich F. Wellner and Tobias Keck*

*Department of Surgery, University of Schleswig-Holstein, Campus Lübeck, Lübeck, Germany*

## Introduction

Chronic pancreatitis can present with enlargement and mass formation of the pancreatic head, mimicking virtually all symptoms of a malignant pancreatic head tumor and confronting the clinician with significant diagnostic and therapeutic challenges. This phenomenon has been termed the "inflammatory (pseudo) tumor" [1], "tumor-forming chronic pancreatitis" [2], and other terms. Here we will use the term inflammatory pancreatic head mass (IPHM).

From a pathophysiological point of view, IPHM is thought to result from recurrent acute and chronic inflammation of the pancreatic parenchyma. At the same time it acts as a "pacemaker," perpetuating the disease progression by causing obstruction of the main pancreatic duct (MPD) leading to chronic ductal hypertension [3]. There is no generally accepted definition of IPHM, but the following criteria may be applied: the presence of an abnormally enlarged pancreatic head, often accompanied by pancreatic calcifications, MPD dilatation and irregularities, and atrophy of the pancreatic parenchyma to the left of the mesentericoportal axis [4–6] (Figs 43.1 and 43.2).

## Incidence

The concept of the IPHM as a pacemaker of chronic pancreatitis was proposed by Beger et al. [3] and is followed mainly by European surgeons. The incidence of IPHM in surgical patients is in the range of 85%, although exact figures have rarely been reported in detail [5,7]. In this respect, the average size of the pancreatic head has been shown to be significantly larger in a study comparing German patients (median 4.5 cm) and North American patients (median 2.6 cm) undergoing surgery for chronic pancreatitis [5]. The significance of this finding lies in the fact that it explains regional differences in operative procedures used to treat chronic pancreatitis, although the underlying cause is not clear.

## Symptoms, Pathophysiology, and Clinical Problems

An IPHM can cause many clinical symptoms and complications, which in principle constitute the classic complications of chronic pancreatitis. Differential diagnosis and decision making may be complicated as almost all of these symptoms can also be caused by pancreatic head cancer.

One of the most frequently reported symptoms is pain [4,8,9]. Typically, the pain maximum is located to the epigastric area and may radiate to the flanks and back. In some cases, however, back pain may be the primary complaint. The pain can be episodic or continuous, with sudden exacerbations of variable frequency from daily to once in several months, often triggered by alcohol or food intake. Signs of acute pancreatitis-like elevation of serum amylase or lipase and edematous swelling of the pancreatic head are often found associated with severe acute pain attacks, but may also be missing, especially with longer duration of disease. In line with this, there is good evidence from histopathologic and experimental studies that pancreatic pain is not only caused by acute inflammation but also by chronic neuropathy of visceral nerves in the pancreas [8,9]. Importantly, about 50–90% of patients do not become pain-free even 10 years after disease onset [10].

**Figure 43.1** Inflammatory pancreatic head mass. Computed tomography showing a large inflammatory pancreatic head mass in a patient with chronic pancreatitis, with typical diffuse pancreatic calcifications. The impacted dislocated main pancreatic duct stent was removed during surgery.

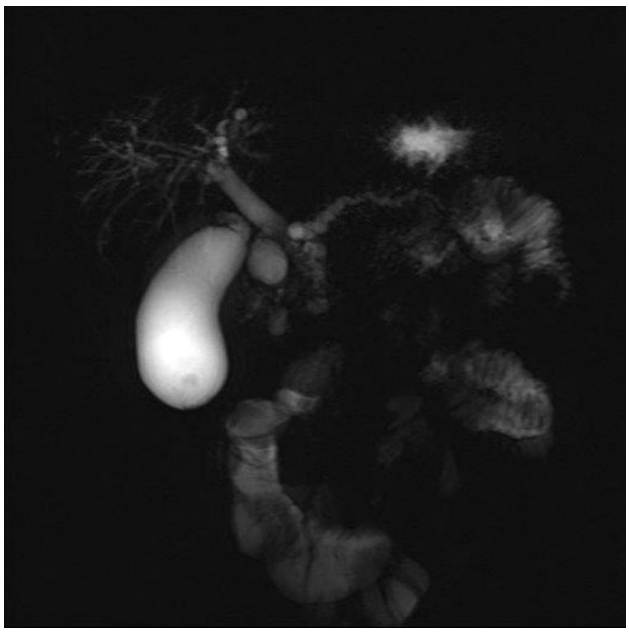

**Figure 43.2** Irregularities of the main pancreatic duct. Magnetic resonance cholangiopancreatography disclosing marked pancreatic duct irregularities and narrowing of the common bile duct in a patient with inflammatory pancreatic head mass.

Episodes of acute pancreatitis can lead to the development of pancreatic pseudocysts or walled-off necrosis (WON) (Fig. 43.3) [11], with secondary complications such as superinfection, hemorrhage, compression of the duodenum or bile duct, internal pancreatic fistula, and

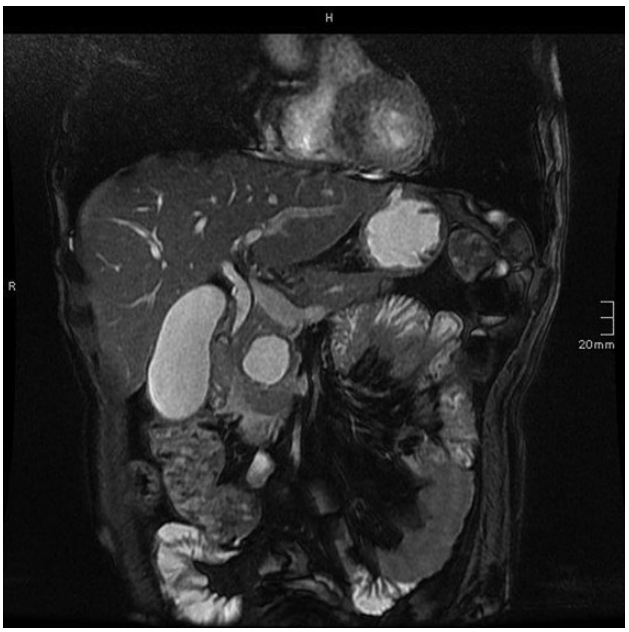

**Figure 43.3** Walled-off necrosis. Magnetic resonance imaging depicting an inflammatory pancreatic head mass with walled-off necrosis which developed after an episode of acute pancreatitis in a patient with chronic pancreatitis.

pancreatic ascites. Biliary stricture is reported in up to 35% of patients [6], leading to jaundice and recurrent cholangitis. Note that subclinical common bile duct (CBD) narrowing can be aggravated to frank obstruction by acute edematous swelling of the pancreatic head during episodes of acute pancreatitis. Maldigestion and malabsorption with steatorrhea, coagulopathy, and malnutrition occurs as a result of persistent cholestasis. Duodenal stenosis is found in about 10% of patients [6], resulting in gastric dilatation, postprandial bloating and vomiting, anorexia, and malnutrition. Malnutrition may be exaggerated by pancreatic exocrine insufficiency. Loss of endocrine function typically occurs later and will affect around 80% of patients [10]. Stenosis and finally thrombotic occlusion of the mesentericoportal vessels is usually a late complication. Occlusion of the splenic vein results in left-sided portal hypertension with development of gastric fundal varices and splenomegaly. As complete occlusion of the portal vein usually develops gradually, extensive collaterals develop around the pancreatic head, a phenomenon called cavernous transformation [6]. Patients with chronic pancreatitis have a tenfold elevated risk (about 3%) of developing pancreatic cancer [10].

## Clinical Workup and Differential Diagnosis

The most important differential diagnoses are pancreatic head cancer and autoimmune pancreatitis. Careful clinical history taking can yield important hints.

Long-standing complaints or recurrent attacks over a period of years rather than months, accompanied by signs of chronic malnutrition, point toward benign IPHM, whereas clinical deterioration over weeks to months with weight loss or new-onset diabetes mellitus are suggestive of malignancy. Jaundice can occur with IPHM but should always prompt efforts to rule out malignancy. Associated autoimmune disease points to autoimmune pancreatitis [12]. Laboratory workup should include serum amylase and lipase activity and carbohydrate antigen 19–9 (CA19–9), as elevated serum enzyme activity indicates an episode of acute pancreatitis, whereas marked elevation of the tumor marker in the absence of acute pancreatitis is suggestive of malignancy. Sensitivity and specificity of CA19–9 for discrimination of chronic pancreatitis from pancreatic ductal adenocarcinoma (PDAC) were reported as 84% and 75% [13]. Serum immunoglobulin G4 (IgG4) can be increased in autoimmune pancreatitis [14]. Because of the risk of tumor spillage and lack of therapeutic consequences, tissue biopsy is not recommended when resectable malignancy is suspected [15].

Cross-sectional imaging by contrast-enhanced computed tomography (CE-CT) or magnetic resonance imaging (MRI) is mandatory. In IPHM, the pancreatic head is enlarged with loss of the lobular parenchymal architecture, calcifications and narrowing of the pancreatic duct (Fig. 43.1). There can be mass-forming lesions in the pancreatic head virtually indistinguishable from pancreatic cancer. Upstream MPD dilatation is often absent in autoimmune pancreatitis [12]. Accuracy of modern cross-sectional imaging for differentiation of IPHM and pancreatic cancer has been reported in the range of 90% [16]. Magnetic resonance cholangiopancreatography can be a valid substitute for invasive endoscopic retrograde cholangiopancreatography (ERCP) to assess configuration of the biliary tree and MPD (Fig. 43.2) and has better ability to distinguish liver metastasis from other lesions [17]. In view of eventual surgical intervention, it is important to assess mesentericoportal vein status and signs of portal hypertension.

## Treatment

Asymptomatic IPHM almost does not exist, although symptom-free periods of weeks to months are common. Indications for invasive treatment are persistent pain or dependence on analgesics, recurrent acute pancreatitis, obstructive cholestasis, gastric outlet obstruction, development of persistent large or symptomatic pancreatic pseudocysts or WON, and suspicion of malignancy. Conservative management is chosen in case of inoperability or as a strategy to avoid operative treatment during a period of recovery, either after an episode of acute pancreatitis or as a bridge to operation.

Medical therapy consists of pain control and eventual substitution of pancreatic enzymes and insulin. It must be stressed that clinical remission of symptoms can be achieved by cessation of alcohol consumption in alcohol-induced chronic pancreatitis. Furthermore, the major role of tobacco smoke as a causal agent has recently been recognized [18,19]. At least initially, surveillance of a pancreatic head mass by cross-sectional imaging should be performed every 3–6 months to rule out malignancy.

Endoscopic stenting of the MPD can be effective to induce remission of pancreatic cysts, pancreatic fistula, and pain by decompression of the MPD. However, two randomized trials and a current Cochrane review show that surgical treatment provides more effective and durable pain control than endoscopic or conservative treatment [20–23]. Another disadvantage of endoscopic therapy is the necessity of regular stent exchange every 3–6 months to prevent cholangitis and tissue overgrowth. When a stent cannot be removed due to incrustation or migration, surgical intervention is needed (Fig. 43.1). Stenting of the CBD for obstructive jaundice is only a short-term option as remission of CBD obstruction can only be expected in cases of acute edematous swelling of the IPHM in acute pancreatitis.

Operative therapy can be divided into drainage and resectional procedures. Although drainage procedures aim at decompression of the MPD by pancreatojejunostomy, removal of the IPHM is the goal of resectional procedures, which can be combined with longitudinal MPD drainage. On surgical exploration, the IPHM is usually found to be heavily indurated and the inflammatory fibrotic process may extend into the peripancreatic tissues, causing heavy adhesions to nearby organs, such as the retropancreatic blood vessels, duodenum, and hepatoduodenal ligament. These conditions render operative procedures involving the pancreatic head very challenging and in rare cases even technically impossible, especially when associated mesentericoportal hypertension leads to diffuse bleeding.

Radical pancreatoduodenectomy with (Longmire–Traverso [24]) or without (Kausch–Whipple [25,26]) preservation of the pylorus is the procedure of choice when malignancy is suspected and offers very good long-term pain control in chronic pancreatitis. For the IPHM, duodenum-preserving pancreatic head resection (DPPHR) was developed by Beger and colleagues [3]. In the subsequently reported Frey procedure [27], pancreatic parenchyma is spared by excoriation of the IPHM without transection at the pancreatic neck, and laterolateral pancreatojejunostomy ensures adequate MPD decompression. The Berne/Farkas modification of the Beger procedure [28] omits pancreatic transection and laterolateral pancreatojejunostomy, while in the Hamburg modification [6], drainage of the MPD is extended by a V-shaped excision along the MPD.

With regard to the evidence for the choice between these surgical options, five randomized controlled trials (RCT) have shown reduced perioperative and short-term morbidity in DPPHR compared to pancreatoduodenectomy, whereas rates of pain relief and long-term outcomes seem to be equal [29]. However, a current Cochrane review of the reported RCT did not confirm significant differences [30]. A drawback of the reported RCT is a relatively low methodological quality [30] and the fact that they were not adequately powered for analysis of long-term results [29]. Equal results were reported from four RCT comparing Beger versus Frey procedures [29], and one RCT involved the Berne modification [31], reporting improved perioperative outcome compared to the Beger procedure.

Pure MPD drainage procedures such as the Puestow–Gillesby [32] (pancreatic left resection with splenectomy and laterolateral pancreatojejunostomy), Partington–Rochelle [33] (laterolateal pancreatojejonostomy) or Izbicki [34] (longitudinal V-shaped excision and laterolateral pancreatojejunostomy) operations do not remove the IPHM. MPD drainage in unselected patients only achieved 50–65% permanent pain control [6], which is inferior to that of pancreatic head resection with 75–95% [35–47]. Although no randomized trial has compared drainage versus resection procedures, drainage procedures are reserved for patients without IPHM. However, in case of mesentericoportal vein occlusion with portal hypertension and cavernous transformation, pancreatic head resection becomes impossible and therapy is limited to operative or endoscopic MPD drainage. Preoperative recanalization of the portal vein can be performed in selected patients with short-segment portal vein occlusion [48]. Gastroenterostomy and hepaticojejunostomy are measures of last choice for biliary or duodenal obstruction.

Correct timing is an important aspect in the management of patients with IPHM. A current systematic review confirms that the best results are achieved by early surgical therapy [49]. Maximum duration of a trial of nonoperative management of IPHM should be 6 months, as optimal operative treatment usually becomes impossible in an advanced stage. In the presence of mesentericoportal vein narrowing or partial thrombosis, elective surgery should be performed as soon as possible, and prophylactic anticoagulation is advocated prior to surgery.

Certain contraindications impede early surgery. Cachexia should be treated by high-caloric nutrition with adequate simultaneous supplementation of pancreatic enzymes and vitamins, and in case of gastric outlet obstruction by jejunal tube feeding, to achieve adequate nutritional status for operation. Elective surgery is also not indicated until at least 3 months have passed since the last episode of acute pancreatitis. Serum pancreatic enzyme activity can be used to monitor acute pancreatitis activity.

On histopathologic workup, IPHM is characterized by fibrotic atrophy of exocrine acinar epithelium, the remaining ductal and islet epithelia becoming "skeletonized" in fibrous connective tissue. Strong inflammatory granulocytic or lymphocytic infiltration is uncommon. In contrast, autoimmune pancreatitis typically shows duct-centric inflammation, with IgG4-positive plasma cells or granulocytic epithelial lesions [12]. As overall tissue organization is heavily disturbed and chronic pancreatitis can be associated with pancreatic intraepithelial neoplasia, distinction from PDAC can be difficult even for experienced pathologists. Intraoperative frozen section examination, at least of the surgical resection margins, is mandatory and in case of any doubt, radical oncologic resection is warranted.

## Conclusions

Chronic pancreatitis with IPHM is a domain of surgical therapy. The main differential diagnoses are pancreatic head cancer and autoimmune pancreatitis. Best results are achieved by resection of the pancreatic head mass with adequate drainage of the pancreatic duct early in the course of the disease, but pancreatic head resection may become impossible in advanced disease. Adequate workup and timing of conservative and surgical therapy ensure successful management.

## Introduction

The concept of chronic pancreatitis as a disease was established by Comfort et al. at the Mayo Clinic in 1946. They proposed that chronic pancreatitis occurs when pancreatic fibrosis has been gradually enhanced by repetitive acute inflammation and is characterized by the progressive destruction of the pancreas [1]. Later, the disease concept was described by the Marseille classification [2], the revised Marseille classification in 1984 [3], the Cambridge classification in 1984 [4], and the Marseille–Rome classification in 1988 [5]. In these classification systems, irreversible pancreatic changes associated with chronic pancreatitis were considered to cause progressive or permanent loss of pancreatic endocrine and exocrine functions. Because it has been shown that the mean life expectancy of patients with chronic pancreatitis is short and their rate of contracting pancreatic cancer is high [6,7], preventing the progression of the disease through early diagnosis and early intervention is desirable. In addition, the identification of genes responsible for hereditary pancreatitis, the clarification of the genetic background of idiopathic pancreatitis [8–11], and the discovery of pancreatic stellate cells [12–14] have been reported. Furthermore, it has been shown in an animal model of chronic pancreatitis that the disease conditions can recover completely by early treatment intervention [15,16], suggesting the importance of early intervention as well as early diagnosis. These findings led to the revision of the Clinical Diagnostic Criteria for Chronic Pancreatitis in Japan in 2009 to include a category of early chronic pancreatitis.

## Diagnosis of Early Chronic Pancreatitis

In Japan, the clinical diagnostic criteria were revised in 2009 and published as the "Japanese Clinical Diagnostic Criteria for Chronic Pancreatitis 2009" [17]. Early chronic pancreatitis was defined and incorporated as a disease concept in the new criteria (Fig. 44.1).

Early chronic pancreatitis is a disease that does not satisfy the conditions for the definitive diagnosis or probable diagnosis in the Clinical Diagnostic Criteria for Chronic Pancreatitis 2009 but satisfies two or more of the following conditions: (i) repetitive episodes of upper abdominal pain, (ii) abnormal pancreatic enzyme values in the blood/urine, (iii) pancreatic exocrine dysfunction, and (iv) a history of persistently consuming 80 g of alcohol or more per day. In addition, a patient should also have imaging findings of early chronic pancreatitis, as shown in Box 44.1. With regard to diagnostic imaging for early chronic pancreatitis, findings on either endoscopic retrograde pancreatography (ERP) or endoscopic ultrasound (EUS) are used, with the Cambridge classification [4] as a reference for ERP and the Rosemont classification [18] as a reference for EUS. However, findings from EUS, which can be more easily obtained for outpatients, are valued more than findings from invasive ERP. In addition, the guidelines indicate that diagnostic imaging, including EUS, within 3 months of diagnosis is desirable for suspected cases of chronic pancreatitis and that EUS is essential for diagnosing early chronic pancreatitis [19]. International consensus guidelines for chronic pancreatitis are currently being created. In the near future international criteria for diagnosis of early chronic pancreatitis will be needed.

**Box 44.1 Imaging findings required for a diagnosis of early chronic pancreatitis**

**a. More than two features present from among the following seven features of EUS findings, including at least one of (1) through (4)**

1) Lobularity with honeycombing
2) Lobularity without honeycombing
3) Hyperechoic foci without shadowing
4) Stranding
5) Cysts
6) Dilated side-branches
7) Hyperechoic MPD margin

**b. Irregular dilatation of more than three duct branches on ERCP findings**

Either a or b is required for diagnosis

ERCP, endoscopic retrograde cholangiopancreatography; EUS, endoscopic ultrasound; MPD, main pancreatic duct.

## Clinical and Genetic Definitions

Hereditary pancreatitis is a syndrome that encompasses acute pancreatitis, recurrent acute pancreatitis (RAP), and chronic pancreatitis. A new mechanistic definition of chronic pancreatitis is useful for framing hereditary pancreatitis as a process extending from asymptomatic risk to end-stage disease. Chronic pancreatitis is now defined both by its essence and its character as "a pathologic fibro-inflammatory syndrome of the pancreas in individuals with genetic, environmental and/or other risk factors who develop persistent pathologic responses to parenchymal injury or stress" [1]. In addition, "Common features of established and advanced chronic pancreatitis include pancreatic atrophy, fibrosis, pain syndromes, duct distortion and strictures, calcifications, pancreatic exocrine dysfunction, pancreatic endocrine dysfunction and dysplasia" [1]. The definition was designed to assist in the early diagnosis of chronic pancreatitis, the prognosis, and in the type and timing of potential therapies.

Hereditary pancreatitis is defined by clinical presentation in a family or by genetic test results in an affected individual. In families, hereditary pancreatitis is defined as two or more first-degree relatives or three or more second-degree relatives with RAP or chronic pancreatitis in two or more generations, consistent with an autosomal dominant inheritance pattern [2, 3]. Less commonly, families may appear to follow alternative inheritance patterns (e.g., autosomal recessive and complex). Alternatively, hereditary pancreatitis can be diagnosed in an individual with pancreatitis and a known pathogenic germline mutation, regardless of family history. Of importance, the penetrance of *PRSS1* hereditary pancreatitis is incomplete and, therefore, identification of a pathogenic *PRSS1* mutation in an asymptomatic individual is not sufficient for a diagnosis but does indicate high risk. Some families presenting with hereditary pancreatitis have pathogenic variants in the serine protease inhibitor Kazal type 1 gene (*SPINK1*), the cystic fibrosis transmembrane conductance regulator gene (*CFTR*), *SPINK1* plus *CFTR*, the chymotrypsin C gene (*CTRC*), or a more complex genotype [4]. Therefore, the absence of a pathogenic *PRSS1* variant does not preclude the diagnosis of hereditary pancreatitis in a family. A diagnosis of hereditary pancreatitis should always be considered for patients with idiopathic pancreatitis or early-onset pancreatitis, or in a family with multiple affected individuals.

Familial pancreatitis refers to the occurrence of pancreatitis of any cause in a family with an incidence greater than would be expected by chance alone. Familial pancreatitis does not follow an observable monogenic pattern of inheritance. Kindreds with familial pancreatitis may have shared genetic and/or environmental (e.g., alcohol, smoking, stress) risk factors that predispose them to pancreatitis above the general population risk.

## Epidemiology

Hereditary pancreatitis is a rare genetic disorder. In 1952, Comfort and Steinburg described a large family with hereditary pancreatitis [5]. Since this initial report, hundreds of hereditary pancreatitis kindreds have been identified in several regions in the United States [5–7] and Europe [8–10]. A few families have also been identified in Japan [11, 12], Korea [13], China [14, 15],

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

Malaysia [16], South America [17, 18], and Thailand [19]. The vast majority of hereditary pancreatitis kindreds identified in the United States are of European ancestry linked to large pedigrees (>500 people), suggesting founder effects (DC Whitcomb, unpublished data). However, haplotype analysis on local clusters of individuals with *PRSS1* R122H mutations in northern Germany suggested the presence of a mutation hotspot and excluded a single founder effect [20]. The reason that hereditary pancreatitis is rare in African and Asian populations is unknown.

The prevalence of hereditary pancreatitis differs by geographic region; hereditary pancreatitis has been observed most frequently in the United States and Europe. A national series of hereditary pancreatitis in France estimated a population prevalence of at least 0.3 per 100,000 [21]. In Denmark, 1% of persons with pancreatitis of unknown etiology were found to be positive for a *PRSS1* mutation [22]. The fraction of chronic pancreatitis patients with hereditary pancreatitis varies greatly from region to region and country to country as a result of founders originating from multiple generations in the past.

## Clinical Presentation

Hereditary pancreatitis typically presents with acute pancreatitis in early adolescence, with a high risk of progression to chronic pancreatitis by early adulthood (Fig. 45.1). In hereditary pancreatitis, the phenotypic features are confined to the pancreas, whereas *CFTR*-related disorders affect multiple organs as seen in cystic fibrosis. In patients who develop chronic pancreatitis, major comorbidities include pancreatic exocrine insufficiency, diabetes mellitus, and chronic pain syndromes. In comparison to chronic pancreatitis of other etiologies, hereditary pancreatitis has earlier age of onset and appears to have higher cumulative risks for exocrine and endocrine failure in patients that develop chronic pancreatitis, as well as increased risk for pancreatic cancer.

The disease penetrance for a *PRSS1* mutation has been consistently estimated as ~80% [9, 10, 23, 24]. However, a national series of *PRSS1*-tested patients in France identified a penetrance of 93% [21]. Of note, estimates of penetrance may be inflated by biased study ascertainments. This is evidenced by the discovery of an R122H *PRSS1* kindred with low penetrance of pancreatitis [18]. Penetrance may also differ by type of mutation and presence of modifying risk factors. Assessment of six families in northern Spain identified a penetrance of 40.9% for the R122C *PRSS1* mutation [25]. Lifespan is not reduced as compared to the general population, except in patients who develop pancreatic adenocarcinoma [26].

### Acute Pancreatitis

The median age of onset of acute pancreatitis is 10–12 years [10, 21]. Some studies have shown that the age of symptom onset is earlier in R122H *PRSS1* carriers compared to N29I carriers and mutation negative patients [10, 23, 27]. A multicenter European (EUROPAC) study of 418 subjects from 112 families identified an age of onset of 10 years for the *PRSS1* R122H mutation, 14 years for the N29I mutation, and 14.5 years in patients without an identified mutation [10]. Severity, length, and frequency of attacks are variable and can vary dramatically by family. In one large kindred, 58% of *PRSS1* R122H subjects were <5 years at the age of symptom onset [23]. Shared modifier genes and environmental factors in families contribute to age of onset and severity. For example, disease onset in four twin pairs differed by median of 1 year (range 0–2.4 years) as compared to 7 years (range 2–15 years) in a nonsibling comparison group matched for mutation, gender, and age [24].

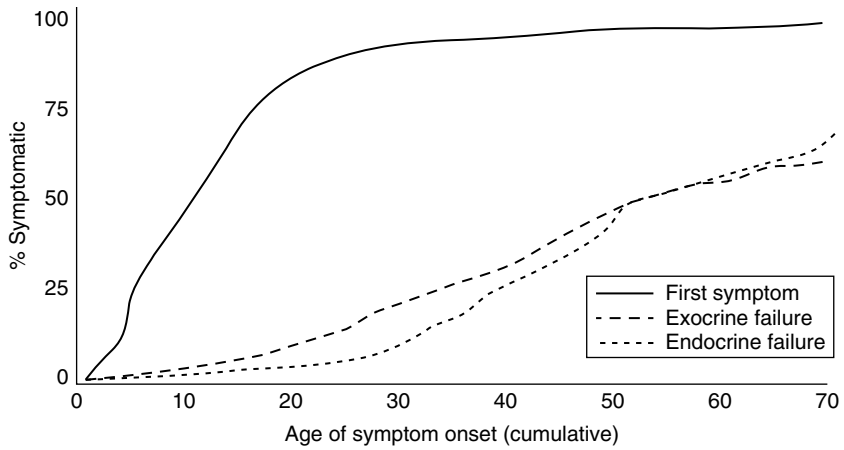

**Figure 45.1** Age at onset of first symptoms, pancreatic exocrine insufficiency and pancreatic exocrine insufficiency. *Source:* Data from [10].

At least 83% of patients experience epigastric abdominal pain [21]. The number of reported hospitalizations for acute pancreatitis varies by family and mutations status, with nearly 90% of affected individuals reporting more than five hospitalizations [10, 23, 27, 28]. The EUROPAC study found a significant reduction in hospital admission rates for patients with a *PRSS1* N29I mutation (0.19 per year) as compared to patients with a *PRSS1* R122H mutation (0.33 per year) [10]. However, the difference in number of attacks between patients with an N29I mutation (1.4 per year) and an R122H mutation (2 per year) was not significantly different, suggesting that the N29I mutation results in less severe attacks [10]. The same study found that the majority of attacks are ≤7 days in length [10], but smoldering pancreatitis and/or persistence of pain that lasts weeks or months has been reported in patients with hereditary pancreatitis [2].

### Chronic Pancreatitis

RAP progresses to chronic pancreatitis by the second or third decade of life in the majority of patients with hereditary pancreatitis. Rate and severity of pancreatic fibrosis and parenchymal destruction is highly variable, with a cumulative incidence of ~50% in a lifetime (Fig. 45.1). A trend exists between the number of attacks and degree of fibrosis, and this process is highly influenced by modifying factors. A study on pancreas histopathology in 10 patients with *PRSS1* hereditary pancreatitis demonstrated progressive lipomatous atrophy and adipose replacement of peripheral parenchyma [29].

### Pancreatic Exocrine Insufficiency

Progression of inflammation and fibrosis eventually leads to pancreatic exocrine insufficiency in a significant subset of patients. Pancreatic exocrine insufficiency occurs when the pancreas cannot supply a sufficient quantity of digestive enzymes to the intestines, leading to maldigestion. This is believed to occur with the loss of about 90% of pancreatic exocrine function [30]. The EUROPAC study identified cumulative risks for exocrine failure of 8.4% at 20 years, 37.2% at 50 years, and 60.2% at 70 years, with a median time to malabsorption of 53 years [10]. No significant difference in time to malabsorption was found between men and women [10].

### Diabetes Mellitus

As with other forms of chronic pancreatitis, chronic inflammation and progressive fibrosis also lead to islet cell injury. Glucose intolerance progresses to pancreatic endocrine insufficiency from loss of insulin-secreting beta cells. However, these patients also lose alpha cells so that they are at high risk for hypoglycemia. Diabetes mellitus from pancreatic exocrine disease and loss of the entire islets is classified as type 3c [31]. The danger of hypoglycemia is enhanced by untreated pancreatic exocrine insufficiency, since the ingestion of nutrients is not well coordinated with digestion and absorption. The cumulative risks for endocrine failure are 4.4% at 20 years, 47.6% at 50 years, and 79.1% at 80 years [10]. Median time to development of diabetes mellitus has been estimated to be 53 years and is not significantly influenced by gender and mutation status [10].

### Pancreatic Cancer

Hereditary pancreatitis is associated with a >50-fold increased risk for pancreatic adenocarcinoma [10, 26, 32–36]. Cumulative risk for pancreatic cancer at 70 years has been estimated to be as high as 40% to <54% [10, 21, 34]. The risk for pancreatic cancer is highest in smokers and individuals with diabetes mellitus. Smokers with hereditary pancreatitis have about a twofold increased risk for pancreatic cancer, with development of cancer 20 years earlier than nonsmokers [35]. The increased risk for pancreatic cancer appears to result from chronic inflammation rather than a *PRSS1* mutation itself, since all forms of chronic pancreatitis are associated with pancreatic cancer [37–40]. Early-onset pancreatitis in hereditary pancreatitis is one of the strongest known risk factors for pancreatic cancer.

Incidence of pancreatic cancer varies extensively between hereditary pancreatitis families, and some families have high incidences of pancreatic cancer in the absence of clear environmental factors, suggesting the presence of risk and/or protective variants. Screening for pancreatic cancer is recommended for patients with a known mutation associated with hereditary pancreatitis [41], but the approach remains unclear since hereditary pancreatitis is associated with significant morphologic changes in the pancreatic gland, making imaging approaches challenging.

## Management

As with pancreatitis of nongenetic etiology, management is aimed at prevention, reduction of symptoms such as fibrosis, pancreatic exocrine insufficiency and pancreatic endocrine insufficiency, and alleviation of pain. The approach should be based on targeting the underlying genetic factors, minimizing environmental stressors, and considering new therapeutic interventions as indicated. Alcohol, emotional stress, and dietary fat can exacerbate pancreatitis and should be avoided [9, 21]. Patients should also be counseled to refrain from smoking, which

doubles the already increased risk for pancreatic cancer [35]. Antioxidants may reduce pain in a subset of patients [42, 43]. Common recommendations include a low-fat diet with multiple small meals a day and proper hydration to reduce the risk of an attack, but these recommendations are not based on strong evidence.

Pancreatic exocrine insufficiency should be anticipated and managed with early initiation of pancreatic enzyme replacement therapy. The diagnosis of pancreatic exocrine insufficiency currently relies on clinical suspicion from abdominal bloating, diarrhea, steatorrhea, deficiency of fat-soluble vitamins or vitamin B12, or unexplained weight loss. The most common diagnostic tests include measuring low levels of human fecal elastase, low serum trypsinogen levels, or clinical response to a trial of pancreatic enzyme replacement therapy.

Diabetes mellitus is common both in patients with pancreatitis and in the general population. In hereditary pancreatitis, type 3c diabetes mellitus typically develops years after the onset of chronic pancreatitis [44]. The diagnosis is challenging, and standardized protocols are not widely accepted. However, the clinical context of advanced chronic pancreatitis, especially with pancreatic exocrine insufficiency, should indicate caution and a multidisciplinary approach involving endocrinologists and pancreatologists [44]. The destruction of the islets may limit the use of some antidiabetic medications, and the use of insulin must be balanced with the ingestion and digestion of the meal, which may require the addition of pancreatic enzyme replacement therapy.

In the absence of pancreatic cancer, the primary indication for surgery is pain [45, 46]. Total pancreatectomy with islet cell autotransplantation (TPIAT) can be considered in younger patients with intractable, narcotic-dependent pancreatic pain [47, 48]. Total pancreatectomy without islet autotransplantation can be considered in older patients with chronic pancreatitis for 20 years or more to reduce pain and as a last resort to reduce the risk of developing pancreatic cancer [45, 49]. The need and timing of this radical procedure requires both experience with the procedure and clear prognostic understanding of what will happen with and without TPIAT.

## Molecular Genetics

In 1996, a missense mutation in the cationic trypsinogen gene (*PRSS1*) was identified in a large hereditary pancreatitis family [50]. Mutations in *PRSS1* have since been identified in 65–100% of hereditary pancreatitis kindreds with an estimated penetrance of 80%. Since this discovery, additional genes associated with recurrent acute and chronic pancreatitis have been identified, particularly *SPINK1*, *CFTR*, and *CTRC* [51–54] (Tables 45.1 and 45.2). Other important genes that have been associated with chronic pancreatitis include *CLDN2* [55–57], *CASR* [3, 58], *CTSB* [59], *CPA1* [51, 55–57, 60], and *GGT1* [61]. Disease mechanisms for many of the genes associated with pancreatitis are complex, and gene–gene and gene–environment interactions are not fully defined [4, 51].

### *PRSS1*

Cationic trypsinogen is the most abundant isoform of trypsinogen (~65%), followed by anionic trypsinogen (*PRSS2,* ~30%) and mesotrypsinogen (*PRSS3*, ~5%) [62].

**Table 45.1** Genes associated with pancreatitis.

| Gene | Chromosome | Type of mutation | Mechanism |
|---|---|---|---|
| *CTRC* | 1 | Loss of function | Diminished trypsin degradation in pancreas |
| *CASR* | 3 | Loss of function; inappropriate localization | Elevated pancreatic calcium levels<br>Hypothesized premature activation of trypsin |
| *SPINK1* | 5 | Loss of function | Diminished trypsin degradation in pancreas |
| *PRSS1* | 7 | Gain of function<br>Loss of function | Premature activation of trypsinogen in pancreas<br>Hypothesized misfolding-induced endoplasmic reticulum stress; associated with nonalcoholic, early-onset CP |
| *CFTR* | 7 | Loss of function | Loss of or diminished bicarbonate conductance leads to detainment of trypsinogen in the pancreas |
| *CPA1* | 7 | Loss of function | Hypothesized misfolding-induced endoplasmic reticulum stress; associated with nonalcoholic, early-onset CP |
| *CTSB* | 8 | Unknown—hypothesized gain of function | Hypothesized to induce premature activation of trypsinogen |
| *CLDN2* | X | Altered regulatory element | Unknown; associated with alcoholic CP |

CP, chronic pancreatitis.

**Table 45.2** Genotype–phenotype correlations and multiorgan syndromes.

| Genotype (variants) | Phenotype (syndromes) | Comment |
|---|---|---|
| *PRSS1* | Hereditary pancreatitis | Genetic counseling recommended |
| *CFTR*$^{sev}$/*CFTR*$^{sev}$ | CF | Manage with a CF center |
| *CFTR*$^{sev}$/*CFTR*$^{m\text{-}v}$ | Atypical CF | Manage with a CF center |
| *SPINK1*/*SPINK1* | Familial pancreatitis | Usually progresses to severe CP |
| *CFTR*$^{bicarb}$/*CFTR*$^{any}$ | Pancreas/sinus/CBAVD | Newly defined syndrome |
| *CFTR*$^{any}$/*SPINK1* | RAP/CP | Pancreas only |
| *CTRC*/*SPINK1* | RAP/CP | Pancreas only—not well studied |
| *CASR*/*SPINK1* | RAP/CP | Pancreas only—not well studied |

*CFTR*: sev, severe mutations (typically functional class I–III); m-v, mild-variable mutations (typically *CFTR* functional class IV); bicarb, bicarbonate conductance-disrupting variant (e.g., R75Q); any, either severe, mild-variable, or bicarbonate-disrupting variants; CF, cystic fibrosis; CP, chronic pancreatitis; RAP, recurrent acute pancreatitis; CBAVD, congenital bilateral absence of the vas deferens.

Trypsinogen is the inactive zymogen of trypsin, a digestive enzyme and regulator of all pancreatic zymogens, except amylase and lipase. The trypsinogen activation peptide maintains the inactive enzyme until it is cleaved by enterokinase or another trypsin, generally in the duodenum. Self-destruction (autolysis) occurs at R122, which is located on the single chain that links the two globular domains of trypsin [63, 64]. Two calcium-binding pockets serve as "on–off" switches in response to calcium concentrations, inducing distinct conformational changes. Increased calcium concentrations facilitate trypsin activation, whereas reduced calcium levels permit autolysis [65].

*PRSS1* gain-of-function mutations fall into two categories: (i) premature activation of trypsin in the pancreas or (ii) resistance to degradation [27, 66, 67]. Archer et al. confirmed the pathogenicity of *PRSS1* R122H mutations in transgenic mice that presented with early-onset acinar cell injury and dedifferentiation, inflammatory cell infiltration, and progressive pancreatic fibrosis [68]. In humans, elevated levels of pancreatic trypsin lead to progressive lipomatous atrophy of the pancreatic parenchyma and adipose replacement [29]. Fibrosis is thin and loosely packed, in contrast to alcoholic and obstructive chronic pancreatitis [29]. Many of the less common *PRSS1* variants found in patients with pancreatitis do not appear to be gain-of-function mutations. Instead, they may represent coding region variants causing protein misfolding, and triggering an unfolded protein stress response that drives fibrosis in a poorly defined way [69].

The most common *PRSS1* mutations are R122H and N29I (90%), previously designated as R117H and N21I by the chymotrypsin numbering system [10, 21, 70]. Less common mutations include A16V, R122C, N29T, D22G, and K23R. Mutations have primarily been identified in exons 2 and 3, but rare variants have also been identified in the 5′ UTR, introns 1–4, and exons 4 and 5 (see www.pancreasgenetics.org). Copy number variations of the *PRSS1-PRSS2* locus have also been associated with chronic pancreatitis [71].

### *SPINK1*

The serine protease inhibitor Kazal type 1 (*SPINK1*; *PST1*) is a trypsin inhibitor secreted from pancreatic acinar cells. Loss-of-function mutations in *SPINK1* reduce its protective function and predispose to pancreatitis [72]. Mutations are found in ~2% of the population and confer a 12-fold increased risk for pancreatitis [72, 73]. Nevertheless, fewer than 1% of *SPINK1* carriers develop pancreatitis. Biallelic loss of function mutations in *SPINK1* may lead to autosomal recessive pancreatitis. However, the majority of affected patients with *SPINK1* mutations are heterozygous, indicating the presence of complex gene–gene and gene–environment interactions [74]. For example, *SPINK1* can act as a disease modifier, and compound heterozygosity for pathogenic variants in *SPINK1/PRSS1* and, more commonly, *SPINK1/CFTR* has been reported [53, 75].

*SPINK1* mutations have been detected in 16–23% of patients with idiopathic chronic pancreatitis [72, 76, 77]. The most common high-risk haplotype identified in the United States and Europe is *SPINK1* N34S [72]. The *SPINK1* IVS3 + 2 T > C splicing variant is common in Japan, China, and Korea [78–80].

### *CFTR*

Mutations in the cystic fibrosis transmembrane conductance regulator (*CFTR*) are more common among patients with idiopathic chronic pancreatitis [81–83]. *CFTR* mutations may impair both chloride and bicarbonate conductance (e.g., severe mutations) or only

bicarbonate conductance [84]. Homozygosity or compound heterozygosity for two "severe" *CFTR* mutations generally causes cystic fibrosis [85], whereas "mild-variable" or other mutations are associated with RAP, chronic pancreatitis, and/or other CFTR-related disorders [86]. *CFTR* carriers that develop pancreatitis are also likely to have an additional genetic (e.g., *SPINK1, CTRC*) or other (e.g., pancreas divisum) risk factor [53, 75, 87, 88]. CFTR-associated pancreatitis is considered in Chapter 47.

### *CTRC*

Chymotrypsin C (CTRC) is a digestive enzyme and the primary regulator of trypsin. The action of chymotrypsin C is twofold and dependent on calcium concentrations. In the calcium-rich duodenum, chymotrypsin C promotes trypsinogen activation, but in solutions with lower calcium concentrations, it mediates trypsin degradation [89]. As with *SPINK1*, chymotrypsin C is believed to protect the pancreas from premature trypsin activation, with genetic defects increasing the risk of trypsin-mediated pancreatitis [90, 91]. Two mutations, R254W and K247_R254del, were found to be overrepresented in patients with idiopathic or hereditary chronic pancreatitis [90, 92]. The c.180 T > G variant has been identified in about 10.8% of persons of European ancestry in North America and moderately increases the risk of progression from recurrent acute to chronic pancreatitis, particularly in the presence of alcohol, tobacco, or *PRSS1*/*SPINK1* mutations [93]. The independent effects of pathogenic *CTRC* variants appear to be low, but they clearly increase the risk of chronic pancreatitis in the context of other risk factors such as pathogenic *CFTR* variants [53], and can contribute to familial clustering of chronic pancreatitis cases.

## Genetic Testing and Counseling

When a patient or family is suspicious for hereditary pancreatitis, a (minimum) three-generation pedigree should be collected, including family history of pancreatitis, age of onset, age at diagnosis for multiple pancreatic episodes, and pancreatic cancer [94]. Other information valuable for assessment of a family includes smoking and alcohol exposure, diabetes mellitus, pancreatic insufficiency, male infertility, cystic fibrosis chronic sinusitis, and nasal polyps [94]. Calculation of risk in a family depends on genotype, pattern of inheritance in the family, and environmental exposures (e.g., tobacco, alcohol).

Indications to offer genetic testing in a symptomatic patient include unexplained RAP and/or chronic pancreatitis, a first- or second-degree relative with pancreatitis, and/or unexplained pancreatitis in a child requiring hospitalization [95]. Genetic testing is commercially available for *PRSS1, SPINK1, CFTR,* and *CTRC,* including full gene sequencing. Deletion/duplication analysis may be considered in a proband if a mutation is not identified from sequencing or targeted mutation analysis.

Genetic testing should always be preceded and followed by appropriate genetic counseling [96, 97]. Results may have implications for patient risk, risk to other family members, and family planning [96, 98]. Another concern for genetic testing in this patient population, especially in the United States, is insurance discrimination [98]. The Genetic Information Nondiscrimination Act of 2008 (GINA, Pub. L, 110–233) protects against genetic discrimination in health insurance and employment in the United States, but does not cover life, disability, or long-term care insurance. Patients and families should understand the benefits, limitations, and costs of genetic testing before the test is ordered [97]. Therefore, clinicians must understand the consequences of genetic testing and should provide counseling directly or refer patients to a genetic counselor to obtain appropriate informed consent.

Genetic testing in a symptomatic patient can clarify etiology and provide information on risk for related complications, such as pancreatic cancer. Identification of a responsible mutation may clarify risk for family members and provide information relevant to family planning. *PRSS1*-related hereditary pancreatitis follows an autosomal inheritance pattern, and each child of a parent with a *PRSS1* mutation has a 50% or 1 in 2 chance of inheriting the deleterious allele. About 80% of individuals who inherit a *PRSS1* mutation develop pancreatitis. Therefore, each child of a parent with a *PRSS1* mutation has a ~40% chance of developing hereditary pancreatitis. However, variation in penetrance and severity exists between hereditary pancreatitis kindreds, and family history should always guide interpretation of results and risk calculation. Identifying a responsible genetic mutation in a family may also expedite diagnosis of family members and prevent unnecessary evaluation for other etiologies.

Predictive genetic testing in an asymptomatic individual is available when a mutation has been identified in a close family member. Testing for this mutation can clarify risk to develop pancreatitis and risk to descendants. Genetic testing may also identify family members that would benefit from lifestyle interventions to reduce risk and severity, such as avoidance of alcohol, smoking, and fatty foods.

A negative test result in a patient from a family with a known mutation reduces but does not remove the risk for hereditary pancreatitis. Families may share additional, unidentified risk factors that predispose to pancreatic disease. Furthermore, not all families in which

hereditary pancreatitis appears have an identifiable mutation in *PRSS1*, *SPINK1*, *CFTR*, or *CTRC*. In a family without an identifiable mutation, genetic testing of asymptomatic family members will be uninformative and discussions of risk must be tailored according to the presentation of disease within the family.

### Genetic Testing in Children

The decision to pursue genetic testing in a child is the responsibility of the parents or legal guardian. When a child is 7 years or older, the child should provide assent for genetic testing. Testing of a symptomatic child can explain or confirm the diagnosis of pancreatitis and prevent unnecessary further evaluations.

Predictive genetic testing for hereditary pancreatitis is generally not recommended for patients less than 16 years of age [95]. There are no clear medical benefits to identifying asymptomatic carriers at a young age, and waiting to pursue testing gives the patient the opportunity to make an informed adult decision [96, 99]. Predictive testing to identify children who would benefit from diet, lifestyle, medication, or surveillance interventions has been advocated [99]. However, avoidance of pancreatitis risk factors, particularly fatty foods, alcohol, tobacco, and stress, are advised for all children regardless of mutation status [96].

# Epidemiology and Pathophysiology of Tropical Chronic Pancreatitis

*Shailesh V. Shrikhande*[1] *and Savio George Barreto*[2]

[1] *Gastrointestinal and Hepato-Pancreato-Biliary Surgical Oncology, Tata Memorial Centre, Mumbai, India*
[2] *Department of Gastrointestinal Surgery, Gastrointestinal Oncology, and Bariatric Surgery, Medanta Institute of Digestive and Hepatobiliary Sciences, Medanta, The Medicity, Gurgaon, India*

## Introduction

In 1937, Kini [1] published a report on chronic calcific pancreatitis from India and in 1954 similar findings in autopsy studies were reported from the south of India [2]. Although the features presented in these reports were strikingly similar to the report on 45 malnourished patients from Indonesia published a couple of decades later, the credit for describing tropical (chronic) pancreatitis (TCP) as a distinct entity rests with Zuidema [3,4]. These patients were from poor families and were suffering from protein calorie malnutrition.

GeeVarghese [5,6] provided detailed descriptions of the features that constituted TCP based on his analysis of patients in Kerala, southern India. This body of work now forms the framework on which our understanding of TCP resides.

TCP is considered a distinct subtype of chronic pancreatitis, comprising calcifying, nonalcoholic chronic pancreatitis that affects younger, generally malnourished individuals from the tropical regions of Asia [7–11], Africa [12–15], and South America [16,17]. A male predominance was also noted [18–20]. There have been occasional reports of the disease from developed nations, usually due to diagnosis in migrants arriving from the developing world [21]. In the past, the entity has been given various names, including tropical calcific pancreatitis, tropical pancreatic diabetes, nutritional pancreatitis, juvenile pancreatitis syndrome, Afro-Asian pancreatitis, tropical calculous pancreatopathy, and fibrocalculous pancreatopathy, or fibrocalculous pancreatic diabetes (FCPD). However, the name most commonly employed today is tropical chronic pancreatitis [22,23].

GeeVarghese described the natural history of TCP as "recurrent abdominal pain in childhood, diabetes around puberty and death at the prime of life" [5]. Barman and colleagues presented the triad of symptoms that comprised TCP, namely, abdominal pain, maldigestion and steatorrhea, and diabetes mellitus [24].

To date, there have been few large-scale epidemiologic studies on the prevalence of TCP. A field study from Kerala in southern India, involving 28 567 inhabitants, determined the prevalence of TCP to be 1:793 in that region [8] based on well laid out criteria for diagnosis of the disease. The study revealed that contrary to previous hospital reports, TCP in Kerala appeared to have a female preponderance (male:female ratio of 1:1.8), older age at disease onset (mean 23.9 years), and evidence of milder disease. Early attempts to understand the nature of the disease had included hospital studies and a couple of monographs published by GeeVarghese [5,22] based on his experience of more than 1500 patients with the disease. Balaji et al. [8] pointed out that the findings in these prior studies were potentially influenced by need for healthcare (patients presenting only when symptomatic) as well as access to healthcare being preferentially available to males.

A large nationwide study from India that included 1086 chronic pancreatitis patients has determined that that idiopathic chronic pancreatitis is now the most common subtype of the disease in the country (accounting for 60% of cases) [25]. These findings are not too dissimilar from those of a survey in the Asia-Pacific region which found that the 70% of patients from India and China could be labeled as having idiopathic chronic pancreatitis [9]. Interestingly, in the study by Balakrishnan

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

et al. [25], when well-defined criteria for TCP were applied, TCP was found in only 3.8% of patients. The authors conjectured that these findings may reflect overrepresentation of the disease owing to the interchangeable use of the terms "idiopathic chronic pancreatitis" and "tropical chronic pancreatitis," with the possibility that the true incidence of the TCP lies somewhere in between this wide variation.

A declining incidence of TCP has also been noted in other studies from India [26,27]. Whether this is a reflection of improving socioeconomic conditions accompanied by improved nutrition [25,28], an increase in smoking and alcohol consumption among young people [26], or simply a better definition of the entity "idiopathic chronic pancreatitis," leading to more individuals fitting these criteria rather than TCP [29], remains to be determined.

## Pathophysiology

The initial documentation of cases of TCP in malnourished patients from the tropics and from poorer populations [1,4] instinctively led researchers to focus on dietary components as a cause for the disease [30]. Over the years, detection of TCP in apparently healthy individuals with a normal nutritional status (as per their body mass index [BMI]) [31,32] led to micronutrient deficiency being more intensively investigated. Eloquent studies teasing out pathologic changes [33] and genetic mutations and comparing these with other subtypes of chronic pancreatitis have heralded a possibly more objective approach to the understanding of the entity [34,35].

### Pathology

Gross appearance of the gland depends on the duration of disease, degree of fibrosis, the presence of cysts, and location and size of calculi [36]. With the passage of time, the gland undergoes uneven fibrosis and atrophy, often leading to an eccentric ductal location [23] with the gland often appearing finger-like with a nodular and irregular surface [37].

One of the hallmarks of TCP is the presence of large calculi composed of 95.5% calcium carbonate (mainly in the form of calcite [38]), a small amount of calcium phosphate and traces of magnesium, urate, and oxalate distributed throughout the ductal system varying in color, shape, and size [23]. The calculi possess an amorphous nidus and a cryptocrystalline periphery [39]. The biochemical and structural nature of calculi in TCP is similar to those in other subtypes of chronic pancreatitis [23]. The larger stones tend to form towards the head, with their size decreasing towards the tail region.

On microscopic examination, the hallmark of TCP is the degree of intralobular fibrosis [33], which is uniform throughout the pancreatic parenchyma [40]. Nair [36] found that TCP was characterized by a lack of inflammation, and suggested that the name "tropical calcific pancreatopathy" would be more appropriate. However, these findings have not been corroborated by others. Shrikhande and colleagues [33] compared the histologic appearance of TCP with that of alcoholic chronic pancreatitis (ACP) and idiopathic chronic pancreatitis and revealed similar histologic features and a comparable inflammatory cell reaction in all three subtypes, although the extent of the pathologic change was variable in the individual types. The degree of endophlebitis and plasma cell density was significantly higher in TCP [33]. This finding of plasma cell infiltration of the pancreas is in keeping with the report of Nagalotimath, who also found a lymphocyte infiltration mainly around the ducts [37]. Cyriac and colleagues [41] have recently demonstrated that stellate cell activation occurs in a similar manner to other subtypes of chronic pancreatitis. Total fatty replacement of parenchyma has been noted to be a striking feature in TCP, and is seen exclusively in patients with diabetes with gross atrophy of the islets of Langerhans [40]. Moreover, in patients with established diabetes secondary to TCP (FCPD), histopathologic examination and immunohistochemistry have revealed varying extents of acinar atrophy and parenchymal destruction [23], along with a lack of alpha and beta cells and a reduction in glucagon positivity, and areas of nesidoblastosis [37,42].

An interesting observation in the pathologic assessment of tissues of patients with TCP when compared with alcoholic and idiopathic chronic pancreatitis is the increase in neural tissue and neural alterations associated with progression of the disease towards a stage amenable to surgery [43], a hallmark of pain accompanying chronic pancreatitis [44]. It is not only the neural alterations that are identical but other histologic aspects including the degree of endophlebitis, overall density of plasma cells, and inflammatory cell reaction, suggesting that independent of the underlying etiology, the pathologic changes accompanying chronic pancreatitis eventually reach a common immunologic stage beyond which chronic pancreatitis appears to progress as a single distinctive entity [33].

### Nutrition (Including Cassava)

The initial reports of TCP originating from regions in the developing world coupled with the clinical picture of young emaciated patients, intuitively led clinicians to focus on the nutritional aspect, or more specifically, protein calorie malnutrition [4,12,45]. However, over the years, a more objective approach to investigating the role

of malnutrition as a causative agent has led pancreatologists to infer that malnutrition in itself is not the main cause for TCP [46] and the nutritionally deprived state may rather be an effect of the malabsorption associated with disease [47,48]. Patients with kwashiorkor do not develop features of TCP [23,49]. Moreover, although malnutrition exists in many countries in the world, there are no reported cases of TCP/FCPD from some of them [50]; on the other hand TCP cases have been reported even among patients from well-nourished families [23]. Nonetheless, whether it is cause or effect, malnutrition remains a major issue in TCP and addressing it in its entirety forms an essential part of the work-up and management of patients with TCP [51].

Although malnutrition may not be the only etiologic factor in the causation of TCP, it is very likely that micronutrient deficiency, along with varying degrees of macronutrient deficiency and oxidant stress are cofactors in the causation of TCP.

#### Cassava Toxicity

Cassava (tapioca, *Manihot esculenta* Crantz) was implicated as a cofactor in the causation of TCP based on three factors: (i) the observation that the geographic area of Kerala where cassava is the staple diet of people of low socioeconomic class has a high incidence of TCP [52]; (ii) the cyanogenic glycoside composition of cassava (93% linamarin and 7% lotaustralin), which requires sulfur derived from the sulfur-containing amino acids (such as cysteine and methionine, which are believed to be inherently deficient in malnourished individuals) for its detoxification [53]; and experimental induction of hyperglycemia on feeding cyanide to rats [30] or hypoinsulinemia and histopathologic changes of necrosis, hemorrhage, and fibrosis of the exocrine and endocrine portions of the pancreas in dogs fed on cassava [54].

Although the activity of the cyanogen-detoxifying enzyme rhodanase has been shown to be reduced, accompanied by a decrease in sulfur-containing amino acids and antioxidants such as glutathione in TCP patients [55], neither this study [55], nor any of the other case–control or cohort clinical studies [49,56,57] were able to conclusively prove the role of cassava consumption in the causation of TCP. Besides, TCP has been reported even from regions where cassava is not consumed [9,25]. Even in the experimental setting, long-term ingestion of tapioca by rats failed to result in the development of diabetes or pancreatitis [58].

### Antioxidants (Including Micronutrients)

It has been hypothesized that escalating oxidative stress within the acinar cells as a result of cytochrome p450 superfamily induction, deficiency of micronutrients required to maintain stores of reduced glutathione, and exposure to bioactivated chemicals [59,60] plays a role in the development of chronic pancreatitis.

In patients with TCP the surrogate marker for p450I activity, namely theophylline clearance, was found to be faster in cases than in controls [61]. In addition, the bioavailability of ascorbic acid and beta-carotene that predispose to pancreatic oxidative stress was found to be signficantly reduced in South Indians (from Chennai) with TCP as compared to patients with chronic pancreatitis from Manchester [35]. Girish and colleagues [62] observed enhanced lipid peroxidation with concomitant decrease in antioxidant status in patients with TCP as compared to healthy subjects. Moreover, in the same study, they noted that zinc deficiency appeared to affect the oxidative status in patients with TCP. The same group also noted a correlation between zinc deficiency and exocrine and endocrine insufficiency in chronic pancreatitis patients [63]. They observed a marked effect of diabetes in zinc levels in patients with TCP as compared to those with ACP [63]. Other postulated mechanisms by which zinc deficiency could contribute to the progression of chronic pancreatitis include reduction of free radical scavengers, increased collagen deposition, and possibly an alteration in immune function [64].

### Genetics of Tropical Chronic Pancreatitis and Familial Clustering

The finding that aggregations of patients with TCP occur in certain families [65], reported as occurring in up to 8% of TCP patients [66], raised the possibility of heredity as another potential contributory factor to the development of TCP. Although there has been no further evidence to support this initial finding, the role played by genetic mutations as important regulators of pancreatic secretion, as well as the innate protective mechanisms against premature zymogen activation have been extensively studied in patients with TCP. Table 46.1 provides a comprehensive list of the most significantly proven mutations involved in the pathogenesis of TCP [34,67–74]. Mahurkar and colleagues [75] presented an interesting model called the "two-hit model" to hypothesize the pathogenesis of TCP. In this model they proposed that the first hit was the presence of persistent "super trypsin" within the acinar cell—the result of a loss of balance between activation events and degradation of active trypsin as a result of mutations in one or more of the aforementioned genes. This would lead to inflammation in the gland. A second hit in the form of another sequence of genetic mutations with or without environmental factors would then lead to the clinical disease entity of TCP.

## Natural History of the Disease

In the original reports of TCP, the disease was noted to affect young individuals between the ages of 10 and 30 years who also demonstrated features of protein and calorie malnutrition, along with bilateral parotid enlargement and occasionally a cyanotic hue to the lips [5,76]. They also had recurrent severe upper abdominal pain radiating to the back that was relieved by bending forward. In the ensuing years it was noted that although some patients developed features of pancreatic exocrine insufficiency, such as maldigestion and steatorrhoea, others did not do so because of their low-fat diet. They developed diabetes mellitus within 10–20 years from the onset of the initial symptoms of pain [31]. Mohan and colleagues [77] determined that the median time to development of diabetes mellitus in patients with TCP was 9.6 years from diagnosis and this was associated with older age, higher body mass index, and lower fecal chymotrypsin level. The development of diabetes mellitus in TCP has been hypothesized to be a result of two mechanisms: the pathogenetic process of tissue fibrosis eliciting chronic pancreatitis and selective pancreatic beta-cell impairment [78]. TCP is associated with an increased risk of pancreatic cancer development [79]. In a study from Chennai (India), the relative risk of pancreatic cancer in patients with TCP was estimated to be significantly high at 100 (95% CI: 37–218) [80].

In comparison to the initial reports of the poor clinical course of TCP which resulted in death by early adulthood [22], a survival analysis of 370 patients in the mid-1990s determined that patients with TCP were living much longer than before [81], with 80% of patients being alive 35 years from the onset of the first episode of abdominal pain and a mean of 25 years from the diagnosis of diabetes mellitus. The causes of death in TCP include diabetes-related complications, pancreatic cancer [82], and severe infections [24].

## Conclusion

In conclusion, the incidence of TCP is reducing, even in developing countries. The disease is witnessing a paradigm shift in relation to a number of aspects, including the reduced emphasis on macronutrient, protein calorie malnutrition, and cassava ingestion as etiologic factors, in favor of micronutrient deficiency (including zinc) and oxidant stress, an increased appreciation of the role of gene mutations in the pathogenesis of the disease, and, finally, significantly improved survival, possibly as a result of better management of the disease and its attendant complications.

# Cystic Fibrosis (CFTR)-Associated Pancreatic Disease

*Chee Y. Ooi*[1] *and Aliye Uc*[2]

[1] *School of Women's and Children's Health, Medicine, University of New South Wales and Sydney Children's Hospital Randwick, Sydney, NSW, Australia*
[2] *Stead Family Department of Pediatrics, Division of Pediatric Gastroenterology, University of Iowa Children's Hospital, Iowa City, IA, USA*

## Introduction

There is a spectrum of pancreatic diseases associated with cystic fibrosis transmembrane conductance regulator (*CFTR*) [1, 2] mutations that includes classic cystic fibrosis (CF) (pancreatic insufficient or sufficient) and CFTR-associated pancreatitis. The pancreas pathology and damage are dependent on the amount of functional CFTR: the lower the function the more prominent and earlier the sequelae. In addition, *CFTR* mutations may contribute to the development of acute recurrent and chronic pancreatitis.

## Pathophysiology—Genotype and Phenotype Correlations

Although around 2000 *CFTR* mutations have been identified, the functional importance is known only for a small number of them. *CFTR* mutations can be classified into six types of defects (class I–VI mutations) [3]: absence of protein synthesis (class I); protein misfolding and premature degradation (class II); disordered regulation (class III); defective chloride ($Cl^-$) conductance or channel gating (class IV); a reduced number of *CFTR* transcripts due to a promoter or splicing abnormality (class V); and accelerated turnover from the cell surface (class VI) (Fig. 47.1) [4–6]. *CFTR* function is virtually absent with class I–III and VI mutations, whereas class IV and V mutations allow some residual *CFTR* function [7]. Pancreatic function correlates well with gene mutations at the *CFTR* locus. Exocrine pancreatic insufficiency is seen almost exclusively in association with class I–III and VI mutations [5]. The absence of phenylalanine at position 508 (F508del, a class II mutation) constitutes two-thirds of *CFTR* mutations in northern European and North American populations. No other single mutation accounts for more than 5% of *CFTR* mutations worldwide [4]. Patients with at least one mutation belonging to classes IV or V generally present with milder disease, symptoms in late childhood or adulthood and are pancreatic sufficient.

CFTR is expressed in epithelial cells of various organs, including pancreatic ducts, and it functions as an apical membrane anion channel, involved primarily in anion secretion [4, 8–10]. It is generally agreed that the lack of CFTR leads to acidic, dehydrated, and protein-rich secretions [11–15], which then plug the acinar and ductal lumen [16–24] and cause the destruction of the pancreas in CF. Although pancreatic disease is universal in CF, the timing of disease onset and the steps between the lumen-occluding secretions and the pancreatic damage are not well understood. The findings in the CF pig model suggest that the pathogenesis of progressive pancreatic damage in CF may be, in part, a consequence of the activation and progression of proinflammatory, proapoptotic, profibrotic, and complement cascade pathways [25].

Among the various gastrointestinal organs affected by CF, the exocrine pancreas shows the strongest association between genotype and phenotype. In patients with lowest CFTR function, considerable destruction of the pancreas starts *in utero* and functional loss of the exocrine pancreas develops at birth or in early infancy [26]. A group of patients with CF who have residual pancreatic exocrine function (pancreatic sufficient) are prone to recurrent attacks of pancreatitis and may become pancreatic insufficient over time [27, 28].

Early studies suggested that *CFTR* mutations contributed to the development of chronic pancreatitis alone or if additional risk factors were present [29–33]. Many of

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

these studies were limited by relatively small numbers of patients, lack of control groups, and incomplete *CFTR* gene sequencing [18]. Recent studies with larger German, French, and North American cohorts confirmed these earlier findings that *CFTR* variants play a role in idiopathic chronic pancreatitis [34–36]. The recent studies show no increased risk for chronic pancreatitis with common polymorphic alleles T5 and TG12; the role of T5–TG12 complex allele remains to be determined [35]. The potential effect of *CFTR* mutations on risk for chronic pancreatitis is summarized in Table 47.1 [37]. It is not known whether other risk factors modulate CFTR levels and function to cause pancreatic inflammation, but a recent animal study suggests that this may be the case with alcohol-induced pancreatitis [38].

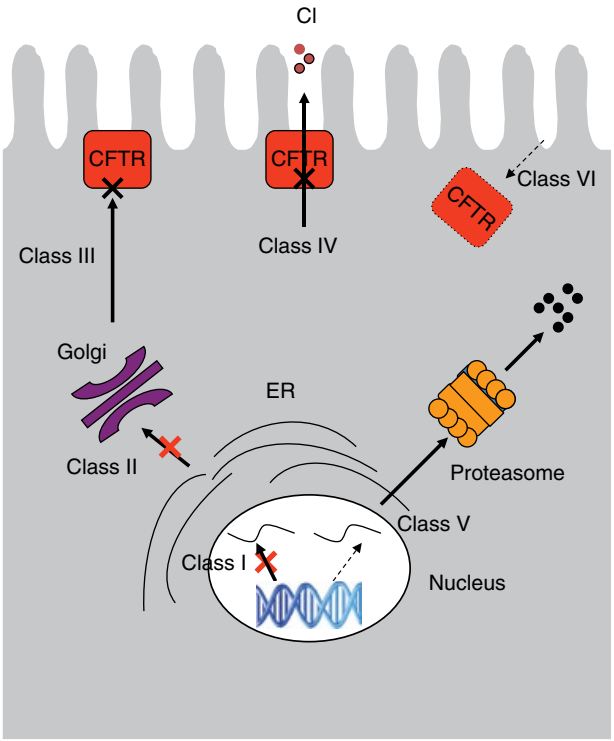

**Figure 47.1** Classes of *CFTR* mutations.

## Clinical Manifestations

The clinical manifestations of CFTR-associated pancreatic diseases correlate with the degree of pancreatic injury. Exocrine pancreatic damage in its severe form manifests as exocrine pancreatic insufficiency (EPI), which is present in 60–75% of infants at time of CF diagnosis [39, 40]. Pancreatic lesions begin *in utero* and continue into early childhood, when complete loss of pancreatic acinar tissue occurs [18, 39]. Fat maldigestion with resultant steatorrhea happens only when pancreatic colipase/lipase secretion falls below 1–2% of normal levels [41], with risk of malnutrition and fat-soluble vitamin deficiencies. A causal relationship between early pancreatic disease in CF and the development of CF-related diabetes has also been reported [42]. Patients with sufficient pancreatic function who either have CF or CFTR-related disorder are at risk of developing symptomatic acute and acute recurrent pancreatitis. Recurrent pancreatic inflammation is a risk factor for further loss of residual function and progression to EPI [43].

With increasing survival of patients with CF, an increased risk of malignancy in the gastrointestinal and

**Table 47.1** Effects of *CFTR* mutations on chronic pancreatitis risk.

| *CFTR* alleles | Pancreatitis risk | Examples |
|---|---|---|
| Severe/severe (compound heterozygotes) | No risk, patients have CF and EPI | F508del/F508del, F508del/G551D |
| Severe/mild-variable (compound heterozygotes) | Pancreatic sufficient CF; 15–20% may have pancreatitis | F508del/R117H; F508del/R334W |
| Mild-variable/mild-variable (compound heterozygotes) | Pancreatic sufficient CF; 15–20% may have pancreatitis | R117H/R117H; R117H/G85E |
| Severe/– (CF carrier) | Low, ~2-fold increase from general population | F508del/– |
| Mild-variable/– | Low, ~4-fold increase from general population | R117H/– |
| Non-CF causing | Possibly low; ~ < 1.5-fold increase from general population | p.R75Q, p.L997F |
| T5 | None | |
| TG12 | None | |
| T5-TG12 | Unknown | |

CF, cystic fibrosis; EPI, exocrine pancreatic insufficiency; CFTR, cystic fibrosis transmembrane conductance regulator.

biliary tracts has been observed [44]. The risk of malignancy in the pancreas was reported in a subanalysis to be greater than the overall risk of cancer in the digestive tract (odds ratio (95% CI) 31.5 (4.8–205) vs. 6.4 (2.9–14), respectively).

Despite treatment with pancreatic enzymes that prevent severe malnutrition, exocrine pancreatic involvement impairs growth and accelerates the progression of lung disease [45–48], the major cause of mortality in CF [49]. CF patients develop diabetes mellitus as they age: ~10% of patients have cystic fibrosis-related diabetes mellitus (CFRD) by 10 years of age, and ~50% of CF patients over 30 years of age have CFRD [50, 51]. CFRD is associated with a rapid decline in pulmonary function, higher morbidity, and greater mortality [26, 52]. The diagnosis of CFRD is preceded by a decline in body weight and lung function, along with insulin deficiency [51, 53].

Recurrent acute and chronic pancreatitis are known complications of CF, and they may occur in ~15–20% of patients with sufficient pancreatic function [4, 54]. It is not known why a subgroup of patients with CF develops pancreatitis, but preservation of acinar cells seems to be a prerequisite for this complication.

## Diagnosis

The rationale for testing for CF is the risk of multiorgan involvement in CF-affected organs and available effective therapies. Several studies have shown that a large proportion of pediatric and adult patients with idiopathic acute recurrent and chronic pancreatitis carry mutations in the *CFTR* gene. In a study of children affected by pancreatitis, *CFTR* mutations were identified in 30 of 89 (34%) and 24 out of 104 (23%) of children with acute recurrent and chronic pancreatitis, respectively [55]. In a separate study of 42 children and adults with idiopathic acute recurrent and chronic pancreatitis, extensive *CFTR* genotyping identified 50% of patients with either 1 or 2 *CFTR* variants [56].

Currently, the diagnostic criteria for CF require the presence of characteristic symptom(s) of CF disease or a positive family history, *plus* an abnormal sweat chloride value (≥60 mmol/L) and/or two CF disease-causing mutations [57]. Consensus guidelines [57, 58] recommend the diagnostic terminologies of: (i) "CF disease," to describe patients who fulfill the currently accepted diagnostic criteria; or (ii) "CFTR-related disorder," to describe individuals with the CF phenotype (e.g., pancreatitis), who have evidence of CFTR dysfunction but insufficient to fulfill the diagnostic criteria for CF disease (e.g., borderline sweat test and/or 1–2 non-CF causing mutation(s).

As the majority of nearly 2000 CFTR mutations have unclear clinical significance, genotyping is the least-sensitive diagnostic test for CF, compared to sweat testing and nasal potential difference (NPD) [32, 56]. If performed, genotyping results should be interpreted with experts in CF genetics since nondiagnostic mutations for CF may be identified [59]. In a study comparing the yield of various diagnostic tests for CF, genotyping identified 1 or 2 *CFTR* mutations in 21 of 42 (50%) patients with idiopathic acute recurrent or chronic pancreatitis but was unable to establish or exclude the diagnosis of CF in any of them [56]. In contrast, sweat chloride and transepithelial NPD were able to diagnose CF in 5% and 29% of patients, respectively [56]. Although NPD is a sensitive and reproducible determinant of CFTR function [60], it has limitations. It is complex to perform, time- and labor-intensive, and operator-dependent. Furthermore, NPD has neither been standardized nor validated for clinical use, and lacks consensus reference values [61]. Access to NPD is also limited to specialized centers with NPD expertise. False-positive results can occur with minor perturbations of the nasal epithelium, allergies, respiratory infections, and smoking.

The sweat test remains the primary diagnostic test for CF [57, 59]. Borderline (40–59 mmol/L) or abnormal (≥60 mmol/L) sweat chloride concentrations should lead to a referral to a CF clinic for further diagnostic evaluation, including for *CFTR* genotyping and alternative ion channel measurements (e.g., NPD or intestinal ion channel measurement), and various end-organ testing (e.g., lung function). Disease-specific counseling (e.g., fertility and smoking cessation) and genetic counseling are also important management considerations.

## Therapy

The only treatment currently available for patients with advanced pancreatic damage and EPI, is pancreatic enzyme replacement therapy [10]. Children <4 years of age require 1000 lipase units/kg per meal; 500 lipase units/kg per meal are used for those >4 years of age and 25,000–40,000 units/meal are used for adults [62, 63]. For snacks, half the dose is recommended. Infants may be given 2000 –4000 units per 120 mL of infant formula or per breastfeeding. The daily dose for most patients is less than 10,000 units of lipase/kg per day or 6000 units of lipase/kg per meal to prevent fibrosing colonopathy [62]. Aggressive nutritional management and fat-soluble vitamin supplementation is mandatory for all patients with EPI. Insulin is the treatment of choice for CFRD [64].

Currently there are no effective therapies to preserve pancreatic function in pancreatic sufficient CF patients or prevent recurrent attacks of pancreatitis. Ideally, the therapeutic strategy should be repairing the basic defect, which is the *CFTR* mutation. There are therapeutic agents designed to target class I (Ataluren) [65], class II (Lumacaftor), and class III (Ivacaftor) *CFTR* mutations [66, 67], some with promising success in improving lung function in patients with CF. Although these novel therapeutic approaches have revolutionized CF therapy, especially in the airways, there are no studies showing that these agents are effective in the pancreas. Gene therapy trials for CF are currently being conducted in the United Kingdom only using a cationic lipid-based vector, again targeting the lungs [68]. By utilizing a minimally invasive method and gene therapy vectors, Griffin et al. successfully targeted CFTR in porcine pancreatic ducts [69], but there are no human studies as yet.

# Clinical and Laboratory Diagnosis of Chronic Pancreatitis

*Julia Mayerle*[1], *Peter Simon*[2], *and Markus M. Lerch*[2]

[1] *Department of Medicine II, University Hospital Munich, Ludwig-Maximilians-University, Munich, Germany*
[2] *Department of Medicine A, University Medicine Greifswald, Greifswald, Germany*

## Introduction

For centuries, the pancreas was a "terra incognita" hidden behind the stomach, and its pathophysiologic role remained obscure. In 1761 Jean-Baptista Morgagni described the first case of chronic pancreatitis in his book *De sedibus et causis morborum* and it took 60 more years until Kuntzmann was able to connect fatty stool to diseases of the pancreas. Even in the twenty-first century the time interval between the onset of symptoms and the diagnosis of chronic pancreatitis is unacceptably long. This is mainly because routine blood tests are not usually helpful in diagnosing chronic pancreatitis and because clinical symptoms are often nonspecific. The modern clinical concept of clinical chemistry for pancreatic diseases began in 1929 with the introduction of serum amylase (diastase) measurements [1]. Thereafter Comfort and coworkers [2] combined clinical observations, surgical findings, and autopsy studies to characterize chronic pancreatitis and first reported a chronic relapsing course of the disease. They also commented on its frequent association with longstanding alcohol intake, its common onset in the third and fourth decade of life, and the typical complications of the disease such as exocrine and endocrine pancreatic insufficiency.

## Clinical Presentation

With an incidence of 8.2, a prevalence of 27.4 per 100,000 population and a frequency of 0.04–5% among all autopsies, chronic pancreatitis represents a rather common disorder of the gastrointestinal tract [3,4]. Chronic pancreatitis also accounts for substantial morbidity and healthcare costs. The worldwide incidence of chronic pancreatitis is reported to be between 1.6 and 23 per 100,000, and it has an increasing prevalence. Although most patients with chronic pancreatitis are treated as outpatients, in 2015 there were 18 612 (ICD-10: K86) hospital admissions for chronic pancreatitis in Germany alone (Federal Statistics Office). This does not include those patients who were coded as having acute pancreatitis, including those reporting an acute episode of chronic pancreatitis (55 221 cases). Records from the United States, United Kingdom, the Netherlands, and Finland confirmed an increasing number of annual hospital admission amounting to an 30% increase within 6 years [5]. This indicates the high socioeconomic significance of the disease. Mortality from chronic pancreatitis is reported to be 12.8–19.8% over a mean observation period of 6.3–9.8 years [6–8]. Total mortality in the same studies was reported to be 28.8–35%. Continued alcohol consumption results in a significantly reduced survival rate [9]. The number of patients who leave the workforce and abandon gainful employment due to prolonged illness or continued alcohol consumption, or become disabled and are forced to retire prematurely during the course of the disease amounts to 40%. The 10-year survival rate is 7% and the 20-year survival rate is 4%, in comparison with 93% and 65%, respectively, for an age-adjusted cohort.

With regard to the time interval between the onset of symptoms and the diagnosis of chronic pancreatitis a median interval of 30–55 months was reported in alcoholics [3,10]. In nonalcoholics the diagnosis was even more delayed (median 81 months) and frequently only established if complications of the disease such as pseudocysts or gastric outlet obstruction occurred. The

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

major reason for this delay lies in the natural course of the disease. The clinical presentation of patients with chronic pancreatitis is highly dependent on the stage of the disease. It varies between severely ill patients with symptoms of an acute abdomen to slowly progressing cachexia. Often the first signs of the disease that prompt the patient to seek medical attention are belt-like abdominal pain that frequently radiates to the back, loss of body weight (in 80%), and steatorrhea (in less than 50%) [11].

Several attempts have been undertaken to establish histologic and morphologic criteria that clearly define chronic pancreatitis. Unfortunately an exact correlation between clinical symptoms, morphologic signs, and histologic criteria is still not available [12,13].

## Etiology

In Western countries alcohol consumption is assumed to be the leading cause (70–90%) of chronic pancreatitis [14]. The prevalence of chronic pancreatitis clearly correlates with the alcohol consumption in a given population [15].

It is reported that 24.1% of all patients suffering from acute pancreatitis will progress to chronic pancreatitis [16]. Of those, 48.2% have alcoholic pancreatitis and smoking was identified as the only independent but dose-dependent risk factor for disease progression [17]. With regard to the etiology of chronic pancreatitis more recent studies suggest that in addition to alcohol consumption smoking increases the risk and can independently cause chronic pancreatitis [18].

The second most common form of chronic pancreatitis (25%) is so-called idiopathic pancreatitis [19,20]. Patients without identifiable risk factor for chronic pancreatitis are classified as having idiopathic pancreatitis. This group has decreased in incidence since Comfort and Steinberg reported in 1952 an inherited form of chronic pancreatitis that follows an autosomal dominant inheritance pattern [2]. Knowledge about these genetic susceptibility factors is accumulating. Hereditary pancreatitis represents a genetic disorder closely associated with mutations in the cationic trypsinogen gene and presents with a disease penetrance of ≈ 80% [21]. Shortly after the identification of mutations in the trypsinogen gene associated with chronic pancreatitis another important observation was made by Witt et al. [22]. They found that mutations in the serine protease inhibitor Kazal type 1 (*SPINK1*) gene, which encodes the pancreatic secretory trypsin inhibitor (PSTI), were associated with idiopathic chronic pancreatitis in children. *SPINK1* mutations are frequently detected in patients who do not present with a family history of pancreatitis and are devoid of classical risk factors for chronic pancreatitis [23,24].

Cystic fibrosis is an autosomal-recessive disorder with an estimated incidence of 1:2500 characterized by pancreatic exocrine insufficiency and chronic pulmonary disease. The extent to which the pancreas is affected varies between a complete loss of exocrine and endocrine function to clinically normal pancreatic function. Recurrent episodes of pancreatitis occur in 1–2% of all patients with cystic fibrosis who have normal exocrine pancreatic function and much more rarely in patients with exocrine pancreatic insufficiency. This means that cystic fibrosis transmembrane conductance regulator (*CFTR*) gene mutations that would not cause cystic fibrosis still confer a twofold increased risk of developing pancreatitis.

Metabolic disorders associated with hypertriglyceridemia above 1000 mg/dL may be responsible for the development of recurrent episodes of pancreatitis [25]. In addition to lipidapheresis and glucose/insulin treatment to lower triglyceride levels, a gene therapy approach has recently been developed. Alipogene tiparvovec (Glybera®) is a gene therapy product approved in Europe under the "exceptional circumstances" pathway as a treatment for lipoprotein lipase deficiency (LPLD), a rare genetic disease resulting in chylomicronemia and a concomitantly increased risk of acute and recurrent pancreatitis, with potentially lethal outcome. In a retrospective study the frequency and severity of pancreatitis in 19 patients with LPLD up to 6 years after a single treatment with alipogene tiparvovec were analyzed. Therapy was associated with an approximately 50% reduction in pancreatitis events [26]. In a few cases chronic calcifying pancreatitis has been reported due to hypercalcemia in patients with untreated hyperparathyroidism. The underlying mechanism of hyperparathyroidism-associated pancreatitis is most likely related to the established role of calcium in the premature intracellular activation of digestive proteases [27–29].

## Pain

Pain is the most commonly encountered symptom in chronic pancreatitis (80–95% of patients) [24]. Up to 50% of patients with chronic alcoholic pancreatitis suffer from chronic pain, while the remaining portion either present with intermittent attacks followed by pain-free intervals or have never experienced severe pain due to pancreatitis [20,30,31]. Most patients report continual, numb pain lasting for more than 24 hours and 68% report epigastric pain. Pain that radiates to the back is reported in 39%, to the left upper quadrant in 50%, and to the right upper quadrant in 32%. About 6% of patients feel their pain radiating between the shoulders. In general, patients with abdominal pain take a "jackknife" posture to relax

**Figure 48.1** Erythema ab igne in a female patient aged 45 with chronic alcoholic pancreatitis.

abdominal musculature affected by peritonitis. An erythema ab igne is associated with intense acute pain (Fig. 48.1). In chronic alcoholic pancreatitis a relationship between alcohol ingestion and recurrent pain has been described. Pain often begins between 12 and 48 hours after ceasing alcohol intake.

## Malabsorption and Weight Loss

Fat excretion of patients with pancreatic steatorrhea frequently exceeds that of patients with other causes of steatorrhea. Leaking oily stool from the anus is virtually pathognomonic of exocrine pancreatic insufficiency. In general, weight loss is a cardinal symptom of pancreatic exocrine insufficiency with steatorrhea, whereas hypoproteinemia or malabsorption of the fat-soluble vitamins is less common. Two publications have reported decreased bone mineral density, but no comparison to an age-matched control cohort was included [32,33]. Overt steatorrhea occurs in approximately 30% of patients with chronic calcific pancreatitis.

With rare exceptions, steatorrhea and azotorrhea (excessive discharge of nitrogenous substances in the feces or urine) only occur when the reduction in lipase and protease secretion, respectively, exceeds 90% [34,35] (Fig. 48.2).

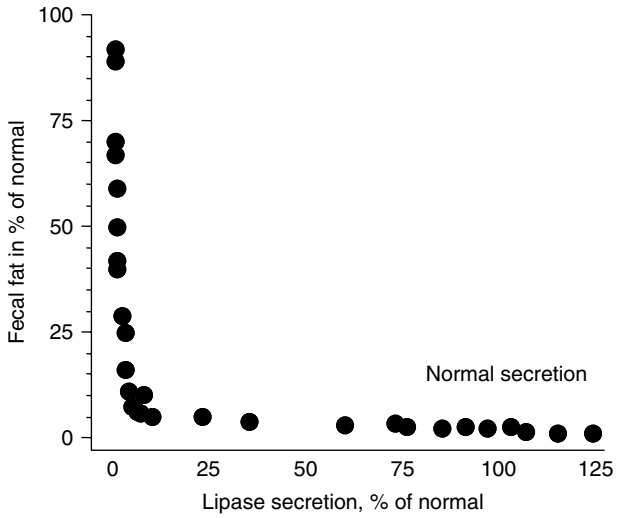

**Figure 48.2** Reduction in lipase secretion is paralleled by an increase in fecal fat. With rare exceptions, steatorrhea and azotorrhea only occur if there is greater than 90% reduction in pancreatic lipase and trypsin secretion. *Source:* Redrawn from [34].

In alcoholic chronic pancreatitis it is usually 10–20 years before severe exocrine insufficiency develops, but according to DiMagno and coworkers [34] lipase secretion decreases more rapidly than protease secretion. In decompensated chronic pancreatitis with less than 5% of the normal enzyme output, about 40% of nutrients from a readily digestible low-caloric meal are malabsorbed and enter the colon.

## Endocrine Insufficiency

More rarely, patients seek medical attention because they develop diabetes mellitus with a loss of endocrine function or cachexia as the initial symptoms of chronic pancreatitis. A history of diarrhea with recent onset of diabetes mellitus should always raise the suspicion of chronic pancreatitis as the underlying cause. The symptoms of diabetes "of other specific types" according to the World Health Organization (WHO) classification system released in 2003 (e.g., loss of insulin production due to diseases of the exocrine pancreas) are similar to those of diabetes mellitus of other causes. Overall, 45% of the patients with chronic pancreatitis suffer from overt diabetes. The cause of chronic pancreatitis bears no relationship to the subsequent likelihood of developing diabetes, but it does seem to influence the time lag between onset of pancreatitis and onset of diabetes. Alcoholics show symptoms of endocrine insufficiency earlier than nonalcoholics [7,36]. Diabetes mellitus is also an independent predictor of mortality in patients with chronic pancreatitis. The underlying pathophysiology

of diabetes in chronic pancreatitis is the loss of insulin-secreting cells, often combined with a peripheral and hepatic insulin resistance. Oral antidiabetics, especially metformin, might therefore have a role in the treatment of these patients, but control of blood sugar levels should be achieved with exogenous insulin supplementation [37,38].

## Jaundice

In 10–40% of cases of chronic pancreatitis a benign dominant stenosis of the common bile duct develops due to inflammation of the pancreatic head or due to pancreatic pseudocysts or phlegmons, all of which require either endoscopic or surgical intervention. An asymptomatic increase in alkaline phosphatase is the most common laboratory manifestation of a stenosis of the common bile duct secondary to chronic pancreatitis. Jaundice may develop later. However, a raised alkaline phosphatase or increased bilirubin alone does not always point to extrahepatic cholestasis but might be a symptom of parenchymal liver damage caused by hepatitis, steatosis, or even liver cirrhosis. Endoscopic intervention is clinically indicated if the patient presents with jaundice or recurrent episodes of cholangitis and in order to prevent secondary biliary cirrhosis.

## Laboratory Diagnosis

Even after two centuries of pancreatic research, a diagnostic serum marker for chronic pancreatitis is not available. Diagnosis is usually made by a combination of imaging procedures such as ultrasound, endoscopic ultrasound, computed tomography (CT) or magnetic resonance imaging (MRI) or magnetic resonance cholangiopancreatography (MRCP) in combination with exocrine and endocrine function tests.

### Serum Tests for the Diagnosis and Etiologic Characterization of Chronic Pancreatitis

The simplest noninvasive tests would be to measure exocrine pancreatic enzymes or hormones in fasting blood samples. Total serum amylase, in contrast to pancreatic isoamylase or salivary isoamylase, has been measured routinely since 1929, but it is of little use for the diagnosis of chronic pancreatitis. Because amylase secretion into the gut decreases in chronic pancreatitis it has been hypothesized that low serum pancreatic amylase could be used to diagnose chronic pancreatitis. Unfortunately, pancreatic isoamylase is completely normal in many patients with mild to moderate chronic pancreatitis and the sensitivity was reported to be only 60% with a variation between 12% and 100% depending on the severity of the disease. The same problems apply to the measurement of lipase and trypsin. Therefore pancreatic serum enzyme testing lacks diagnostic accuracy as well as specificity.

Provocation tests, in which serum levels of pancreatic enzymes are measured after stimulation of pancreatic secretion by secretagogues or parasympathomimetics, have been found to be rather insensitive, nonspecific, burdened with great interindividual ranges and therefore just as unreliable as markers for chronic pancreatitis. At most they are abnormal in 25% of patients suffering from chronic pancreatitis and at least the same proportion of healthy volunteers show abnormal test results [39–42].

The only hormone measured in serum with some promise as a diagnostic tool for pancreatitis is human pancreatic polypeptide (PP). Pancreatic polypeptide is a 36-amino-acid peptide and is found in the islets of Langerhans as well as in the exocrine parts of the pancreas. Its exact function is unknown but it is known to inhibit exocrine pancreatic secretion. Plasma concentrations of PP rise and fall in synchrony with interdigestive pancreatic secretion and increase in the immediate postprandial period or when the pancreas is stimulated by exogenous factors. Fasting plasma levels below 125 pg/mL have been assigned a sensitivity for chronic pancreatitis of 70% by DiMagno and coworkers, and pancreatic cancer can be differentiated with a specificity of 65%. If normal, this assay will exclude chronic pancreatitis with an accuracy of 90%, although 35% of healthy volunteers will still show levels below 125 pg/mL [43,44].

### Pancreatic Exocrine Function Tests

Tests for exocrine and endocrine pancreatic function serve as a second line of diagnostic tools for chronic pancreatitis. Reduced exocrine function can precede overt morphologic changes and therefore the sensitivity to detect early changes is higher for exocrine pancreatic function tests than for imaging studies. These patients have exocrine pancreatic insufficiency because enzymes and chyme do not mix fully and their fat digestion is accordingly impaired. However, excreted enzymes (e.g., elastase or chymotrypsin) in stool will appear normal.

Several tests for exocrine pancreatic function are now well established in the diagnostic workup of patients with suspected chronic pancreatitis. Assays can be divided into direct and indirect methods, depending on the technique used for determining enzyme output (via duodenal tube or indirectly). When pancreatic function is measured directly, the stimulated output of enzymes and bicarbonate into the small intestinal lumen is

**Box 48.1 Direct and indirect pancreatic function tests**

**Direct tests**

- Secretin–cholecystokinin test
- Endoscopic secretin test

**Indirect tests**

**Serum tests**

- Pancreolauryl test
- NBT-PABA test (commercially discontinued)

**Fecal tests**

- Fecal elastase
- Chymotrypsin
- Stool weight
- Fecal fat quantification

collected via a nasoduodenal tube and then analyzed. Indirect methods detect a decreased amount of pancreatic enzymes in stool or serum or, alternatively, evaluate the digestion of synthetic substrates by pancreatic enzymes, which also indicate impaired exocrine function when reduced (Box 48.1). The disadvantage of indirect tests for pancreatic function is that they cannot distinguish between structural or functional abnormalities. The situation after gastrectomy is a good example of when an impaired synchrony between pancreatic secretion and the gastrointestinal passage of food signals exocrine insufficiency on pancreatic function tests without any structural damage to the pancreas (pancreaticocibale asynchrony) [45].

## Direct Pancreatic Function Tests

### Secretin–Cholecystokinin Test

Pancreatic enzyme activity and bicarbonate concentration are measured in the duodenal juice after stimulation with the enterohormones secretin (1 U/kg intravenously) and cholecystokinin (CCK; 25–100 ng/kg). The secretin–cholecystokinin test used to be the gold standard for pancreatic function testing and its overall sensitivity and specificity is 90%. However, the combined secretin–cholecystokinin test is no longer used since pharmaceutical CCK preparations for human use are no longer marketed (in most countries). Some authors used a standardized test meal (Lund test) rather than hormone stimulation of the exocrine pancreas but this more "physiologic" approach is ultimately less sensitive in detecting early functional changes and bicarbonate cannot be measured in the collected chyme.

As early as 1982 Gregg suggested a new method to determine exocrine pancreatic function by collecting pancreatic juice after intravenous secretin stimulation during endoscopic retrograde pancreatography (ERP) [46]. Until 2003 no large series of this promising approach had been conducted until DiMagno and coworkers presented a modified version of the endoscopic pancreatic function test in a study of 412 subjects. The overall accuracy of the endoscopic secretin test was 79%, with positive and negative predictive values of 73% and 85%, respectively [47].

One way of overcoming the limitations of invasive function testing might be to use secretin-stimulated MRI. Intravenous application of secretin causes the rapid washout of bicarbonate-rich fluid from the exocrine pancreas which can be quantified semiquantitatively but is significantly reduced in patients with impaired exocrine function [48–51]. The sensitivity of secretin-stimulated MRI was calculated to be 69%, while the specificity was 90% [52,53]. As MRI is becoming an alternative to CT scan examination for the diagnosis of chronic pancreatitis, secretin–MRCP could become a valuable diagnostic tool [54].

## Noninvasive Pancreatic Function Tests

### Fecal Elastase 1

Pancreatic elastase accounts for 6% of the protein in pancreatic juice. Compared to other serine proteases this enzyme is highly stable during its passage through the gut and can be detected with a 5- to 6-fold concentration in stool (median concentration of 1200 µg/g). Fecal elastase is measured using an enzyme-linked immunoassay (ELISA) and there are human-specific polyclonal and monoclonal test kits without crossreactivity commercially available so it is not necessary for the patient to discontinue enzyme supplementation treatment that would potentially contain traces of pork elastase. The overall sensitivity of fecal elastase testing is 63% for mild exocrine insufficiency and rises to 100% for severe exocrine insufficiency if compared to the gold standard of the secretin–cholecystokinin test [55,56]. Biochemically the elastase 1 assay is a misnomer since the human pancreas expresses elastase 2 and 3 isoforms but not the elastase 1 isoform, which is known only from pigs.

It is known that 5% of chymotrypsin secreted into the duodenum can be recovered enzymatically active in the feces and measured by a colorimetric enzyme reaction employing the substrate *N*-glutaryl-L-phenylalanine-*p*-nitroanilide (GNPNA). Sensitivity and specificity is thought to be equal or lower compared to fecal elastase but false-negative results occur in 4% of patients with severe exocrine insufficiency, 15–18% of patients with moderate exocrine insufficiency, and 25–40% of patients with mild pancreatic insuffiency [56,57].

Another noninvasive approach used to evaluate pancreatic exocrine insufficiency is the assessment of $CO_2$ exhalation after digestion of $^{13}C$-labeled synthetic substrates such as mixed triglyceride, triolein, and hiolein, which are enzymatically cleaved by pancreatic enzymes in the duodenum. The $^{13}CO_2$ component, which is rapidly resorbed, can therefore be detected in exhaled breath over time [53,58–61]. In patients with severe exocrine insufficiency, sensitivity of the detection of mixed triglycerides is 92–100%, but in patients suffering from mild impairment of exocrine function sensitivity is reduced to 46% [62]. However, in addition to the detection of pancreatic insufficiency these tests can be used for clinical workup of chronic diarrhea or to monitor the efficacy of enzyme supplementation [63,64].

Fecal fat quantification by the classical van de Kamer (alcohol extraction) technique is the standard test to determine steatorrhea as a characteristic symptom of reduced exocrine function. After a 90% loss of exocrine function, fat excretion in stool significantly increases as a sign of fat maldigestion. A mild or intermediate impairment of exocrine function is usually clinically compensated for. The van de Kamer test has fallen out of favor with patients, nurses, and technicians because it requires extensive handling of large amounts of smelly stool.

### Evaluation of Endocrine Function

Overt diabetes occurs in about 20% of patients with alcoholic chronic pancreatitis 6 years after disease onset. Ten years after disease onset about 50% of alcoholic pancreatitis patients display signs of impaired glucose metabolism with diminished insulin production [65]. Pancreatic endocrine function should be evaluated by measuring $HbA_{1c}$ according to the guidelines of the WHO for the diagnosis of diabetes mellitus.

### Genetic Testing

In addition to an evaluation of exocrine and endocrine function considerable attention is now paid to the etiology of the disease (Box 48.2). Recent results from molecular and genetic studies suggest that a significant number of patients with chronic pancreatitis have a genetically determined or inherited disease. This is mainly true for patients who were formerly classified as having idiopathic pancreatitis, for patients with an onset of the disease before the age of 25, or those with a positive family history for chronic pancreatitis or pancreatic cancer. Patients who have chronic pancreatitis due to mutations in the cationic trypsinogen gene are burdened with a 70- to 140-fold increased risk of developing pancreatic cancer, particularly if they smoke [66]. Whether, this is also true for patients who carry *SPINK1* or *CFTR* mutations needs to be determined. Genetic testing for the most common and clinically relevant trypsinogen gene mutations (N29I and R122H or R122C) can be recommended for chronic pancreatitis patients who have first-degree relatives with pancreatitis or pancreatic cancer, and for patients with chronic pancreatitis or recurrent bouts of acute pancreatitis before the age of 25 years and no identifiable risk factor [67]. Genetic testing for clinically unaffected relatives is not indicated and should only be performed within Ethics Committee approved research protocols.

**Box 48.2 Indications for genetic testing in idiopathic or hereditary pancreatitis**

- Recurrent (2 or more) episodes of acute pancreatitis without identifiable cause or etiology; or
- Idiopathic chronic pancreatitis—especially in children and young adults under the age of 25 years; or
- Pancreatitis in patients with a positive family history of pancreatitis (one or more first- or second-degree relatives)

A much more detailed analysis of the genetic risk factors of pancreatitis is found in other chapters of this book.

## Conclusion

Even in the twenty-first century the diagnosis of chronic pancreatitis is made by a combination of clinical symptoms, imaging procedures, such as ultrasound, endoscopic ultrasound, CT, and MRCP, and exocrine and endocrine function tests. Therapy is restricted to symptom control because of a lack of a causal treatment strategy and the time point from first symptoms to diagnosis has not been significantly shortened during the last 15 years. Single markers or tests are urgently needed but presently not available.

## Introduction

Chronic pancreatitis is a chronic inflammatory disease of the pancreas leading to progressive fibrosis and loss of exocrine and endocrine pancreatic parenchyma. Because sensitive and specific biomarkers are not available, diagnosis of chronic pancreatitis is based on morphologic and functional changes that develop in the gland over the natural history of the disease. Complications such as chronic pancreatic pseudocyst, biliary obstruction, and portal and splenic vein thrombosis are frequently seen in cases of severe chronic pancreatitis. Diagnosis of chronic pancreatitis is easy at late stages, when pancreatic atrophy, irregularities and dilatation of the main pancreatic duct and side-branches, and calcifications are present. However, diagnosis is challenging in the early phases, when infiltration of inflammatory cells and activated stellate cells with mild fibrosis are the only histologic signs of the disease.

With the exception of the endoscopic secretin test, pancreatic function tests play a minor role in the early diagnosis of chronic pancreatitis in clinical practice. Imaging methods are therefore the cornerstone of the diagnosis of the disease. Findings at imaging methods are the consequence of the pathology of chronic pancreatitis. Histologically, the two most common features of chronic pancreatitis are atrophy, due to loss of acinar tissue, and fibrosis.

Chronic pancreatitis is frequently a diffuse process, but it can be patchy early in the evolution of the disease, or a localized process with regional involvement as a consequence of ductal obstruction. However, with the exception of the autoimmune form of the disease and the so-called groove pancreatitis, histologic changes are basically not related to the etiology of chronic pancreatitis, and thus morphologic pancreatic changes seen on imaging cannot provide information about the cause of the disease.

Endoscopic ultrasound (EUS) is nowadays considered to be the most sensitive method for the diagnosis of chronic pancreatitis. The relatively poor interobserver agreement for EUS features of chronic pancreatitis limits the wide use of this technique, but EUS-elastography and dynamic EUS examination after contrast enhancement may be of help in providing objective information about the degree of pancreatic fibrosis [1].

Diagnosis of chronic pancreatitis by abdominal ultrasound relies on severe morphologic changes that develop in the setting of advanced disease, but it is not accurate enough to detect mild and moderate changes.

Computed tomography (CT) is widely available and allows for comprehensive detailed evaluation of the abdomen. CT scan is thus usually considered to be the best initial imaging test for chronic pancreatitis. Magnetic resonance imaging (MRI) and magnetic resonance cholangiopancreatography (MRCP) are more sensitive than CT scan for the diagnosis of chronic pancreatitis, mainly for early mild and moderate disease, and they are the most accurate noninvasive imaging methods in this setting. Wider availability and good image quality make CT the mostly used imaging technique, but due to its nonionizing nature, unmatched soft tissue contrast, higher safety profile of intravascular contrast media, and the accurate secretin-enhanced duct examination make MRI/MRCP highly valuable in most cases of chronic pancreatitis. Accepted CT and MRI-MRCP findings of chronic pancreatitis are shown in Table 49.1. Together with that, CT and MRI play a major role in the differential diagnosis between inflammatory pancreatic mass in the context of chronic pancreatitis

| | CT findings | MRI/MRCP findings |
|---|---|---|
| Mild chronic pancreatitis | | Diminished signal intensity on T1-weighted fat-suppressed images<br>Slightly diminished and/or delayed enhancement after IV gadolinium<br>Reduced diffusion coefficient after diffusion-weighted MRI<br>Abnormal pancreatic duct compliance after secretin stimulation |
| Moderate chronic pancreatitis | Dilated MPD (2–4 mm)<br>Irregular MPD<br>Increased enhancement of the MPD wall<br>Slight gland enlargement<br>Heterogeneous parenchyma<br>Irregular gland contour<br>Small pseudocysts (<1 cm) | Dilated MPD (2–4 mm)<br>Irregular MPD<br>Dilated side- branches (>3)<br>Reduced duodenal filling after IV secretin<br>Moderately diminished and/or delayed enhancement after IV gadolinium<br>Slight gland enlargement<br>Heterogeneous parenchyma<br>Irregular gland contour<br>Small pseudocysts (<1 cm) |
| Severe chronic pancreatitis | Dilated MPD (>4 mm)<br>Calcifications<br>Ductal strictures<br>Gross gland enlargement<br>Parenchymal atrophy<br>Pseudocysts >1 cm<br>Contiguous organ invasion | Dilated MPD (>4 mm)<br>Calcifications<br>Ductal strictures<br>Markedly reduced duodenal filling after IV secretin<br>Markedly diminished and/or delayed enhancement after IV gadolinium<br>Gross gland enlargement<br>Parenchymal atrophy<br>Pseudocysts >1 cm<br>Contiguous organ invasion |

MPD, main pancreatic duct.

and pancreatic cancer, as well as in the diagnosis of local complications of the disease. Finally, some specific findings at CT and MRI may be of help to support the diagnosis of specific forms of chronic pancreatitis, such as autoimmune and groove pancreatitis.

## Diagnosis of Chronic Pancreatitis

### CT Scan for the Diagnosis of Chronic Pancreatitis

CT scan is a very accurate technique for detecting pancreatic calcifications, parenchymal atrophy, and inflammatory masses in the context of chronic pancreatitis [2] (Fig. 49.1). Pancreatic calcifications are the most specific though late finding of chronic pancreatitis, but parenchymal atrophy is neither sensitive, as it is only seen in advanced disease, nor specific, as it usually develops with aging. Most common ductal changes on CT include dilatation of the pancreatic duct and its side-branches, which correlate well with endoscopic retrograde pancreatography findings. The ductal contour on CT may be smooth, beaded, or irregular. Different CT findings of chronic pancreatitis can be seen in 30–70% of cases, mainly depending on the severity of the disease. Accuracy of CT scan to detect minimal parenchymal or ductal changes of chronic pancreatitis is even lower, and this technique often shows no abnormalities in early chronic pancreatitis [3]. Nevertheless, recent diagnostic studies are lacking and the accuracy of the most recently developed multiple detector CT (MDCT) for chronic pancreatitis is unfortunately unknown.

### MRI and MRCP for the Diagnosis of Chronic Pancreatitis

Compared to CT scan, association of MRI and MRCP appears to be more sensitive for early changes of chronic pancreatitis [4]. The normal high-intensity signal in T1-weighted sequences of the pancreas is lost in chronic pancreatitis. In addition, the maximal signal intensity of the pancreas after intravenous gadolinium administration is reduced and delayed to the venous phase, and the appearance of the gland becomes heterogeneous [4] (Fig. 49.2). Diffusion coefficient values during diffusion-weighted MRI are also lower in patients with chronic pancreatitis than in normal pancreas due to parenchymal fibrosis, which can be enhanced after intravenous secretin stimulation [5]. These dynamic parenchymal abnormalities, which frequently precede the ductal abnormalities, may be accurately quantified by MRI,

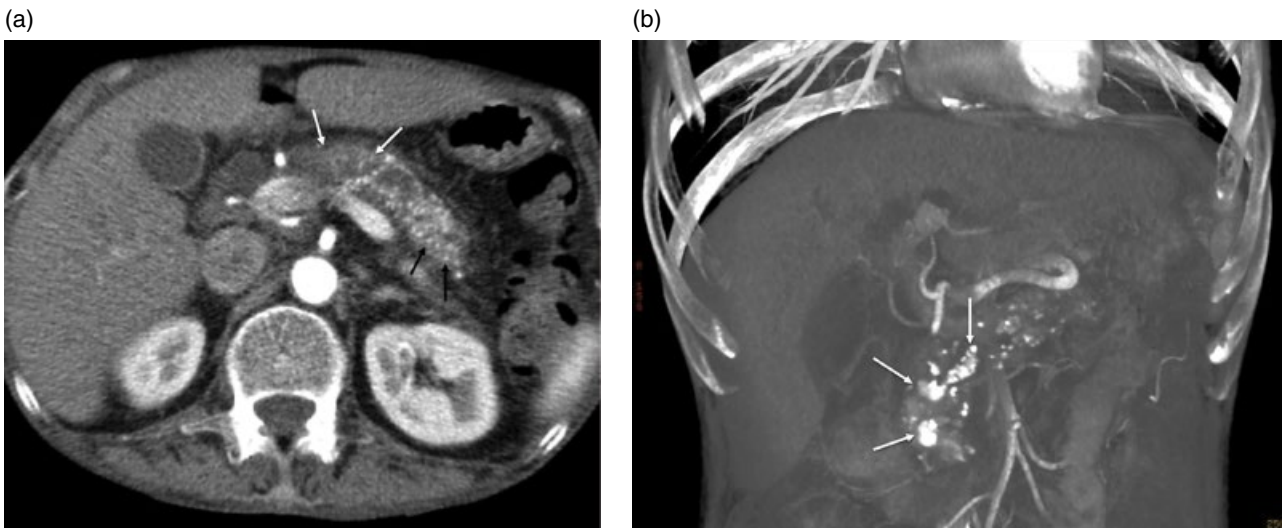

**Figure 49.1** Calcifying chronic pancreatitis on CT scan. (a) Axial contrast-enhanced arterial-phase CT image shows an area of inhomogeneous enhancement in the pancreatic parenchyma (white arrows) and multiple pancreatic calcifications (black arrows). (b) CT volumetric rendering maximum intensity projection in the same patient demonstrates multiple foci of calcification (white arrows).

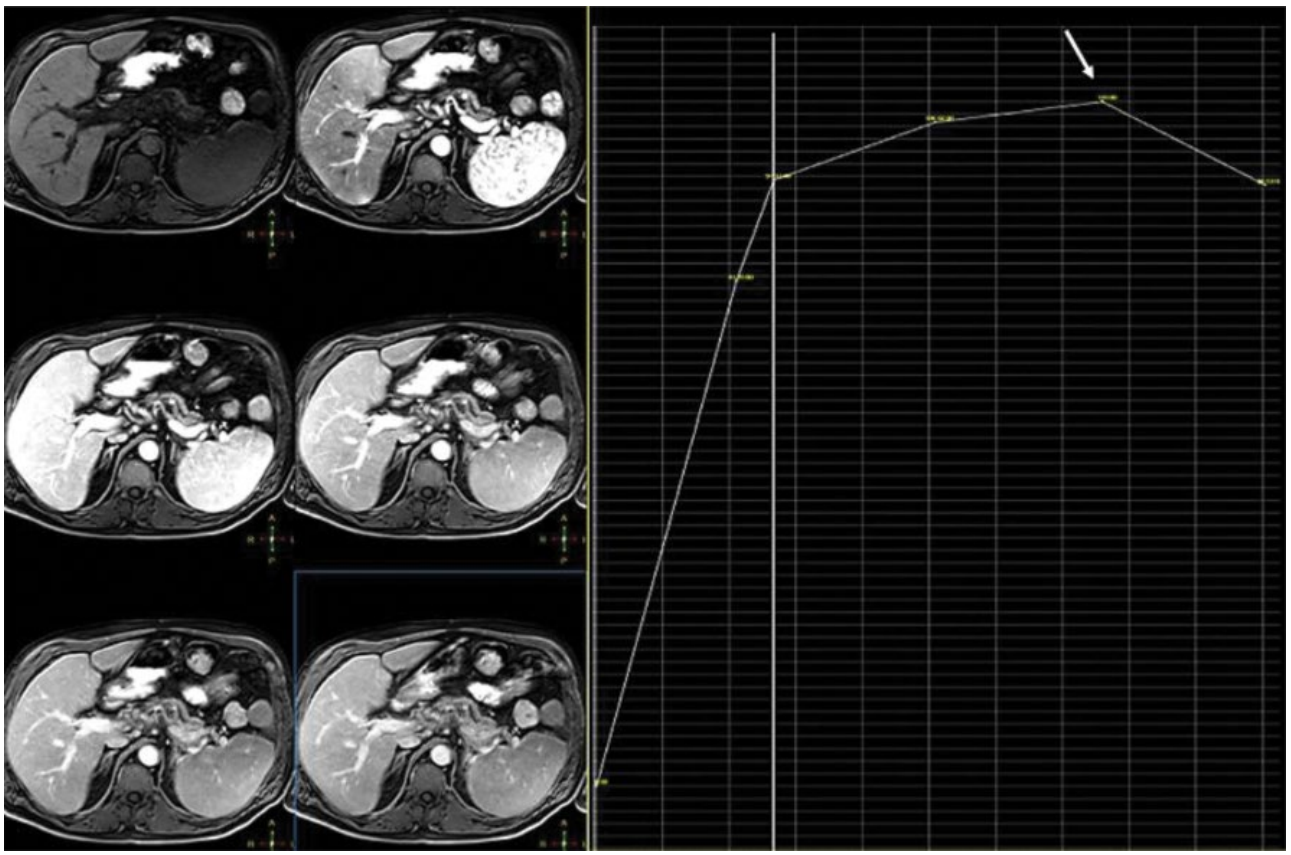

**Figure 49.2** Chronic pancreatitis on dynamic contrast-enhanced MRI. Dynamic contrast-enhanced axial fat-sat T1-weighted MR images (left) and time-intensity curve (right) show delayed enhancement of the pancreatic parenchyma (arrow).

although the accuracy of quantitative dynamic MRI in detecting early changes of chronic pancreatitis should be further investigated (Fig. 49.3).

MRCP is able to detect the typical ductal changes of chronic pancreatitis previously described for endoscopic retrograde pancreatography [6]. Pancreatic duct abnormalities include irregular dilatation and a beaded appearance of the main duct, which may contain intraductal calculi, and dilation of side-branches (Fig. 49.4). Intravenous injection of secretin significantly improves visualization of the main pancreatic duct and side-branches during MRCP (sMRCP) (Fig. 49.5); in addition, it allows the dynamic assessment of the duct compliance. The normal dynamic behavior of the duct after secretin is defined by a rapid distension of at least 1 mm or about 50% of the basal diameter, and recovery of the duct diameter to baseline 10 minutes after secretin stimulation (Fig. 49.6). This dynamic ductal compliance is early altered in chronic pancreatitis due to fibrosis [7]. The exocrine pancreatic secretion can also be evaluated by sMRCP; pancreatic secretion is frequently evaluated semiquantitatively based on a simple grading of the duodenal and jejunal filling after secretin stimulation (Fig. 49.6), but it can be measured quantitatively using a multislice fast T2-weighted sequence and a simple mathematical model. Taken together, the static and dynamic features of the pancreas at gadolinium-enhanced MRI, diffusion-weighted MRI, and sMRCP allow accurate information for the diagnosis of chronic pancreatitis to be obtained even at early phases (Table 49.1).

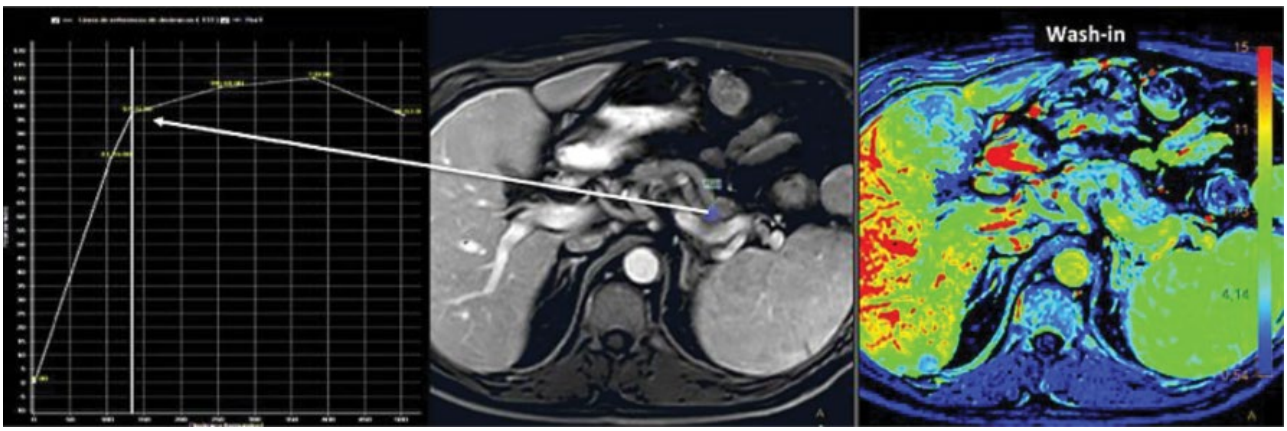

**Figure 49.3** MR perfusion study of the pancreas in chronic pancreatitis. Time-intensity curve (left), axial contrast-enhanced arterial-phase fat-sat T1-weighted MR images (middle), and wash-in parametric map (right).

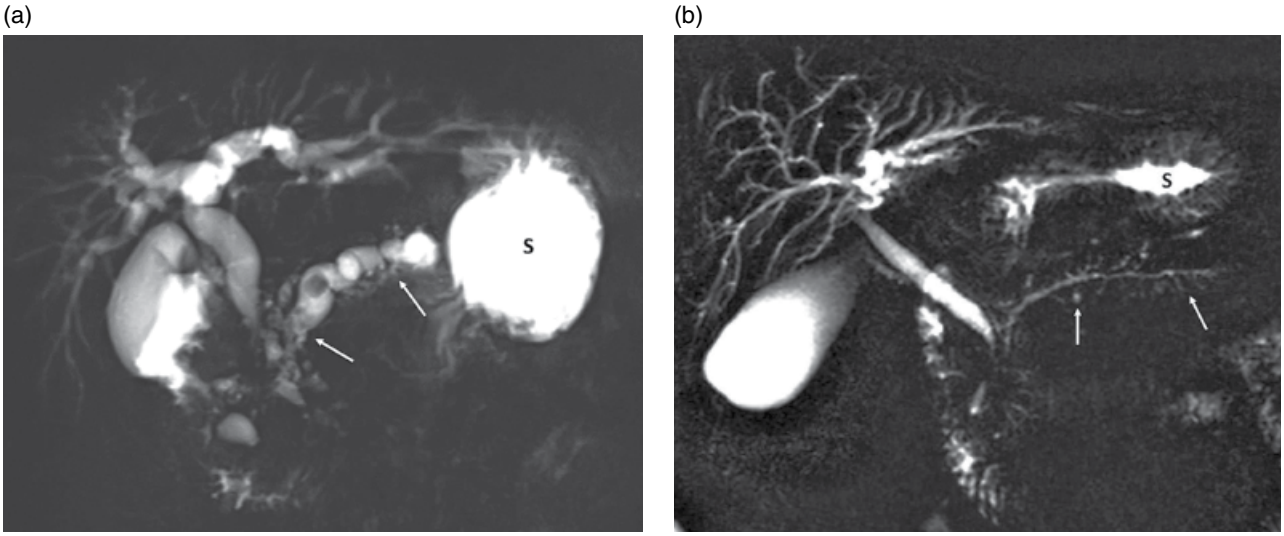

**Figure 49.4** Severe (a) and mild (b) ductal changes of chronic pancreatitis at MR cholangiopancreatography. (a) Diffuse pancreatic duct dilatation (arrows) with filling defects representing pancreatic calculi. The bile duct is dilated due to stricture at the level of the pancreatic head. (b) Diffuse dilatation of the lateral side-branches of the pancreatic duct (arrows) in a different patient. S, stomach.

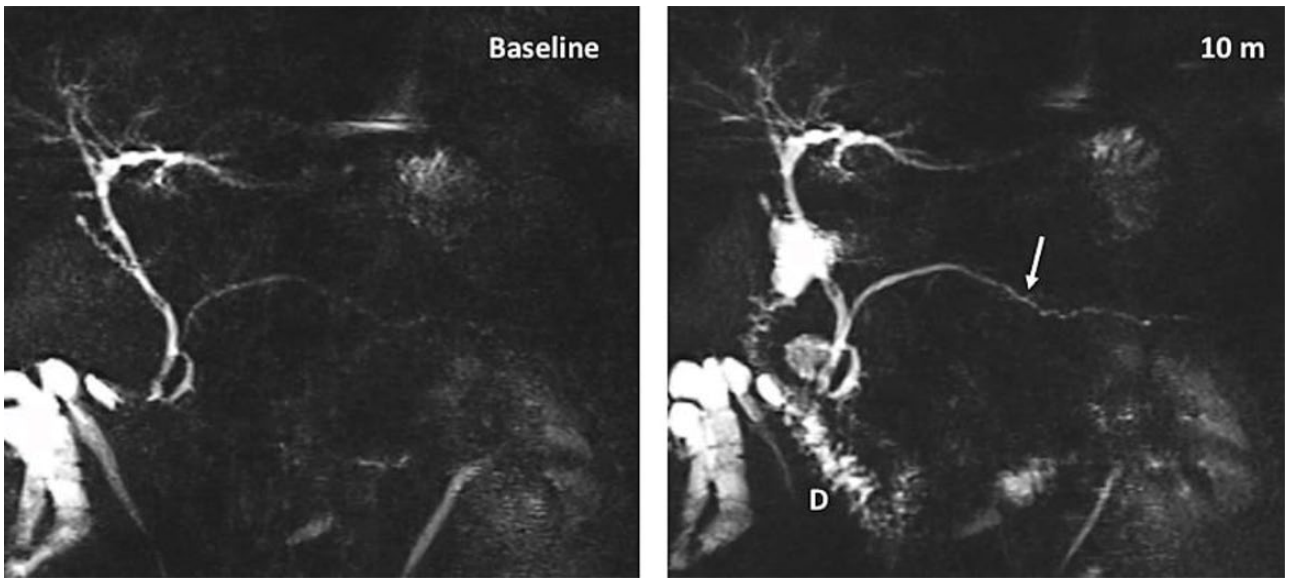

**Figure 49.5** Early ductal changes of chronic pancreatitis at secretin-enhanced MRCP. MR pancreatography obtained at baseline (left) and 10 minutes after intravenous administration of secretin (right). The use of secretin is able to demonstrate the dilatation of side-branches of the pancreatic duct (arrows) as a sign of early chronic pancreatitis.

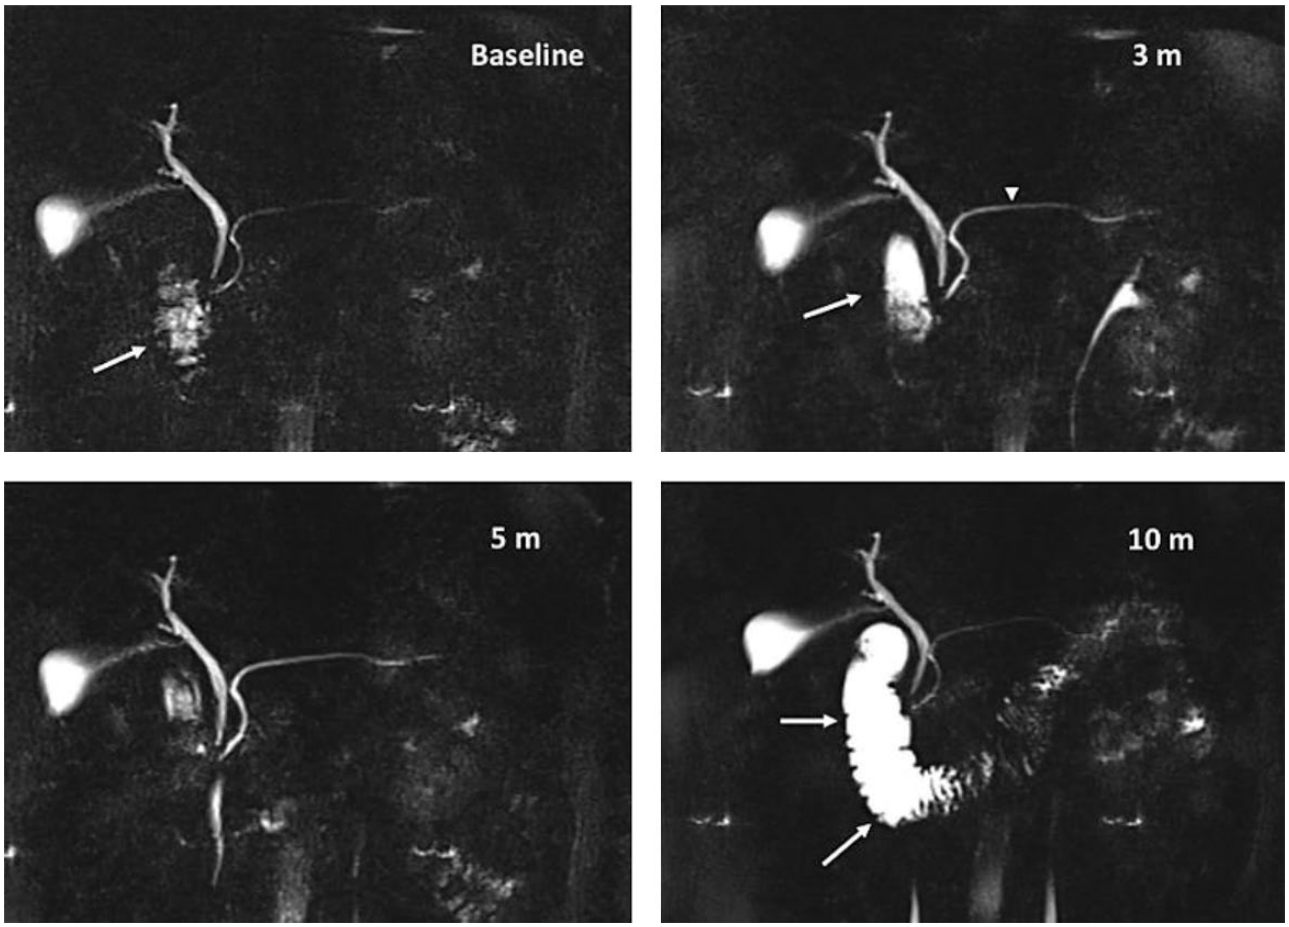

**Figure 49.6** Normal MR pancreatography obtained at baseline and at 3, 5, and 10 minutes after intravenous secretin administration. Normal dynamic changes of the pancreatic duct after secretin are characterized by early dilatation (arrowhead) and late recovery to normal size at 10 minutes. Increased duodenal filling after secretin stimulation correlates to pancreatic exocrine secretion (arrows at 10 minutes).

## Differential Diagnosis of Mass-Forming Chronic Pancreatitis and Pancreatic Cancer

Differential diagnosis of mass-forming chronic pancreatitis and pancreatic cancer remains a clinical challenge. In addition, chronic pancreatitis increases the risk for cancer and therefore both diseases may coexist. As for the diagnosis of chronic pancreatitis, CT scan and MRI are essential diagnostic tools in this setting.

### CT Scan

CT scan is the most widely used imaging modality for the evaluation of solid pancreatic masses and the most comprehensive tool for the diagnosis and staging of pancreatic malignancies. Nevertheless, differential diagnosis between mass-forming chronic pancreatitis and ductal adenocarcinoma based on CT scan can be challenging. Local pancreatic cancer is usually hypovascular and will therefore show a low attenuation on contrast-enhanced CT. In triple-phase CT scan, contrast enhancement peak in normal pancreatic tissue occurs during the first phase (early-washout pattern), it is delayed to the second phase in chronic pancreatitis (delayed-washout pattern), and it gradually increases in pancreatic cancer [8]. Secondary signs such as abrupt cut-off of the pancreatic duct with significant proximal dilatation and presence of double duct sign suggest pancreatic adenocarcinoma, whereas irregular dilatation of the main pancreatic duct with gradual narrowing and presence of intraductal calcifications are specific findings of mass-forming chronic pancreatitis. MDCT scan allows a better recognition of some typical signs of advanced malignancy such as vascular encasement, lymphadenopathy, or distant metastasis. Diagnostic sensitivity, specificity, and overall accuracy of this technique for pancreatic adenocarcinoma are 94.1%, 83.0%, and 90.4%, respectively [8]. The use of dual-energy CT can be used to improve the sensitivity and specificity of MDCT for differentiating mass-forming chronic pancreatitis from pancreatic cancer [9]. By the use of this technique, normalized iodine concentrations during two double phases are significantly lower in chronic pancreatitis than in pancreatic cancer.

### MRI/s-MRCP

MRI with the use of conventional sequences is considered to be less sensitive than other imaging modalities for the differential diagnosis of solid pancreatic masses. In fact, sensitivity of MRI for the diagnosis of pancreatic cancer was shown to be 84% in a meta-analysis, compared to the sensitivity of 91% obtained with CT scan [10]. However, MRI appears to be superior to other imaging modalities in visualizing tumors within areas of pancreatic inflammation. T1-weighted images have similar features but T2-weighted images show different signal intensity patterns in chronic pancreatitis and pancreatic cancer [11] (Figs 49.7 and 49.8). MRCP may provide additional information related to the involvement of the main pancreatic and bile ducts, which may be of help in this clinical setting. MRCP may demonstrate obliteration and dislocation of the dilated side-branches caused by a tumor, and duct distortion within the mass in chronic pancreatitis (Figs 49.7 and 49.8). After secretin injection, the main pancreatic duct remains irreversibly stenotic and obstructed due to the neoplastic process. However, it appears patent, although narrowed, in mass-forming chronic pancreatitis. The delineation of the duct penetrating through the stenotic area means that a smoothly stenotic or normal pancreatic duct penetrates through the mass, which is frequently seen in inflammatory pancreatic masses (Fig. 49.7). These findings have a sensitivity of 86% and specificity of 95% in distinguishing between benign and malignant pancreatic masses [12]. Finally, new techniques such as diffusion-weighted MRI, gadolinium-enhanced 3D gradient echo, time signal intensity curve during contrast enhanced MRI, and magnetic resonance spectroscopy may allow increased accuracy of MRI in this setting.

## CT and MRI for Autoimmune Pancreatitis

Autoimmune pancreatitis is important to distinguish from other forms of chronic pancreatitis and pancreatic cancer. Imaging plays an important role in the diagnosis of autoimmune pancreatitis, but it is not diagnostic by itself. Three different patterns of autoimmune pancreatitis can be recognized on imaging: diffuse or sausage-like pancreas enlargement, focal or well-defined mass, and multifocal. Thus, diffuse or localized enlargement of the pancreas with diffuse or segmental narrowing of the pancreatic duct with irregular wall are typical findings of autoimmune pancreatitis on CT and MRI [2].

On contrast-enhanced CT there is decreased enhancement of the involved parenchyma in the arterial phase and delayed enhancement in the late phase.

On MR imaging, the pancreas shows decreased T1 fat-suppressed signal intensity, increased T2 signal intensity, and delayed enhancement. A rim-like capsule of decreased

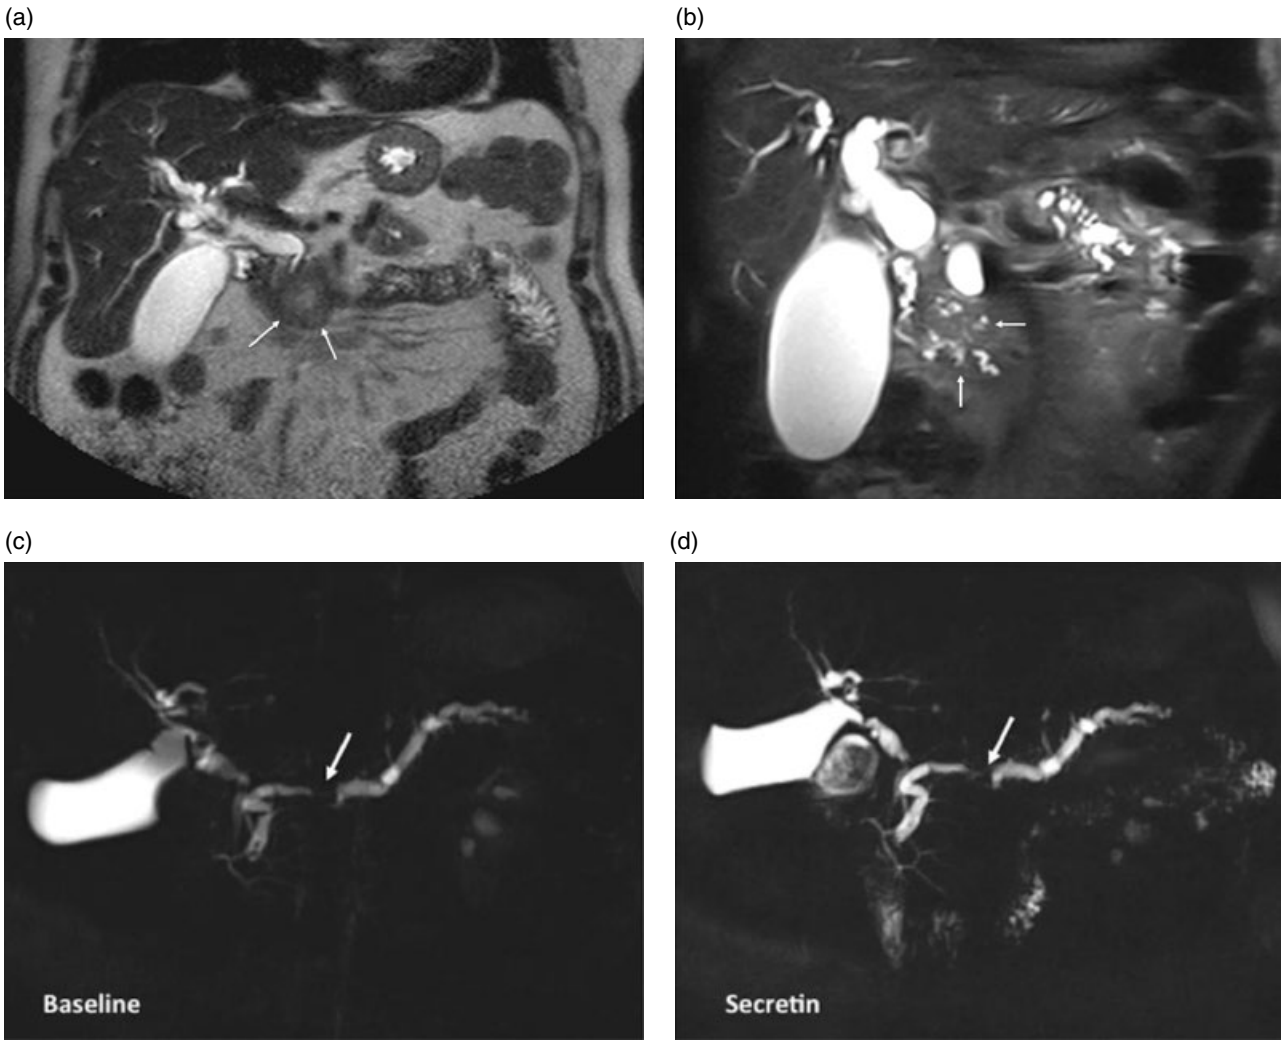

**Figure 49.7** MR imaging of inflammatory pancreatic mass in the context of chronic pancreatitis. (a) Coronal T2-weighted turbo spin echo (TSE) MR image reveals a heterogeneous mass in the head of the pancreas (arrows) associated with bile duct and gallbladder dilatation. (b) MR cholangiography demonstrates a bile duct dilatation and stricture at the level of the intrapancreatic segment in the same patient. The duct-penetrating sign is also evident. (c,d) Dynamic MR pancreatography does not show changes in ductal size after intravenous secretin administration but it allows the delineation of the duct penetrating through the stenotic area (arrows).

T1 fat-suppressed signal intensity and increased T2 signal intensity with associated delayed enhancement is suggestive of fibrosis [13]. MRCP can show diffuse or segmental irregular narrowing of the main pancreatic duct that usually resolves after steroid therapy.

In cases of focal mass, multiplicity, geographic shape, delayed enhancement, capsule-like rim enhancement, low apparent diffusion coefficient value, and segmental strictures of the common bile duct or main pancreatic duct favor focal autoimmune pancreatitis over pancreatic cancer [13].

## CT and MRI for Groove Pancreatitis

Groove pancreatitis is an uncommon type of focal chronic pancreatitis affecting the pancreaticoduodenal groove. The classic MDCT features are ill-defined soft tissue within the pancreaticoduodenal groove with or without delayed enhancement due to fibrosis. Small cysts may be seen along the medial wall of the duodenum or in the pancreatic groove. Fibrotic changes affecting the pancreatic head may also be observed as a hypointense mass-like appearance of the parenchyma.

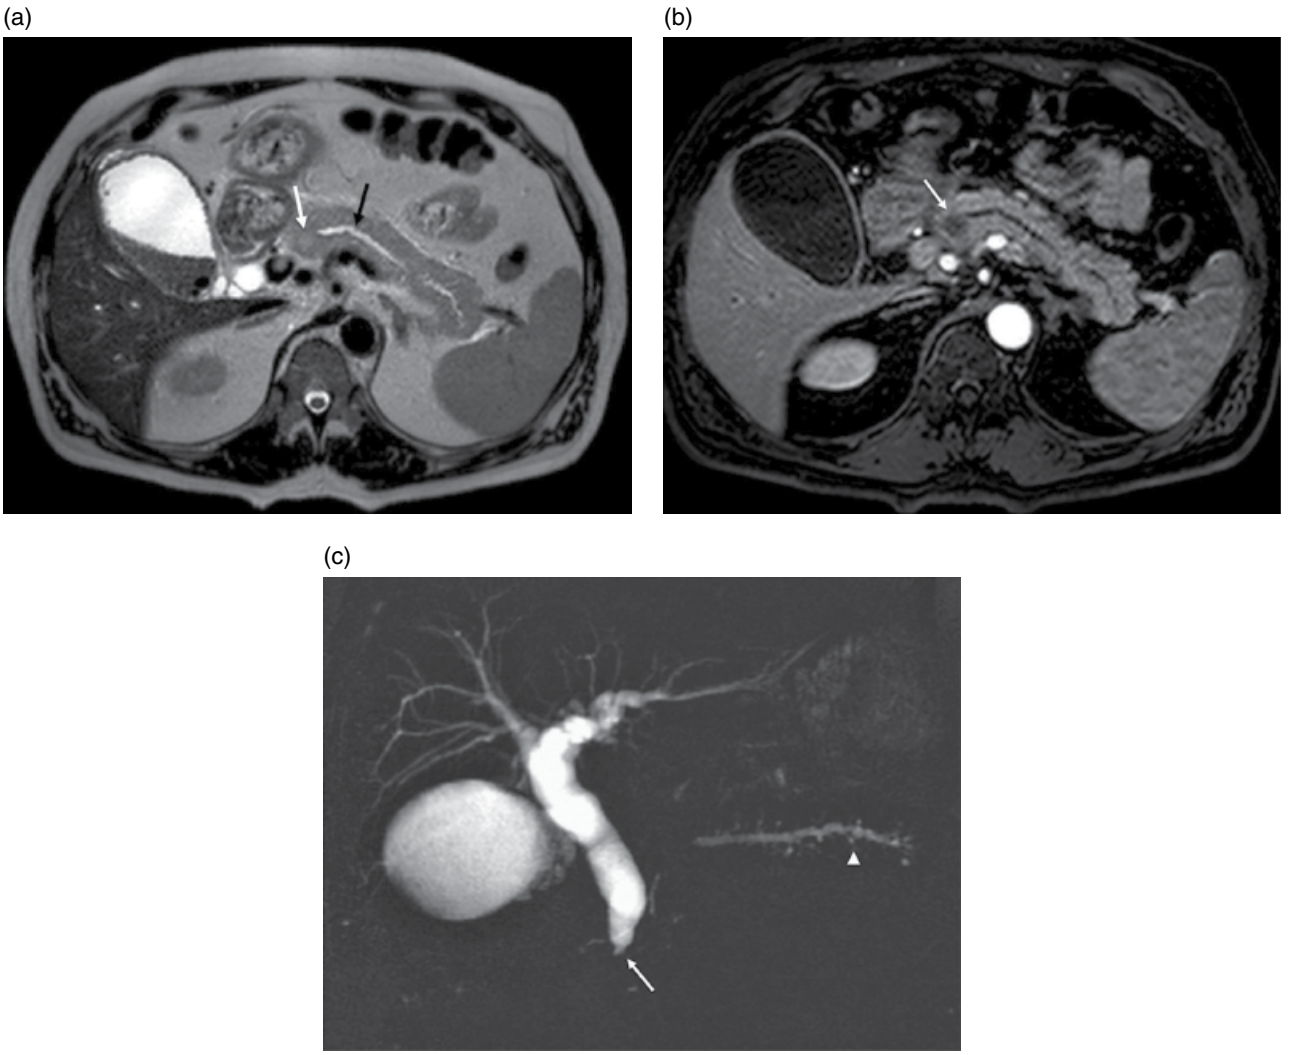

**Figure 49.8** MR imaging in a patient with a small pancreatic cancer. (a) Axial T2-weighted turbo spin echo (TSE) MR image at the level of the head of the pancreas evidences a discrete nodular mass (white arrow) associated with irregular ductal dilatation (black arrow). (b) Dynamic contrast-enhanced portal-phase axial fat-sat T1-weighted MR image evidences a hypovascular pattern of the lesion. (c) MRCP shows a bile duct dilatation and stricture (arrow) at the level of the intrapancreatic segment. Note the presence of changes suggestive of chronic pancreatitis in the tail of the gland with dilatation of the main duct and lateral branches (arrowhead).

On MR imaging, groove pancreatitis is characterized by sheet-like mass that is hypointense on T1-weighted images and isointense or slightly hyperintense on T2-weighted images relative to the pancreas (Fig. 49.9). As in CT scan, this mass may show a delayed and heterogeneous gadolinium enhancement on MRI. If the pancreatic head is affected, pancreatic parenchyma is hypointense on T1-weighted images, frequently associated with atrophy, smooth ductal narrowing, and pre-stenotic ductal dilatation. Duodenal thickening and cysts may be found and better displayed on T2-weighted images [2] (Fig. 49.9).

Focal thickening and abnormal increased enhancement of the second part of the duodenum, and cystic changes in the region of the pancreatic accessory duct support the diagnosis of groove pancreatitis over pancreatic cancer with an accuracy of 87.2% and negative predictive value for cancer of 92.2% [14].

## Complications of Chronic Pancreatitis

The most common complications of chronic pancreatitis include pseudocysts, portal and splenic vein thrombosis, biliary obstruction, duodenal obstruction, pseudoaneurysms, and pancreatic cancer. Diagnosis of pancreatic cancer in the context of chronic pancreatitis is discussed above. Non-neoplastic complications of chronic

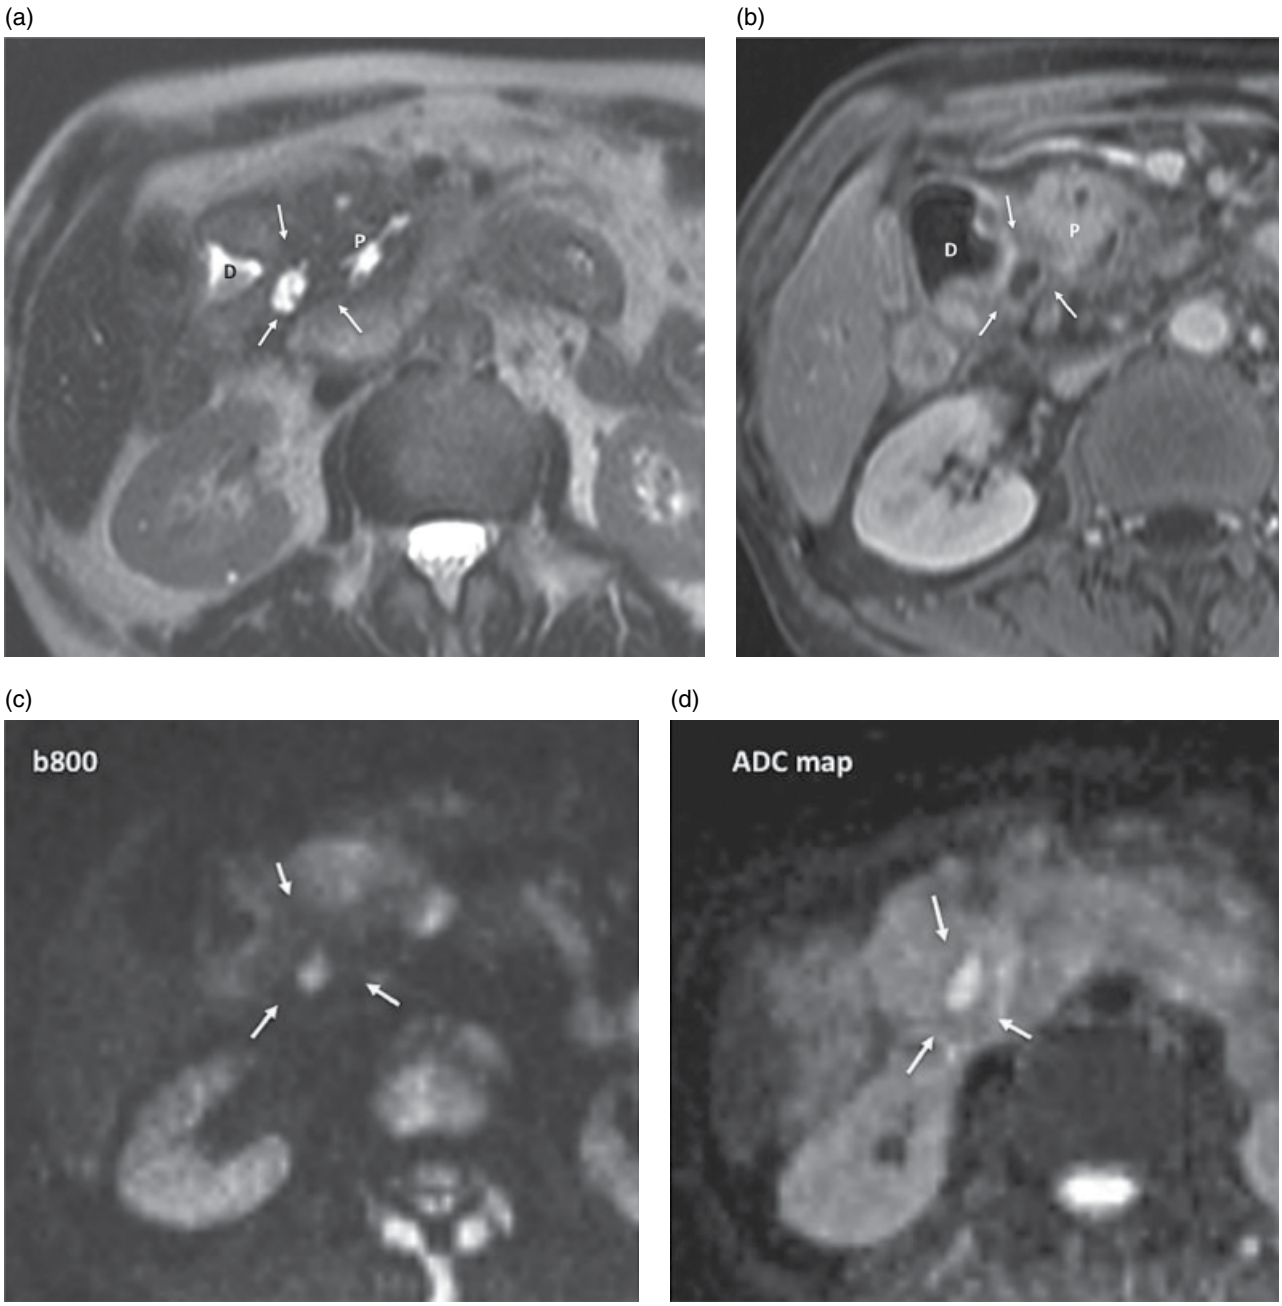

**Figure 49.9** Groove pancreatitis on MR imaging. (a) Axial T2-weighted turbo spin echo (TSE) MR image at the level of the head of the pancreas evidences a subtle hypointense mass (white arrows) involving the "groove" between the pancreatic head (P) and the duodenum (D). (b) Contrast-enhanced portal-phase axial fat-sat T1-weighted MR image shows a hypovascular mass (white arrows) with cystic areas in the duodenal wall. (c,d) Diffusion-weighted image (c) (*b* value = 800) and ADC map (d) do not evidence restriction at the level of the mass (arrows). Discrete low signal on ADC map and hypointensity on high *b*-values images (*b* = 800) suggest fibrosis.

pancreatitis are well detected and evaluated with CT and MRI (Figs 49.7 and 49.10). MRI and MRCP may be superior to CT in detecting specific complications such as pseudocysts, fistula formation, distal common biliary dilatation, and vascular complications [3]. However, CT is especially helpful because it can better exclude other causes of abdominal pain or weight loss besides chronic pancreatitis.

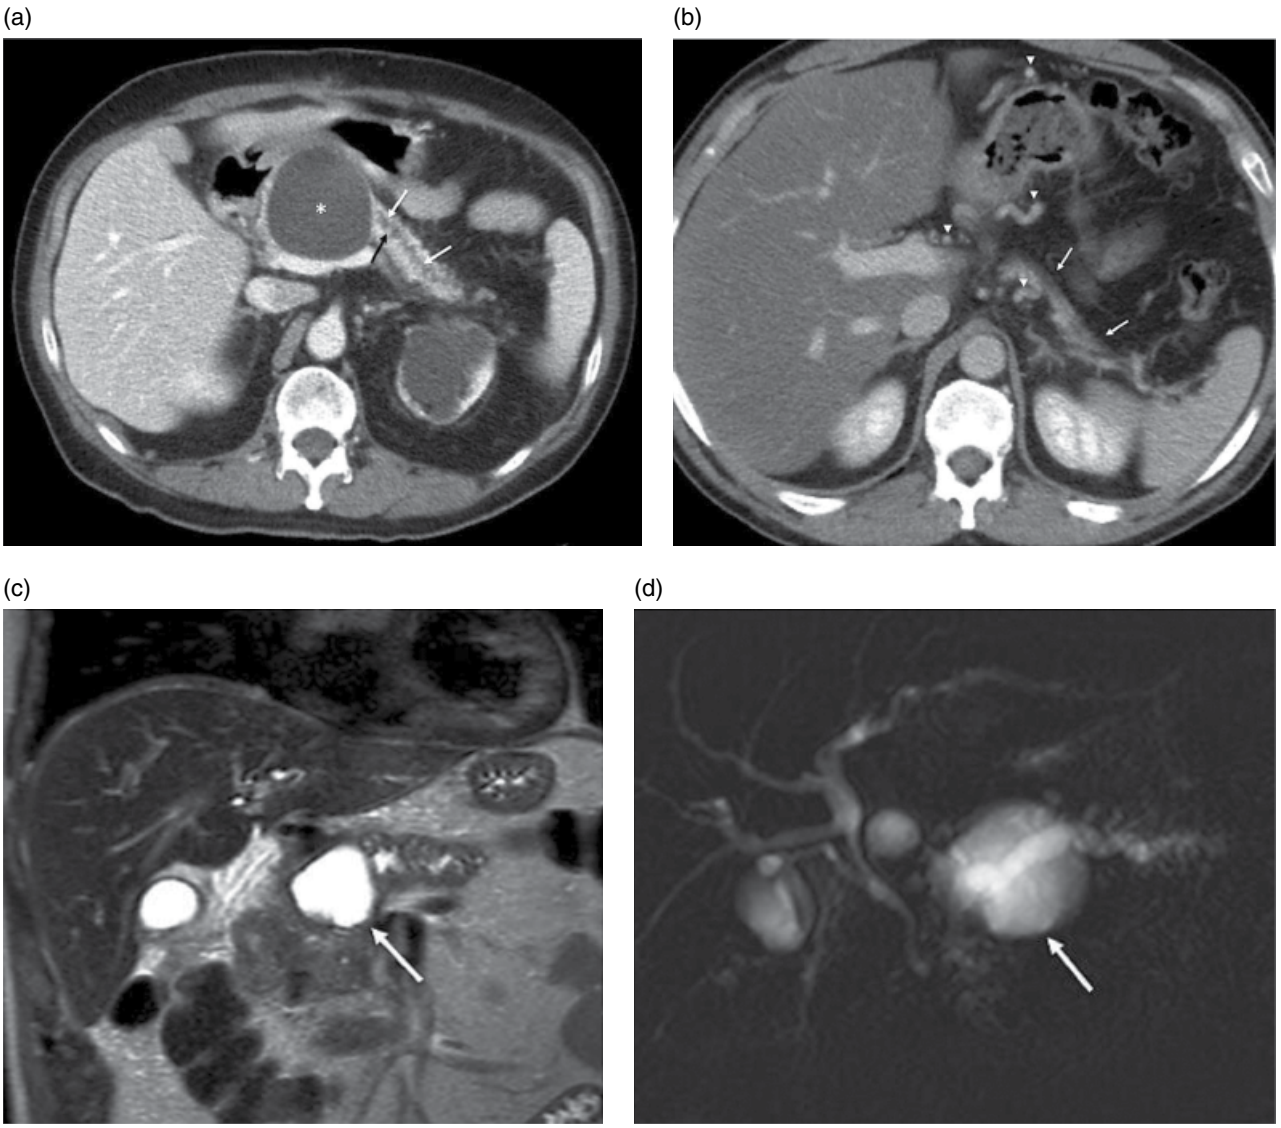

**Figure 49.10** Complications of chronic pancreatitis. (a) Axial contrast-enhanced portal-phase CT image demonstrates a pseudocyst (asterisk), dilatation of the main pancreatic duct and its side-branches (white arrows) and intraductal calculi (black arrow). (b) Axial contrast-enhanced portal-phase CT image demonstrates marked parenchymal atrophy (arrows) and collateral circulation secondary to splenic vein thrombosis (arrowheads). (c) Coronal T2-weighted turbo spin echo (TSE) MR and (d) MRCP show a cystic mass (white arrows) corresponding to a pseudocyst and imaging findings of chronic pancreatitis (dilatation of main duct and side-branches).

## Introduction

In the late nineteenth century, the German pathologist Rudolf Virchow proposed that there was a close link between inflammation and cancer, based on cellular studies made possible by microscopy. Since then it has been observed that inflammatory diseases such as esophagitis, gastritis, and colitis sometimes precede the development of cancer in these organs. Throughout the twentieth century anecdotal reports of pancreatitis preceding pancreatic cancer have emerged. These isolated reports suggested a possible link between chronic pancreatitis and pancreatic cancer and eventually led to a large retrospective cohort analysis conducted near the end of the twentieth century. In this chapter we review and summarize the evidence linking chronic pancreatitis and pancreatic cancer.

## Descriptive Findings

Acute pancreatitis, chronic pancreatitis, and pancreatic cancer are the three most common pancreatic diseases. How does their incidence compare? Acute pancreatitis is one of the commonest gastrointestinal disorders and has an estimated incidence of about 13–45/100,000 per year [1]. The incidences of chronic pancreatitis and pancreatic cancer are similar to each other, with age-standardized incidence rates of around 10/100,000/year.

Figure 50.1 illustrates the relationship between these three diseases and the potential pathways for progression from acute to chronic pancreatitis and, in some patients, to pancreatic cancer. In patients with gallstone-related pancreatitis, cholecystectomy performed on a timely basis eliminates the major source for gallstones and precludes additional attacks. But acute pancreatitis also develops from many other causes, and if the cause is heavy drinking, smoking, or a genetic disorder, recurrent attacks of acute pancreatitis (recurrent pancreatitis) may occur and disease progression may then lead to chronic pancreatitis. Of patients who develop chronic pancreatitis, a small proportion will develop pancreatic cancer. The average age at diagnosis of chronic pancreatitis in patients with alcohol-related disease is about 45–55 years, approximately a decade earlier than the average age of onset of pancreatic cancer. This time sequence indicates that the direction of causality is compatible with a progression from benign to malignant disease.

Other than age, what are some of the other similarities and differences between chronic pancreatitis and pancreatic cancer? For both diseases smoking and obesity are recognized risk factors, whereas heavy drinking is strongly linked to chronic pancreatitis, but is associated only with a modest increased risk for pancreatic cancer [2]. Both diseases are also more frequent in black than in white populations, and diabetes frequently accompanies both diseases.

## Measuring the Strength of the Pancreatitis–Pancreatic Cancer Association

In the initial multicenter cohort study of 2015 patients with well-documented chronic pancreatitis followed up for a minimum of 5 years after the diagnosis of chronic pancreatitis, the risk of pancreatic cancer was 14.4 (95% CI: 8.5–22.8) times higher than that in the background population. The risk was similar in all six study countries and was also similar in patients with either alcoholic or

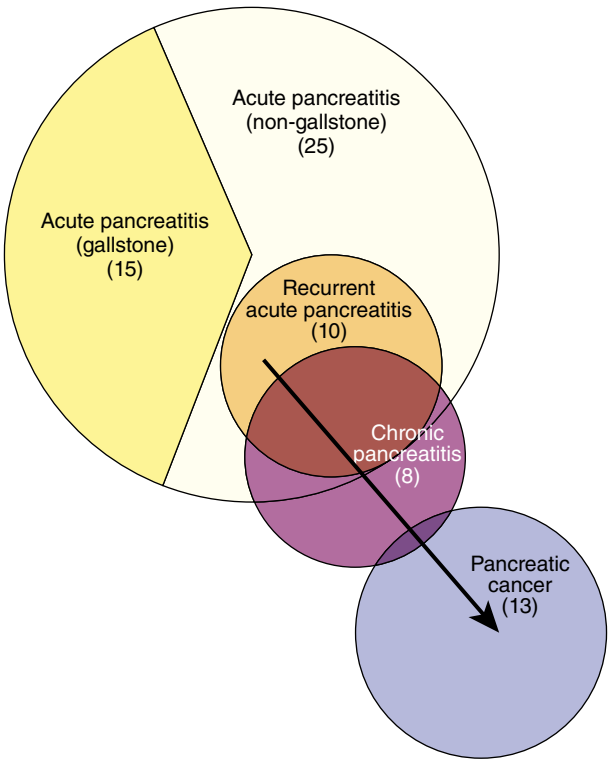

**Figure 50.1** Incidence rates for pancreatic diseases in the United States. Numbers inside circles indicate incidence rates per 100,000 population. The arrow indicates the progression from benign to malignant disease. Note the small overlap between the circles representing chronic pancreatitis and pancreatic cancer. *Source:* Yadav and Lowenfels 2013 [1]. Reproduced with permission of Elsevier.

nonalcohol pancreatitis [3]. Over a follow-up period of up to 20 years, the cumulative incidence of pancreatic cancer was 4%. This implies that chronic pancreatitis, although a strong risk factor, explains only a small proportion of the total burden of pancreatic cancer. Also, in contrast to the 29 patients who died from pancreatic cancer, 137 patients in the group died from other types of cancers. Because of lifestyle factors such as smoking and heavy alcohol drinking, most cancer deaths in patients with chronic pancreatitis will be from nonpancreatic cancer.

Since publication of this report, several additional studies have looked at the relationship between chronic pancreatitis and pancreatic cancer [4–6]. Raimondi and coworkers published a meta-analysis in 2010 which included 18 additional studies [4]. There were 11 studies of pancreatitis, type unspecified, four new studies of chronic pancreatitis, and three studies of hereditary pancreatitis. The pooled risk estimates were as follows: pancreatitis (type unspecified) relative risk (RR) = 5.1 (95% CI: 3.5–7.3), chronic pancreatitis RR = 13.3 (95% CI: 6.1–29), and hereditary pancreatitis RR = 69 (95% CI: 56–84). This meta-analysis also included one report of the risk of pancreatitis in tropical pancreatitis where the RR was 100 (95% CI: 37–218) (Fig. 50.2).

In 2014 Tong and coworkers published a systematic review of epidemiologic studies linking pancreatitis and pancreatic cancer [5]. This report contained 14 case–control studies and three cohort studies and found a pooled odds ratio of 7.1 (95% CI: 6.4–7.8). As in the previous meta-analysis, the results were stronger in cohort studies than in case–control studies. In another pooled analysis of 10 case–control studies, Duell and coworkers reported a nearly threefold increased risk of pancreatic cancer in patients where there was a minimum of 2 years separating the diagnosis of pancreatitis from pancreatic cancer [6].

A nationwide report from Denmark provides further evidence for a strong link between pancreatitis and pancreatic cancer [7]. In this follow-up study of nearly 12,000 patients with chronic pancreatis and nearly 120,000 matched controls the authors found a 6.9-fold increased risk of death from pancreatic cancer in pancreatitis patients as compared to the control population. Again, the risk of pancreatic cancer was similar in patients with either alcoholic or nonalcoholic pancreatitis.

## Discussion

Reviewing the evidence accumulated over several decades reveals a strong link between chronic pancreatitis and pancreatic cancer. Clinicians must still be aware of reverse causality because one symptom of pancreatic cancer can be sudden onset of pancreatitis in the absence of known risk factors. However, the evidence from several long-term follow-up studies with exclusion of early-onset pancreatic cancer confirms the pancreatitis–pancreatic cancer link. The findings of this relationship in the pancreas agrees with information from other organs, and confirms Virchow's nineteenth-century hypothesis. As yet we do not have a full understanding of the mechanisms underlying the transformation from a nonmalignant disease to cancer.

All the reports indicate that the cumulative risk of pancreatic cancer in patients with longstanding confirmed chronic pancreatitis is low—probably less than 5%. This implies that until we develop noninvasive screening procedures with greater sensitivity and specificity than are currently available, screening patients with chronic pancreatitis is not likely to be rewarding.

Hereditary pancreatitis is a rare inherited autosomal dominant genetic disorder that causes early-onset pancreatitis characterized by recurrent attacks eventually leading the chronic pancreatitis. As with other risk factors, such as smoking, long duration of exposure

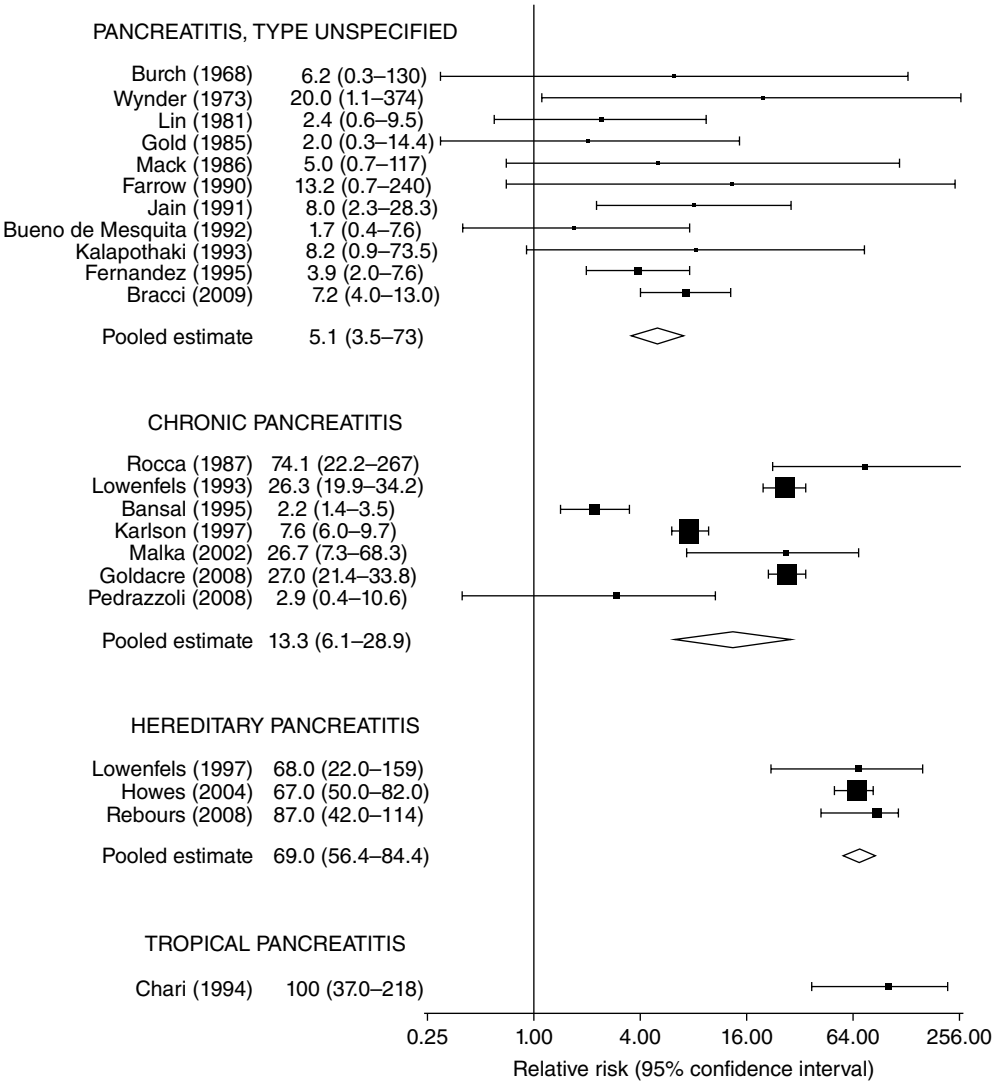

**Figure 50.2** Meta-analysis showing study-specific and summary risk estimates with 95% confidence intervals for the association between different types of pancreatitis and pancreatic cancer. *Source:* Raimondi et al. 2010 [4]. Reproduced with permission of Elsevier.

increases the risk of cancer. Because patients with this type of pancreatitis have about a 70% lifetime risk of developing pancreatic cancer, minimally invasive imaging screening with endoscopic ultrasound (EUS), multiphasic helical computed tomography (CT) or magnetic resonance imaging/magnetic resonance cholangiopancreatography (MRI/MRCP) have been proposed for patients with the hereditary pancreatitis phenotype, beginning at the age of 40 years [8].

What are fruitful areas for additional research that might benefit patients with underlying pancreatitis? Pancreatic cysts are now being detected with increasing frequency and we need to be able to identify subgroups of these patients who have an increased risk of pancreatic cancer. Pancreatic cancer can mimic nonmalignant disease such as autoimmune pancreatitis, leading in some patients to unnecessary pancreatic surgery [9,10]. We need to develop biological tests and/or biomarkers that can reliably distinguish between chronic pancreatitis and pancreatic cancer. Finally, collecting and storing biologic samples from patients with well-documented chronic pancreatitis will help us improve our understanding of the gradual transition of pancreatitis to pancreatic cancer.

The irreversible pathologic changes characteristic of chronic pancreatitis make this disease difficult to treat and the progressive cellular disruption of glandular and ductal tissues leads eventually, in some patients, to pancreatic cancer. Efforts to reduce lifestyle factors such as smoking and alcohol drinking in patients with recurrent bouts of acute pancreatitis offer an opportunity to reduce the burden of this disabling disease and prevent the occurrence of pancreatic cancer [2].

## Pain Management in Chronic Pancreatitis

*Kai Bachmann, Stephanie Plagemann, Yogesh Kumar Vashist, and Jakob R. Izbicki*

### Introduction

Pain is the leading symptom in patients with chronic pancreatitis. The aim of treatment is symptom control, improvement in quality of life, and prevention of ongoing damage to the gland. Chronic pancreatitis cannot be cured.

The main reason for hospitalization in patients with chronic pancreatitis is a constant severe and dull pain located in the mid-epigastrium, which radiates to the back and worsens after fatty meals. Because the pain has a multifactorial etiology, treatment needs to be variable. There are various theories as to the origin of the pain but, to date, its development is not fully understood and various different theories exist. More detailed information is presented in Chapter 41.

### Neuropathologic Theory

The pancreas is highly innervated through the vagal and splanchnic nerves. Unlike other visceral organs, it has primary afferent nociceptors that only respond to pain stimuli. These fibers have a subgroup called "silent nociceptors," which are only active during inflammation. Pancreatic nociceptors are activated by a variety of noxious stimuli. Those located on the supplying blood vessels are activated mechanically through stretching, ischemia, and necrosis. Others are affected chemically by inflammatory mediators [1].

The inflammation is mostly caused by noxious stimuli (the most common being alcohol and nicotine). These damage the parenchyma and the damaged tissue supports the inflammation by releasing proinflammatory mediators. The nerve endings then become sensitized to further stimulation. The silent nociceptors can be activated by peripheral inflammation, which increases the afferent activity in the spinal cord. The stimulation is transferred to the central nervous system and by repeated stimulation a peripheral sensitization develops. Released neurotransmitters are also transported to nerve endings located on the pancreas where they act as proinflammatory transmitters, resulting in neurogenic inflammation which causes edema and the infiltration of inflammatory mediators.

In summary, three factors lead to neurogenic pain: chronic stimulation through nociceptive pathways, peripheral sensitization due to inflammatory processes in the pancreas itself, and neural damage [2]. Currently these neurophysiologic aspects are the main focus of studies on pain in patients with chronic pancreatitis.

### The Plumbing Theory

According to the "plumbing theory," pain in patients with chronic pancreatitis originates in the plumbing of the pancreatic duct and is caused by intraductal calculi or duct strictures, leading to increased pressure in the gland. This is the theory on which interventional therapy is based. Compared to recently discovered neuropathologic factors, the theory that pancreatic duct hypertension causes pain is rather old. It was first described in the 1970s and interventions to drain the pancreatic duct based upon it became an option for treating pain.

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

Presently, few studies exist on the measurement of intraductal and intraparenchymal pressure. In addition, there is no evidence for the impact of developing chronic pancreatitis and evolving chronic pain in existing studies.

According to the plumbing theory, intrapancreatic pressure is described as a "compartment-like-syndrome," with chronic inflammation leading to fibrosis of the parenchyma and capsule, resulting in tension [3]. Different studies, however, have failed to substantiate these theories. The neurophysiologic theory seems to be closest to reality.

If pain in chronic pancreatitis develops due to a combination of the neuropathic pathway and the plumbing theory, it explains why treatments aiming at the nociceptive pain, such as opioid analgesia, and endoscopic or surgical interventions sometimes fail to ease the pain. To visualize possible central sensitization, electroencephalography and (functional) magnetic resonance imaging have been used [4].

## Pain Measurement

When evaluating therapy for a patient with chronic pancreatitis, objective parameters are needed to find out how much the patient is limited in his or her daily life by the symptoms of chronic pancreatitis. To measure quality of life, the European Organisation for Research and Treatment of Cancer (EORTC) questionnaire is a reliable base. The Izbicki pain score questionnaire correspondingly measures pain that lowers the quality of life with regard to pain frequency, its intensity (using a visual analog scale), the effectiveness of analgesia, and disease-related inability to work or take part in social activities [5] (Table 51.1). It is designed specifically for patients with chronic pancreatitis and is a reliable and comparable instrument, which focuses on the particular burdens of these patients. The score ranges from 0 to 100 in total [5]. A pain score of ≥50 is considered to be strong pain.

Examples of analgesic medication are given in Table 51.2.

**Table 51.1** Izbicki pain score.

| | | | | | | | | | | Points |
|---|---|---|---|---|---|---|---|---|---|---|
| **Frequency of pain attacks** | | | | | | | | | | |

**Table 51.2** Examples of analgesic medication for chronic pancreatitis.

| Medication | Dose |
|---|---|
| Morphine | |
| Buprenorphine | Partial opioid agonist with full effect at the μ-receptor |
| | Not first choice for acute pain |
| | Daily dose depends on chosen application form |
| Pethidine | Opioid agonist with high affinity to the μ-receptor |
| | max. 500 mg/day |
| | Metabolism through the liver with active metabolite norpethidine and elimination through the kidneys |
| | May induce a serotonin syndrome |
| Tramadol | Serotonin and noradrenaline reuptake inhibitor and μ-agonist (strong relation to nausea and vomitus, may induce a serotonin syndrome) |
| | Max. 400 mg/day |
| | Metabolism through the liver |
| Metamizole | As prodrug activation through hydrolysis, bioavailability is a bit higher when taken orally rather than parenterally |
| | Unselective COX inhibitor |
| | Analgesic, antipyretic, and spasmolytic |
| | Max. 4 g/day |
| | Elimination mostly through the kidneys |
| Acetylic acid (as representative for NSAID) | Unselective and irreversable COX inhibitor, analgesic, antipyretic, and anti-inflammatory, high first-pass effect |
| | Max. 3 g/day |
| | Inactivation through the liver and elimination through the kidneys |

This is not a complete list. Prior to any medical treatment the daily medication, individual risk factors, and side-effects should be evaluated.

## Treatment Options for Patients with Chronic Pancreatitis

As the cause of pain in chronic pancreatitis is not completely clear, the most useful hypothesis for optimal therapy might be a multifactorial understanding of the development of pain.

Change of lifestyle, diet, and medical treatment form the basis of initial treatment and in a small number of patients symptoms will be treated satisfactorily. In most cases, however, nutritional and medical treatments are the first step in the management of chronic pancreatitis before considering endoscopic or surgical approaches.

Even when patients remain abstinent from alcohol and nicotine, pain often persists. Abstinence is recommended to reduce the noxious stimuli to decelerate the progression of the chronic inflammation. Pain relief is attempted by analgesia, beginning with nonsteroidal anti-inflammatory drugs and ending with a combination of strong opioids (as recommended by the World Health Organization). Opioids may have substantial adverse gastrointestinal effects, including constipation, reflux, nausea, and abdominal pain—a phenomenon known as opioid-induced bowel dysfunction.

Recent studies have shown a positive effect of pregabalin in pain management, including in patients with persistent pain after surgery. The side-effects of pregabalin were only moderate. Patients complained of a slightly drunk feeling, which is negligible compared to strong opioids and their gastrointestinal side-effects [6,7].

Because of the pain, patients often abuse analgesics. Medical and dietary therapy can ameliorate the symptoms for a small number of patients. Nonetheless, alcohol abstinence does not disrupt the destructive progress nor alleviate the pain [8,9]. In patients where conservative treatment fails to provide improvement, interventional procedures are indicated.

The major challenge in managing chronic pancreatitis seems to be the evaluation of the optimal interventional treatment for each patient individually. Not only is it a question of what kind of therapy the patient will profit from, but also a question of finding the right time when each therapy is best.

The vast majority of patients present with dilatation of the duct or enlarged pancreatic head. Therefore, endoscopic procedures such as extracorporeal shock wave lithotripsy (ESWL) or stenting and surgical drainage or resection procedures are offered. Thoracoscopic splanchniectomy is also described as an alternative treatment with adequate pain relief [10].

Various interventional treatment options are available to restore pancreatic drainage. Endoscopic drainage of the pancreatic duct is an alternative to surgical intervention [11]. Another alternative is ESWL combined with endoscopic clearance [12,13]. Endoscopic interventions must often be repeated and are seen as more symptom control than definite therapy. Stents must be removed and replaced after a short period of time and are still accompanied by complications which may be severe.

Current studies have shown that a surgical approach is superior to endoscopic therapy with regard to pain reduction and drainage [14,15]. Studies also show that patients who undergo surgical treatment as initial therapy have fewer consecutive interventions, shorter hospital stay, and a better quality of life [16]. Nevertheless,

the surgical approach must be evaluated carefully with regard to personal risk of mortality and morbidity. There are different approaches depending on a patient's leading symptoms/complications. Therapeutic options are either drainage of a pancreatic or intestinal stricture, resection of the inflammatory center, or denervation of the supplying nerves [17].

In addition to the Whipple procedure, duodenum-preserving pancreatic head resection (DPPHR) has become the standard operation procedure for treatment of chronic pancreatitis [18]. Overall it can be concluded that because of the significantly better short-term outcome results and reproducible long-term results the DPPHR is the favorable surgical procedure.

## Timing

The greatest challenge seems to lie in evaluating the right time and the right treatment for each patient individually. Traditionally, surgery was evaluated as adequate treatment at an advanced stage of the disease because of its higher morbidity and mortality compared to conservative treatments.

Current studies have shown that an early surgical approach may be beneficial for pain relief and should be performed before the gland is irreversible damaged in its functional and morphology [19,20]. Patients who underwent surgical treatment earlier than 3 years after symptom onset had a higher chance of pain relief and lower odds of developing endocrine insufficiency, regardless of the surgical technique [21]. Therefore surgical treatment should be evaluated 1–3 years after onset of the disease.

## Conclusions

Pain treatment in patients with chronic pancreatitis is interdisciplinary. The baseline therapy for patients dealing with chronic pancreatitis lies in the reduction of noxious stimuli supporting the chronic inflammation and in the medical pain treatment. Endoscopic treatment is beneficial at the beginning of the disease, while dealing with complications, and prior to surgery to reduce the individual surgical risk. Considering the individual's reduction in quality of life and personal morbidity, surgical intervention should be evaluated at an early stage of the disease.

# Medical Treatment of Chronic Pancreatitis: Pancreatic Digestive Enzymes: Lipases, Proteases

*Mark E. Lowe*

*Department of Pediatrics, Division of Gastroenterology, Hepatology and Nutrition, Washington University School of Medicine, St. Louis, MO, USA*

## Introduction

The major macronutrients of the human diet are protein, fats, and carbohydrates. In the Western diet, proteins contribute about 15% of the total calories, carbohydrates as simple sugars or starches provide around 50%, and fats account for the remainder [1]. Dietary macronutrients require digestion into smaller molecules before uptake into the bloodstream. Proteases cleave proteins into short peptides and amino acids before transport into enterocytes (Table 52.1). A series of glycosidases release glucose from starch. Transporters in the intestinal epithelium absorb glucose and other simple sugars. Absorption of fats requires the release of the acyl chains by lipases and uptake of the fatty acids by enterocytes (Table 52.2). If digestion of macronutrients is incomplete, malabsorption results and macronutrients are excreted in the stool. The loss of energy and of building blocks for proteins, cell membranes, and signaling molecules compromises health in patients with chronic pancreatitis and pancreatic insufficiency.

Efficient digestion of macronutrients requires digestive enzymes produced by the exocrine pancreas. Pancreatic acinar cells are prodigious protein factories, secreting 6–20 g of protein every 24 hours. About 20 digestive enzymes account for most of the secreted protein [2]. The large number of digestive enzymes and their various specificities allow humans to adapt to varied diets and consume a wide range of foods. Failure of the exocrine pancreas to produce adequate digestive enzymes—exocrine pancreatic insufficiency (EPI)—occurs in 30–50% of patients with chronic pancreatitis, 85–90% of patients with cystic fibrosis, and 50–100% of patients after partial or complete pancreatic resection [3–5].

Patients with EPI have a number of symptoms and nutritional deficiencies related to maldigestion of dietary macronutrients. Maldigestion of starch can cause diarrhea; maldigestion of protein can lead to essential amino acid deficiency; maldigestion of fat can cause large-volume malodorous stools, abdominal pain, bloating, weight loss, and, in children, poor linear growth. Pancreatic insufficiency also leads to deficiencies of micronutrients including fat-soluble vitamins, magnesium, calcium, essential fatty acids, zinc choline, and folate [6]. Because incomplete digestion of dietary fats causes most of the clinical signs and symptoms of pancreatic insufficiency, treatment is guided by how well fat digestion and absorption is restored.

## Management of Exocrine Pancreatic Insufficiency

Pancreatic enzyme replacement therapy (PERT) with extracts of porcine pancreas has been the cornerstone of EPI management for over a century. Nevertheless, challenges still exist in the treatment of EPI [7]. First, the diagnosis of EPI can be problematic [8,9]. Second, PERT fails to resolve symptoms in some patients. The lack of a simple, accurate test for EPI hampers diagnosis and treatment [10]. At present, none of the tests for EPI perform adequately. For a long time the standard has been the quantitative 72-hour fecal fat test, but this presents difficulties with collection and analysis. The fecal elastase-1 test is only suitable as a screening test [11]. The endoscopic function test and mixed triglyceride breath test have their advocates, but both have shortcomings limiting their usefulness for identifying and treating patients with EPI.

**Table 52.1** Predominant human pancreatic proteases.

| Enzyme | Abundance | Specificity | Products |
|---|---|---|---|
| Trypsins | 20% | Endopeptidase; cleaves after lysine or arginine | Oligopeptides |
| Cationic trypsinogen (*PRSS1*) | | | |
| Anionic trypsinogen (*PRSS2*) | | | |
| Mesotrypsin (*PRSS3*) | | | |
| Chymotrypsinogens | 10% | Endopeptidase; cleaves after aliphatic amino acids | Oligopeptides |
| Chymotrypsinogen B, B2 | | | |
| Chymotrypsin C | | | |
| Chymotrypsin-like elastases | 10% | Endopeptidase; cleaves after alanine, glycine, serine | Oligopeptides |
| Elastase 2A, 2B | | | |
| Elastase 3A, 3B | | | |
| Carboxypeptidase A1, A2 | 10% | Exopeptidase; cleaves aromatic amino acids from C-terminus | Aromatic amino acids and peptides |
| Carboxypeptidase B1 | 10% | Exopeptidase; cleaves arginine or lysine from C-terminus | Arginine, lysine and peptides |

**Table 52.2** Predominant human pancreatic lipases.

| Enzyme | Abundance | Specificity | Products |
|---|---|---|---|
| Pancreatic lipase (*PNLIP*)—requires colipase (*CLPS*) | 10% | sn-1 and sn-3 positions of glycerides | Fatty acids monoacylglycerols |
| Pancreatic lipase-related protein 2 (*PNLIPRP2*) | 4% | sn-1 and sn-3 positions of glycerides | Fatty acids lysophospholipids |
| | | sn-1 and sn-2 positions of galactolipids | |
| | | sn-1 position of phospholipid | |
| Carboxyl ester lipase (*CEL*) | 4% | All positions of glycerides | Fatty acids lysophospholipids |
| | | sn-1 and sn-2 positions of galactolipids, | |
| | | sn-1 and sn-2 positions of phospholipids | |
| Phospholipase A2 (*PLA2*) | 2% | sn-2 acyl chain of phospholipids | Fatty acids lysophospholipids |

As shown in Table 52.3, the dosage of PERT varies with age [12]. The timing of the dose has been much discussed. One study suggests that PERT is most effective when given during and after a meal [13]. PERT in infants taking formula and in patients with feeding tubes presents unique problems. Infants can be given PERT by mouth after mixing the microgranules with an acidic food such as applesauce. Microgranules mixed with soft food or thick liquid can be given in feeding tubes without causing clogging [14,15].

If the patient has persistent symptoms, weight loss, or nutrient deficiencies on PERT, you should consider other causes before escalating the dose. In the absence of signs and symptoms of other disease, you should assess diet, timing of dose, and compliance. If the reason is not uncovered, the dose of PERT can be increased up to the maximum for age. Next, a proton pump inhibitor can be trialed. If symptoms persist, evaluate for other diseases such as liver disease, celiac disease, enteric infection, bacterial overgrowth, delayed gastric emptying, Crohn disease, lactose intolerance, functional abdominal disorders,

**Table 52.3** Recommended pancreatic enzyme dose.

| Age | Dose |
|---|---|
| Infants | 2000–5000 lipase units per 120 mL of formula or with each breastfeed |
| 4 years and younger | 1000–2500 lipase units per kg per meal |
| | 500 lipase units per kg per snack |
| 4 years and older | 500–2500 lipase units per kg per meal |
| | 250 lipase units per kg per snack |
| Adolescents and adults | 25,000–75,000 lipase units per meal |
| | 10,000–25,000 lipase units with snacks |

and eating disorders. Aggressive restriction of dietary fat is not recommended, particularly in growing children.

## Emerging Therapies

Although PERT is the mainstay of therapy for EPI, several issues have driven the search for alternative therapies. PERT frequently does not eliminate steatorrhea, requires multiple capsules with each meal, can trigger allergic reactions, has a theoretical risk of transmitting new infections to humans, and may not be accepted by patients who do not eat pork. Consequently, the development of recombinant digestive enzymes to replace porcine extracts has drawn considerable interest. Both bacterial and fungal lipases are in development as single agents or in combination with a protease and amylase [16,17].

# Nutritional Support of Chronic Pancreatitis

*Sinead N. Duggan*[1] *and Stephen J. O'Keefe*[2]

[1] *Department of Surgery, Trinity College Dublin, Ireland*
[2] *Division of Gastroenterology, Hepatology and Nutrition, University of Pittsburgh, Pittsburgh, PA, USA*

## Introduction

Nutrition in chronic pancreatitis has been described as a problem area [1]. There is a high risk of undernutrition, and the etiology is multifactorial. Pancreatic exocrine insufficiency (PEI) results in the malabsorption of macro- and micronutrients. Moreover, pancreatic enzyme replacement therapy (PERT) is often underused and underprescribed [2], and may not fully restore normal digestive function [3]. Poor dietary intake is common due to abdominal symptoms, pain, heavy smoking, and alcohol abuse. However, not all patients with chronic pancreatitis are classically underweight, and many are overweight and even obese.

## Undernutrition

The mean body mass index (BMI) of patients with chronic pancreatitis varies considerably between different countries, reflecting the general nutritional status of the country. Examples of BMI values reported for patients with chronic pancreatitis include: 19.3 kg/m$^2$ in India, 21.9 kg/m$^2$ in Italy, 22.1 kg/m$^2$ in Poland, 23 kg/m$^2$ in Denmark, 24 kg/m$^2$ in the Netherlands, and 25.9 kg/m$^2$/25.5 kg/m$^2$ in males/females in Ireland. Patients with chronic pancreatitis have consistently lower BMIs, lower muscle mass, and handgrip strength than matched controls. The clinical impact of overweight and obesity among patients with chronic pancreatitis is uncertain, but obesity may mask micronutrient deficiencies and sarcopenia. Those who abuse alcohol have an increased risk of undernutrition. High alcohol users tend to have poor nutrient intakes, either due to effects on appetite or due to displacement of food [4]. High alcohol intake also independently increases the risk of osteoporosis, and may be associated with diarrhea and malabsorption [5].

## Nutrient Deficiency

Specific nutrient deficiencies may arise in chronic pancreatitis as a result of steatorrhea (loss of fat-soluble vitamins), alcoholism (increased requirement or loss of water-soluble vitamins), or poor/imbalanced dietary intake. The prevalence of specific nutrient deficiencies varies between studies and countries. For vitamin D, the prevalence varies according to the definitions of deficiency or insufficiency used in various studies. Using serum 25-hydroxyvitamin D (25(OH)D) of less than 50 nmol/L to define deficiency, the prevalence varied from 41% (Czech Republic [6]) to 86% (India [7]). Vitamin E (which should be measured as a ratio of serum lipids) ranged from 24% (Ireland [8]) to 75% (South Africa [9]). Vitamin A deficiency ranged from 3% (the Netherlands [10]) to 40% (Japan [11]). One study reported that 63% of chronic pancreatitis patients had low serum levels of vitamin K [10], but vitamin K deficiency is more correctly measured by undercarboxylated osteocalcin or by measurement of proteins of vitamin K absence, and not by measurement of serum vitamin K or prothrombin time, both of which are inaccurate [12]. There have been few studies on other micronutrients, but isolated studies identified low magnesium [13] and zinc levels [14] among chronic pancreatitis patients, whereas vitamin B12 deficiency [15] was reportedly rare.

Despite the ostensibly common occurrence of biochemical vitamin deficiency, there are few published reports on the clinical manifestation of such deficiencies in chronic pancreatitis. The exception is vitamin

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

D, which contributes (among other factors) to the well-documented high prevalence of osteoporosis. Overt vitamin D deficiency resulting in osteomalacia (adult rickets) has also been reported in several case reports [16,17]. Neurologic abnormalities associated with vitamin E deficiency have also been rarely reported. One patient out of 13 with biochemical vitamin E deficiency had typical neurologic manifestations along with poorly controlled diabetes [18]. A condition known as brown bowel syndrome (associated with vitamin E deficiency) has also been reported in a deficient patient with vitamin chronic pancreatitis, celiac disease, and adenocarcinoma of the colon [19].

Clinical manifestations of vitamin A deficiency tend to manifest as visual defects. One case report [20] described a 45-year-old male with chronic pancreatitis, chronic alcoholism, diabetes, and a history of cholecystectomy. The patient presented with steatorrhea, cachexia, low BMI, and severe weight loss, along with ocular pain, photophobia, and decreased visual acuity. A second report [21] described a patient with chronic pancreatitis, malnutrition, and vitamin A deficiency who developed ulcerative keratitis in one eye and necrotizing stromal ulceration with hyphema in the other eye. In general, clinical deficiencies appear to take years to develop, and occur when there is an additional comorbidity, such as celiac disease or diabetes, or post surgery.

## Micronutrient Supplementation

There is a notable research gap regarding the management of nutrient deficiency in chronic pancreatitis, excepting vitamin D. In a study comparing oral vitamin D supplementation to ultraviolet B (UVB) radiation in chronic pancreatitis, oral supplementation (1520 IU/day) was significantly more effective in increasing serum 25(OH)D, achieving an increase of 32.3 nmol/L (95% 15–50 nmol/L) over 10 weeks [22]. High-dose, single-dose supplementation also appears to be safe and effective in increasing serum 25(OH)D. One study compared 600,000 IU or 300,000 IU single intramuscular injections or intramuscular saline, and found that the higher dose was more effective at increasing serum 25(OH)D, with no reports of hypervitaminosis or hypercalcemia [23].

There are few studies, if any, examining the effectiveness or safety of supplementing vitamins A, E, or K in patients with chronic pancreatitis and biochemical deficiencies. One study documented unexplained excess levels of vitamin A in patients with chronic pancreatitis who were not being supplemented [8]. Therefore mass supplementation of patients is not recommended, nor is it possible to recommended dosage, administration methods, or specific patient types that warrant supplementation. A precision medicine approach is warranted, with measurement of serum vitamins and attention given to optimizing dietary intake and PERT.

## Osteoporosis and Bone Health

Patients with chronic pancreatitis have a higher than normal risk of developing low bone mineral density. In a systematic review [24] of 513 patients who had undergone dual X-ray absorptiometry (DXA), 65% had osteoporosis or osteopenia [10,25–27]. Crucially, this high osteoporosis risk translates into a higher prevalence of low-trauma fractures compared to healthy controls [28,29]. The reasons for premature bone demineralization in chronic pancreatitis is multifactorial, and low serum 25(OH)D, poor dietary intake, heavy smoking, low physical activity, chronic inflammation [30], and malabsorption all contribute [24]. Basic preventative measures should be advised for all chronic pancreatitis patients, including adequate calcium and vitamin D intakes, regular weight-bearing exercise, and smoking and alcohol avoidance [31]. Where there is a diagnosis of osteopenia, a DXA should be repeated every 2 years, and for those with confirmed osteoporosis (or who have vertebral fractures), appropriate medication (such as bisphosphonates) should be prescribed. A referral to a bone specialist may also be required, as well as implemention of basic preventative measures (adequate calcium and vitamin D intakes, regular weight-bearing exercise, and smoking and alcohol avoidance) [31]. Sunshine exposure to optimize serum 25(OH)D should also be encouraged.

## Dietary Intervention

Nutritional status can be improved in chronic pancreatitis with the use of PERT when pancreatic insufficiency exists, and by individualized dietary intervention and dietary counseling by a pancreatic dietitian [32]. Nutritional requirements are up to 35 kcal/kg per day [5,33], and 1.2–1.5 g protein/kg per day [5,33,34]. Low-fat diets (or fat-free diets) are not recommended as they decrease energy intake and make food less palatable [5,35]. Rather, PERT should be optimized to allow for a moderate fat intake. Fat restriction may be trialled as a last resort for those with intractable malabsorption, once PERT has been optimized along with acid-suppression medications and other causes of malabsorption (such as small intestinal bacterial overgrowth) have been excluded. There is no evidence that vegetable fat is better tolerated than animal fat [5].

Where malabsorption continues with apparently adequate PERT, a restriction in dietary fiber might improve absorption, as dietary fiber may reduce enzyme availability [5,33]. However, long-term fiber restriction should be avoided as a diet rich in fruit and vegetables should always be recommended. A frequent, low-volume meal pattern should be advised. Some patients will require oral nutritional supplements, and whole-protein types could be tried first before progressing to peptide-based or medium-chain triglyceride (MCT)-enriched supplements. Antioxidant supplementation for the treatment of chronic pancreatic pain was considered a promising treatment option [36], but more recent studies have cast doubt on its effectiveness [37].

## Enteral and Parenteral Nutrition

The vast majority of patients with chronic pancreatitis will be maintained on an oral diet, with or without supplementation. Enteral nutrition is indicated for malnourished patients who are unable to meet their requirements orally [34,38,39]. Enteral feeding via the jejunal route should be performed in the case of delayed gastric emptying, chronic subacute obstruction of the upper gastrointestinal tract by pancreatic cysts [40], and persistent nausea or vomiting, or pain [34]. Nasojejunal feeding is associated with a reduction in pain, pseudocysts, and inflammation, as well as improvements in nutritional status [41,42]. Where jejunal feeding is required for a prolonged period, a surgical jejunostomy could be considered [34,43]. With regard to the composition of enteral feeds, peptide-based, MCT-based formulas may be trialled where standard feeds are not tolerated [40,42].

Some patients may require the administration of PERT along with enteral feeds. Parenteral nutrition should be avoided if possible as complication rates are higher in chronic pancreatitis due to pancreatic endocrine insufficiency (hyperglycemia) and immuno-incompetence (catheter sepsis). The use of transnasal endoscopic placement of distal jejunal feeding tubes in chronic pancreatitis usually avoids the need for commonly cited indications of parenteral nutrition, including gastric outlet obstruction secondary to duodenal stenosis, complex fistulating disease, and severe malnutrition prior to pancreatic surgery [38,40,44].

## Combined Pancreatic Exocrine and Endocrine Deficiency

With end-stage calcific chronic pancreatitis, pancreatic endocrine deficiency exacerbates malnutrition and makes nutritional management even more challenging. Type 3c diabetes is termed "brittle diabetes" and carries a high risk of hypoglycemia and neuroglycopenia, due to insulin therapy, glycogen deficiency, enhanced peripheral insulin sensitivity, malabsorption, poor dietary intake, and, for some, persistent excess alcohol intake. Rapid swings in blood glucose between hypoglycemia and hyperglycemia are common, the former due to impaired pancreatic glucagon and polypeptide responses, the latter exacerbated by unsuppressed hepatic glucose production [45]. Attempts to increase dietary intake and the addition of PERT to manage PEI may aggravate hyperglycemia further and have to be carefully covered by increased insulin therapy. Patients must be jointly managed with an endocrinologist, and careful dietary monitoring is essential [35,45].

## Structured Nutritional Assessment

Once diagnosed with chronic pancreatitis, patients should undergo thorough and regular nutritional assessment by a dietitian, along with the multidisciplinary team. Figure 53.1 summarizes the nutritional assessment of patients with chronic pancreatitis and includes six key elements:

1) There should be an anthropometric assessment (including BMI, mid-upper arm circumference, triceps skinfold), and a detailed assessment of current and habitual dietary intake [5].
2) Clinical evaluation should include the presence of nausea/vomiting, diarrhea, malabsorption, anorexia, early satiety, and pain.
3) Exocrine assessment should be performed, including the clinical symptoms and signs of malabsorption, and an objective measure of PEI.
4) A biochemical assessment of nutritional status should include measurement of fat-soluble vitamin levels, as well as measurement of fasting glucose and glycated hemoglobin, with a 75 g oral glucose tolerance test where equivocal.
5) Bone health should be evaluated by measurement of serum 25(OH)D and a baseline bone density scan.
6) The patient should be interviewed regarding smoking and alcohol status, physical activity, relevant social issues, and an assessment of quality of life should be performed.

Routine assessment will inform nutritional management, which should include optimization of dietary intake, appropriate and adequate PERT, and, for some, oral nutritional supplements and micronutrient supplementation. Routine nutritional assessment to maximize nutritional status is vital.

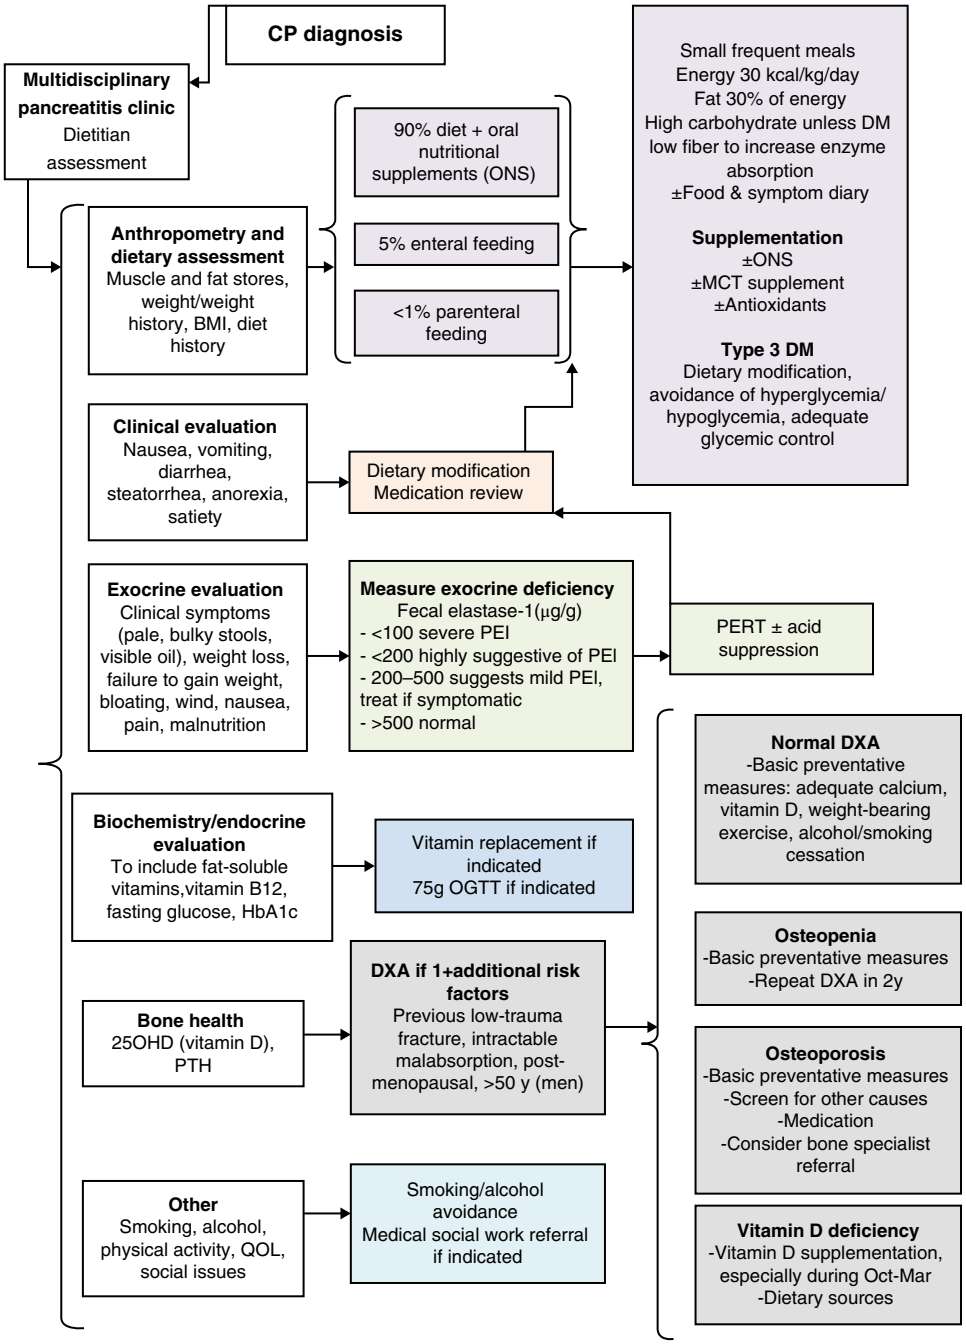

**Figure 53.1** Structured nutritional assessment and intervention for patients with chronic pancreatitis (CP). DM, diabetes mellitus; ONS, oral nutritional supplement; MCT, medium-chain triglyceride; PEI, pancreatic exocrine insufficiency; OGTT, oral glucose tolerance test; DXA, dual X-ray absorptiometry; PTH, parathyroid hormone; QOL, quality of life; PERT, pancreatic enzyme replacement therapy. *Source:* Duggan et al. 2010 [5].

# Medical Therapy for Chronic Pancreatitis: Antioxidants

*Chris E. Forsmark*

*Division of Gastroenterology, Hepatology, and Nutrition, University of Florida, Gainesville, FL, USA*

## Introduction

The medical treatment of chronic pancreatitis includes nutritional assessment and targeted supplementation, avoidance of potential environmental toxins (alcohol and tobacco), replacement of pancreatic enzymes, management of associated diabetes, monitoring for complications, and control of abdominal pain. In many patients, pain is the dominant clinical feature and the most difficult to treat. The effectiveness of medical therapies to relieve or reduce pain is limited. These potential therapies for pain include abstinence from alcohol and tobacco (if applicable), oral analgesics, adjunctive agents (e.g., tricyclic antidepressants, selective serotonin reuptake inhibitors [SSRI], serotonin–norepinephrine reuptake inhibitors [SNRI], gabapentoids), and antioxidants. Antioxidants are attractive as a potential therapy, given the contribution of oxidant stress and reactive oxygen species to acinar cell injury, pancreatic fibrosis and possibly pain; and by the finding that some patients with chronic pancreatitis have deficiencies in antioxidants such as vitamins C and E, methionine, or selenium.

## Pain and Oxidative Stress

The mechanisms of pain in chronic pancreatitis are varied, and include ischemia, direct toxicity (alcohol and its metabolites, tobacco), increased pressure within the gland or duct, associated complications (pseudocyst, secondary malignancy), and neurotoxic mechanisms involving inflammatory cells, nociceptive neurotransmitters, nerve cell injury, and neural remodeling. Chronic pain of any type also produces changes in central neural signaling and processing, which produces a neuropathic pain with features of hyperalgesia (exaggerated pain in response to normal stimuli) and allodynia (pain in response to normal physiologic processes). This centrally sensitized neuropathic pain may persist despite treatment of the underlying cause (e.g., continued pain after total pancreatectomy), and severely limits the effectiveness of therapies for chronic pain syndromes.

Oxidative stress is implicated as a potential mechanism of pain in chronic pancreatitis, and has been documented in some patients with chronic pancreatitis. Deficiencies in baseline antioxidant levels [1,2], increases in antioxidant catalytic enzymes [2,3], and elevations in markers of oxidant-driven lipid peroxidation have been noted [2–5]. Most of these studies include patients with advanced chronic pancreatitis (due to alcohol or tobacco), as well as patients with tropical pancreatitis. These patients, particularly if they are malnourished, may be prone to preexisting deficiencies in antioxidant capacity. In addition, the proportions of patients who smoke vary from study to study, and smoking is a potent inducer of oxidative stress. Thus the presence of smoking or of malnutrition could be important confounders in assessing the pathologic contribution of antioxidants to chronic pancreatitis in general and pain in particular. These studies did not directly correlate the level of antioxidants with the severity (or even presence) of abdominal pain. Replacement or supplementation with antioxidants might change the micronutrient and antioxidant milieu in patients who are deficient, and remediate oxidative stress. This could potentially reduce pain, or could have other beneficial effects in protecting the remaining pancreas from additional damage. The precise mechanism by which a change in oxidative stress could reduce pain is not known. In addition to the treatment of pain in chronic pancreatitis, there has been interest in using antioxidants to treat acute pancreatitis,

prevent relapses of acute pancreatitis, and prevent post-endoscopic retrograde cholangiopancreatography (ERCP) pancreatitis [6], but these topics are not reviewed in this chapter.

## Clinical Studies of Antioxidants for Pain

A number of randomized trials have assessed the efficacy of various antioxidants in reducing the pain of chronic pancreatitis but have reached different conclusions on the overall effect, and on the magnitude of pain relief. They include the use of single antioxidant agents (e.g., allopurinol or curcumin) as well as mixtures of antioxidants (usually vitamins E and C, methionine, selenium, and β-carotene). These randomized studies have been the subject of several meta-analyses [6–10] and a Cochrane systematic review [11]. Interpreting the results is made more difficult by the various types of antioxidant agents and mixtures utilized, and by the various methods of measuring pain. In addition, the studies comprise patients with a wide variety of etiologies, are often small, may only exist in abstract form, and include a mixture of both chronic pancreatitis and relapsing acute pancreatitis. This chapter will focus on studies using mixtures of antioxidants.

An early and widely quoted study by Uden et al. recruited 23 patients with both acute relapsing and chronic pancreatitis in a blinded crossover study [12]. The patients were provided a mixture of selenium, β-carotene, vitamin C, vitamin E, and methionine (or matching placebo) for 10 weeks. Only 20 patients followed the protocol, including 15 patients with chronic pancreatitis. Patients on active therapy reported less background pain, and fewer exacerbations of pain. A trial by Kirk et al. [13] recruited 36 patients with painful chronic pancreatitis into a placebo-controlled crossover trial of a similar mixture of antioxidants. This trial reported on the 19 patients who completed both periods of treatment, and noted improved quality of life. Data from the pain diaries used to assess pain were not analyzed because they were not consistently completed, although there was improvement in pain based on a single question from the quality of life (QOL) instrument. Both of these studies had large numbers of dropouts, and did not employ a washout period between treatments. A washout may be particularly important, as those receiving antioxidants may exhibit improved levels of antioxidants in the subsequent placebo period.

A number of other crossover trials [14,15] and unblinded randomized trials [16,17] suggested benefit, although each was relatively small and had significant numbers of dropouts. Recently, larger and better designed trials have provided estimates of the potential effectiveness of antioxidants.

A large, placebo-controlled, randomized, and blinded study by Bhardwaj et al. [4] recruited 147 patients with painful chronic pancreatitis for a 6-month trial of antioxidants (600 μg selenium, 0.54 g ascorbic acid, 9000 IU β-carotene, 270 IU α-tocopherol, and 2 g methionine daily). The main outcome, reduction in number of painful days per month, was higher in the active treatment arm (10.5 ± 11.8 fewer days per month, vs. 4.4 ± 5.8 in placebo), which also corresponded to less use of analgesics. One-third of the antioxidant group became pain free during treatment, compared with 12.5% of the placebo group. The study also assessed baseline nutritional status and markers of oxidative stress and antioxidant status, and demonstrated significant improvement in these in the active treatment arm. The patients in this trial were relatively young (mean age 30) and two-thirds had idiopathic pancreatitis; with 36% being undernourished at initiation of the trial. There were a significant number of patients lost to follow-up during the trial (40/147 patients lost to follow-up at some time during the 6-month trial). The large number of dropouts is seen with most trials in chronic pancreatitis, but did create imbalances in the two groups which could have introduced bias.

The other large, randomized, blinded, placebo-controlled trial by Siriwardena et al. [18] recruited 92 patients with painful chronic pancreatitis for a 6-month trial of antioxidants (300 μg selenium, 740.4 mg [496 IU] α-tocopherol, 758 mg ascorbic acid, 2.88 g l-methionine, and 25.2 mg β-carotene daily). These dosages are higher than those in the study by Bhardwaj et al. [4]. The primary outcome was the change in pain, using a visual pain score. A variety of other pain scores were also calculated from pain diaries, as well as pain questions on QOL measures. Although the study initially planned to recruit 57 patients, a planned interim analysis by the steering committee led to an increase in sample size. Compared to the study by Bhardwaj et al., these patients were older (mean age 50), more likely to have alcohol and smoking as the etiology, not undernourished, more likely to be on chronic opioid therapy, and more likely to have undergone previous endoscopic or surgical therapy. After 6 months there was a general decrease in overall pain in both groups of around 2 points on the visual scale, but no difference between groups in these measures or in other measures using daily pain diaries, pain questionnaires, need for hospitalization, opiate use, or QOL. The level of antioxidants was significantly increased in the active treatment arm. During follow-up 22/92 patients withdrew or were lost to follow-up.

These two large randomized trials and several smaller trials have been the subject of several systematic reviews

and meta-analyses. A Cochrane review [11] analyzed 12 randomized controlled trials, of which 6 were double-blinded and placebo-controlled. They note that most trials were small and had high rates of dropout. Combining the studies, those randomized to antioxidants had less pain after 1–6 months of therapy (an average difference of 0.33 [95% CI: –0.64 to –0.02] points less on a visual analog scale of 0–10). The number of pain-free patients was not different between groups, and side-effects were more common in the antioxidant group (leading to 16% of participants stopping therapy). The data were not felt to be sufficient to be able to draw conclusions on the effect of antioxidants on analgesic use, exacerbations of pancreatitis, or QOL. It should be noted that although many of the analyzed studies used mixtures of antioxidants, the dose varied, and some studies used allopurinol or curcumin. This Cochrane review concludes that antioxidants can reduce pain slightly in patients with chronic pancreatitis, but that the clinical relevance of this slight decrease is uncertain.

Given this analysis of the existing data, it is logical to try to identify the subgroup of patients most likely to experience benefit from antioxidants. A number of expert opinion and additional meta-analyses have suggested that the response might vary with etiology of chronic pancreatitis [19,20], baseline levels of antioxidant reserve [21], adequacy of baseline nutrition, type of antioxidant [9], duration of opioid analgesia use [21], stage of disease [19], and others. Although many of these seem plausible, they remain unproven.

Antioxidants are not without risk. The randomized trials of antioxidants note a relative risk of side-effects (largely headache and gastrointestinal side-effects) approximately 5 times greater in the antioxidant group (occurring in 1 in 6 patients) [11]. In addition, mortality appears to be slightly increased in patients receiving antioxidants (vitamin E and β-carotene in particular) as part of large primary and secondary prevention trials [22], with a hazard ratio of 1.03–1.05.

## Conclusions

Oxidative stress and reactive oxygen species clearly play an important role in the pathogenesis of chronic pancreatitis. Although the two best studies reach opposite conclusions, the combined analyses of all randomized controlled trials demonstrate a measurable beneficial effect of antioxidants on pain. Even though the overall magnitude of this effect is quite small and not likely to be clinically meaningful, there is the potential that a subgroup of patients might be able to be identified who are much more likely to benefit. The varied and heterogeneous mechanisms of pain and the complexity of nociceptive signaling [19,23,24] imply that no single therapy will be effective in all patients, but the specific subgroup that might respond to antioxidants is not known. Additional studies will be required to identify this cohort.

# Strategies for Endoscopic and Surgical Treatment of Chronic Pancreatitis

## 55

## Evidence of Endoscopic and Interventional Treatment of Chronic Pancreatitis and Pseudocysts

*Jörg Schirra[1], Markus M. Lerch[2], and Julia Mayerle[1]*

[1] *Department of Medicine II, University Hospital Munich, Ludwig-Maximilians-University Munich, Germany*

### Indications for Interventional Endoscopic or Surgical Therapy

Belt-like upper abdominal pain is regarded as a cardinal symptom of chronic pancreatitis, together with weight loss, steatorrhea, and diabetes mellitus. In the absence of causal therapeutic options, treatment is restricted to symptom control by means of enzyme replacement, pain therapy, and optimal control of endocrine insufficiency. Between 30% and 60% of patients develop complications of their disease, such as strictures of the common bile duct, inflammatory masses, pancreatic pseudocysts, or pancreatic duct strictures or ductal stones, which require interventional or surgical treatment.

Chronic pancreatitis with severe pain requiring constant analgesics should be treated by interventional or surgical procedures dependent on the symptom causing pathogenic features [1]. The presence of an inflammatory mass clearly favors a surgical resection. In the case of a dilated pancreatic duct due to strictures and/or ductal stone, both endoscopic as well as surgical drainage procedures are effective. The indication of an endoscopic drainage has not been fully clarified in randomized controlled trials. Endoscopic treatment of a dominant stricture of the main pancreatic duct (MPD) is often followed by pain relief in the short term [2,3]. Retrospective studies reported long-term pain relief in 32–68% of patients [3]. Two randomized controlled studies directly compared endoscopic procedures with resection or a surgical drainage procedure [4–6]. Those studies proved surgery to be superior to endoscopy with respect to long-term outcome. However, endoscopic drainage can achieve a long-lasting complete or partial pain relief in at least one-third of patients, and it is associated with lower mortality and does not impede surgery as a second-line therapy [6].

In the presence of a resectable pancreatic mass suspected to be caused by pancreatic carcinoma surgical resection should be performed. Without surgery, life expectancy for patients with pancreatic carcinoma is less than 1 year; after successful resection 20–25% of patients may survive more than 5 years [7–9].

Gastric outlet obstruction secondary to chronic pancreatitis requires surgical or endoscopic treatment for persistent clinical symptoms. A noninterventional management supplemented by endoscopic dilatation may be sufficient for an adequate quality of life in at least 30% of cases. According to the natural course of chronic pancreatitis further intervention will be necessary in about 30–60% of patients. As there are no studies directly comparing the efficacy of pancreatic head resection, bypass surgery, and endoscopic insertion of self-expanding metal stents (fcSEMS) [10], the decision may be taken in consideration of the patient's comorbidities.

Symptomatic stenosis of the common bile duct (CBD) will develop in 10–40% of cases, requiring endoscopy with dilation and stent insertion. The outcome of endoscopic therapy in patients without acute inflammation of the pancreas improved with new techniques but is still not entirely satisfactory. Stent therapy rarely resolves a stricture beyond 1 year of therapy [11], in particular in the presence of calcifications within the pancreatic head [12]. Lasting patency rates have significantly improved with the use of fcSEMS. Surgical resection should be performed if symptoms or cholestasis persist after temporary endoscopic therapy for not longer than a year.

Fragmentation and removal of stones within the pancreatic duct by extracorporeal shock wave lithotripsy (ESWL) have somewhat replaced surgery since its introduction in 1989. Several retrospective studies have shown ESWL to be an effective and safe management

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

option for pain relief in chronic calcifying pancreatitis, with pancreatic main duct stones greater than 5 mm [13], for which ESWL followed by endoscopic retrograde cholangiopancreatography (ERCP) may be the standard of care. Intraductal lithotripsy under direct endoscopic vision is a promising technique in evolution.

Interventional endoscopic options in chronic pancreatitis will be discussed in more detail below.

## Treatment of Pancreatic Cysts

According to the revised Atlanta classification a pancreatic pseudocyst is an encapsulated collection of fluid with a well-defined inflammatory wall usually outside the pancreas with minimal or no necrotic tissue content. This entity usually arises in connection with chronic pancreatitis [14]. A walled-off necrosis (WON) is defined as a mature, encapsulated collection of pancreatic and/or peripancreatic necrosis that has developed a well-defined inflammatory wall. WON usually occurs >4 weeks after the onset of necrotizing pancreatitis [14]. The prevalence of pancreatic pseudocysts in chronic pancreatitis ranges between 20% and 40% [15]. They occur with the highest frequency in patients with alcoholic chronic pancreatitis (70–78%), followed by idiopathic chronic pancreatitis patients (6–16%) and biliary pancreatitis patients (6–8%) [15,16]. Approximately 40% of the fluid collections resolve spontaneously within the first 6 weeks after an acute attack of pancreatitis. In contrast, spontaneous remission of pseudocysts after 12 weeks is a rare event. Complications are observed in up to two-thirds of cases, encompassing pain, infection, hemorrhage, cystic rupture, or obstruction of adjacent organs such as cholestasis, gastric outlet obstruction, or vascular stenosis. A multivariate analysis showed a pseudocyst/WON size <4 cm as the only favorable factor for spontaneous resolution [17]. The increase in size of a pseudocysts/WON to over 5 cm in diameter is associated with an increased risk of complications [18]. Asymptomatic pseudocysts >5 cm in diameter which do not resolve within 6 weeks can be an indication for treatment. However, symptomatic pseudocysts should undergo treatment regardless of their size.

Only limited information is available with regard to interventional therapy of pancreatic pseudocysts for pain management. Most of the data at hand are based on retrospective case series [19–22], but three systematic reviews are available [23–25]. Pain relief will be achieved in a large number of patients (about 80%). Although medical management of chronic pancreatitis can result in pain relief, in a certain percentage of patients, interventional or surgical drainage is still the more effective form of pain management regardless of the drainage procedure.

A diagnostic needle aspiration of the cyst may be performed for suspected infection or for suspected cancer. If needle aspiration of the cyst confirms an infection, then drainage is indicated. Surgical treatment should be carried out if malignancy is suspected. In 28% of all MRI scans of the abdomen, a cystic lesion of the pancreas is discovered as an incidental finding [26] when population-based cohorts are investigated, although most of these cysts are smaller than 1 cm in diameter. More than two-thirds of these lesions are dysontogenetic cysts or pancreatic pseudocysts. Of the cystic lesions that are not pancreatic pseudocysts but genuine cystic neoplasms, 30% are benign serous cystadenomas. It is found that 45% of the resected lesions are mucinous cystic neoplasms and 25% intraductal papillary mucinous neoplasms (IPMN). Solid pseudopapillary tumors or cystic acinar cell carcinoma are rather rare entities. For the differential diagnosis of cystic tumors in asymptomatic patients, the question of a connection to the pancreatic duct (IPMN and pancreatic pseudocysts) and of the size of the cystic lesion (indication for resection in the case of IPMN or therapeutic indication for pseudocyst) is essential. Diagnostic needle aspiration of a cyst with the aid of endoscopic ultrasound (EUS) helps in differentiating between premalignant cystic neoplasms, cystic malignancies, and pseudocysts. In case the fluid analysis reveals a carcinoembryonic antigen (CEA) >400 ng/mL, a variably increased or low amylase (lipase), high viscosity, mucin, or epithelial cells in the cyst content, then a mucinous neoplasm must be assumed [26–28]. If a connection to the pancreatic duct is excluded, the final diagnosis of a mucinous cystic neoplasm (MCN) can be made. A serous cystadenoma is diagnosed in 30% of cystic lesions and virtually never turns into a malignant lesion. In this case aspiration of the cyst is negative for mucin, CEA, and amylase. Cytology reveals a glycogen-rich epithelium.

Surgical percutaneous or endoscopic drainage of pancreatic pseudocysts demonstrate comparable results regarding technical success, efficacy, and recurrence rates [24,29]. Percutaneous drainage is associated with the risk of external fistula and may affect the patient's quality of life. Endoscopic drainage is less prone to complications if compared to surgical procedures. A systematic review of retrospective series of endoscopic and surgical drainage showed similar morbidity (13.3% vs. 16%) and long-term pseudocyst recurrence (10.7% vs. 9.8%) but lower mortality (0.2% vs. 2.5%) achieved by an endoscopic drainage [30]. Therefore, the endoscopic approach should have first preference as it is less invasive and more convenient for the patient. In a recent randomized controlled trial that compared endoscopic versus surgical cystogastrostomy for pancreatic pseudocyst drainage endoscopic treatment was associated with shorter hospital stays, improved physical and mental

health status of the patients, and lower costs [29]. However, the decision between endoscopic and surgical drainage should take into account the cyst location and additional pathophysiologic features. Surgical drainage may be the preferable therapy in hemorrhagic pseudocysts as endoscopic drainage is associated with a higher risk of bleeding. Approximately 10% of pseudocysts recur in the long term after endoscopic drainage (Table 55.1). Although initial therapy for nonhemorrhagic pseudocysts should be endoscopic drainage, surgery may follow in case of recurrence.

Drainage of pseudocysts can be carried out by transgastric, transduodenal, or transpapillary routes. Transmural drainage should be done under EUS guidance to assess the pseudocyst location, size, wall, content, and adjacent blood vessels. Two randomized controlled trials compared transmural drainage with and without EUS guidance [38,39]. No difference was observed in terms of morbidity and clinical outcome but technical success was higher with EUS. The success rate in 1018 published patients with transmural drainage of a pseudocyst was 87% (Table 55.1), with more recent studies reporting success rates of more than 90%. The mortality rate in larger case series involving more than 30 patients was 0.2%, the recurrence and complications rates are reported to be around 9% and 13%, respectively. Without antibiotic prophylaxis the procedure-related incidence of an infection of a pseudocyst and the risk of development of a pancreatic abscess increases [54,55]. Antibiotic prophylaxis for transmural or transpapillary drainage of

pancreatic pseudocysts is recommended in recent guidelines based on expert opinion [3,56].

Double-pigtail stents should be used for transmural drainage of pancreatic pseudocysts because straight stents are associated with more frequent and severe complications in a retrospective study [51]. Early stent retrieval within 2 weeks after cyst resolution was associated with a higher rate of recurrence in a prospective randomized trial, suggesting that long-term stent placement for more than 2 months may prevent recurrence without an increase of severe adverse events [57]. In its clinical guideline the European Society of Gastrointestinal Endoscopy (ESGE) recommends transmural drainage of pancreatic pseudocysts by inserting at least two double-pigtail plastic stents which should not be retrieved before at least 2 months following stenting [3]. Recently, short, lumen-apposing, fully covered, self-expandable metal stents (LAMS) have been developed for EUS-guided drainage of peripancreatic fluid collections. Due to its ease of use and the large diameter, the LAMS may make drainage of peripancreatic fluid collections more effective, particularly the endoscopic debridement of WON [58,59]. With regard to costs and possible serious adverse events, however, further and prospective studies are needed to investigate the safety, efficacy, and exact role of LAMS in the management of both pseudocysts and WON [60,61].

Whether an attempt should be made to drain the pseudocyst using an ERCP via the papilla instead of primarily transgastric or transduodenal drainage is still a matter of controversy. According to retrospective studies, transpapillary drainage seems to be associated with lower morbidity (mainly pancreatitis) and similar long-term success but was used for smaller pancreatic cysts than transmural drainage [3,36,44,62]. Between 22% and 57% of pancreatic pseudocysts may have a connection with the pancreatic ductal system [63]. Thus, an endoscopic retrograde pancreatography (ERP) can precede endoscopic transmural drainage in order to detect a connection with the duct or to exclude a rupture of pancreatic ducts (8% after acute necrotizing pancreatitis). Transmural drainage in the presence of an undetected rupture of the pancreatic duct or an association of the pancreatic pseudocyst with an obstructed pancreatic duct is less promising with regard to long-term outcome of therapy [64,65]. Treatment of pancreatic duct obstruction and—if possible—bridging of a pancreatic duct rupture is recommended in these cases.

## Therapy of Pancreatic Duct Stenoses and Ductal Stones

Ductal and interstitial hypertension and possible pancreatic ischemia accompanying outflow obstruction due to pancreatic duct stenoses or ductal stones may play an important role in the pathogenesis of pain. The aim of endoscopic and surgical decompression therapy in patients with chronic pancreatitis and pain and/or clinical episodes of acute pancreatitis is to remove the obstruction and to allow outflow of exocrine pancreatic juices into the duodenum. Biliary techniques such as sphincterotomy, dilatation, ESWL, and stent insertion have been modified for the pancreatic duct. Endoscopic decompression represents an alternative to surgery and is associated with low morbidity and low mortality. Endoscopic interventions do not interfere with surgery that might still be necessary later in the course of the disease. Clinical success after endoscopic reduction of the intraductal pressure does provide some indication of the later result of surgical drainage or a resection procedure.

Pancreatic ductal stones are a consequence rather than the cause of chronic pancreatitis. They can, however, lead to consecutive outflow obstruction and thus cause pseudocysts or fistula development, recurrent exacerbations or contribution to the pathogenesis of pain. Under these conditions, treatment of pancreatic ductal stones seems appropriate. Endoscopic treatment appears particularly suitable for treating solitary stones and obstructions close to the papilla or in the body of the pancreas. After pancreatic sphincterotomy, pancreatic duct stones <5 mm may be extracted without prior fragmentation. Radiopaque obstructing stones ≥5 mm should be fragmented by ESWL followed by extraction of the fragments by ERCP [3]. There is evidence from a prospective randomized trial that the subsequent endoscopic removal of the fragments is not a prerequisite for the effectiveness of the procedure [66]. One large-scale single-center retrospective study with follow-up of 272 patients after ESWL and ERCP for >60 months reported no pain in 60% of patients, mild to moderate pain in 36%, and episodic severe pain in 4% of patients [67]. Recurrence of intraductal calculi was seen in 23% of patients. A recent meta-analysis of 27 studies (total of 3189 patients) showed that ESWL is useful for clearing pancreatic duct stones greater than 5 mm and for decreasing pain [13]. The pooled proportion of patients with absence of pain at follow-up (median 2 years) was 53% (95% CI: 50.8–54.6) and mild to moderate pain was 33% (95% CI: 31.4–35.5). Quality of life improved in 88% and complete ductal clearance was achieved in 71%. However, no studies ever compared the treatment of ductal stones with the natural course or a sham intervention. In two studies in which endoscopic treatment was compared with surgery (i.e., drainage operation), the results after surgery were significantly better with respect to long-term pain reduction [4,5]. The treatment of pain in patients with diffuse calcifications by means of ESWL has not been substantiated in any studies.

Dominant pancreatic duct strictures with a prestenotic dilatation ≥6 mm in diameter, which may be responsible for pain, recurrent exacerbations, maintenance of a pseudocyst, fistula, or other complications, can be treated by endoscopic dilatation and plastic stent placement [3] (Fig. 55.1). Removal of the obstruction of the pancreatic duct is effective for the treatment of pain on short to intermediate terms. Success rates between 65% and 95% have been reported [3]. In the largest hitherto examined cohort of 1021 patients, a long-term reduction (mean 4.5 years) of pancreas-related pain was achieved in 85% of cases [68]. However, 24% underwent surgery during further follow-up, which—on an intention-to-treat basis—reduced the rate of successful treatment to 65%. In 79% of the patients stent therapy for control of pain had to be repeated within 1 year and in 97% within 2 years. The only randomized study recruited 41 consecutive patients with chronic pancreatitis with a dominant pancreatic duct stricture to either receive pancreatic duct stenting or to serve as control. During a mean follow-up of 62.5 ± 20.9 months pain recurred in 15% of patients with pancreatic duct stenting (3/20) and in 50.0% of control patients (11/22) ($P < 0.05$). Progression of exocrine insufficiency in the stent group was significantly slower than in the control group ($P < 0.05$), while endocrine function showed no difference between groups [69]. Preliminary studies suggest temporary placement of fully covered fcSEMS into the pancreatic duct for pain relief may be safe and effective short-term treatment [70–72]. Their potential advantage versus plastic stents is the longer period of stent patency. However, long-term results are so far not available. Uncoated self-expandable metallic stents are not recommended due to the rapid proliferation of duct epithelium as a reaction to the metal mesh graft.

Plastic stents inserted into the pancreatic duct can induce secondary changes with subsequent fibrosis and strictures [73,74]. There are currently no reliable data available regarding the necessary duration of stent therapy. Some authors recommend treatment over 1 year with an exchange of the stent at least every 3 months [3]. Other centers suggest exchanging the stent in the case of

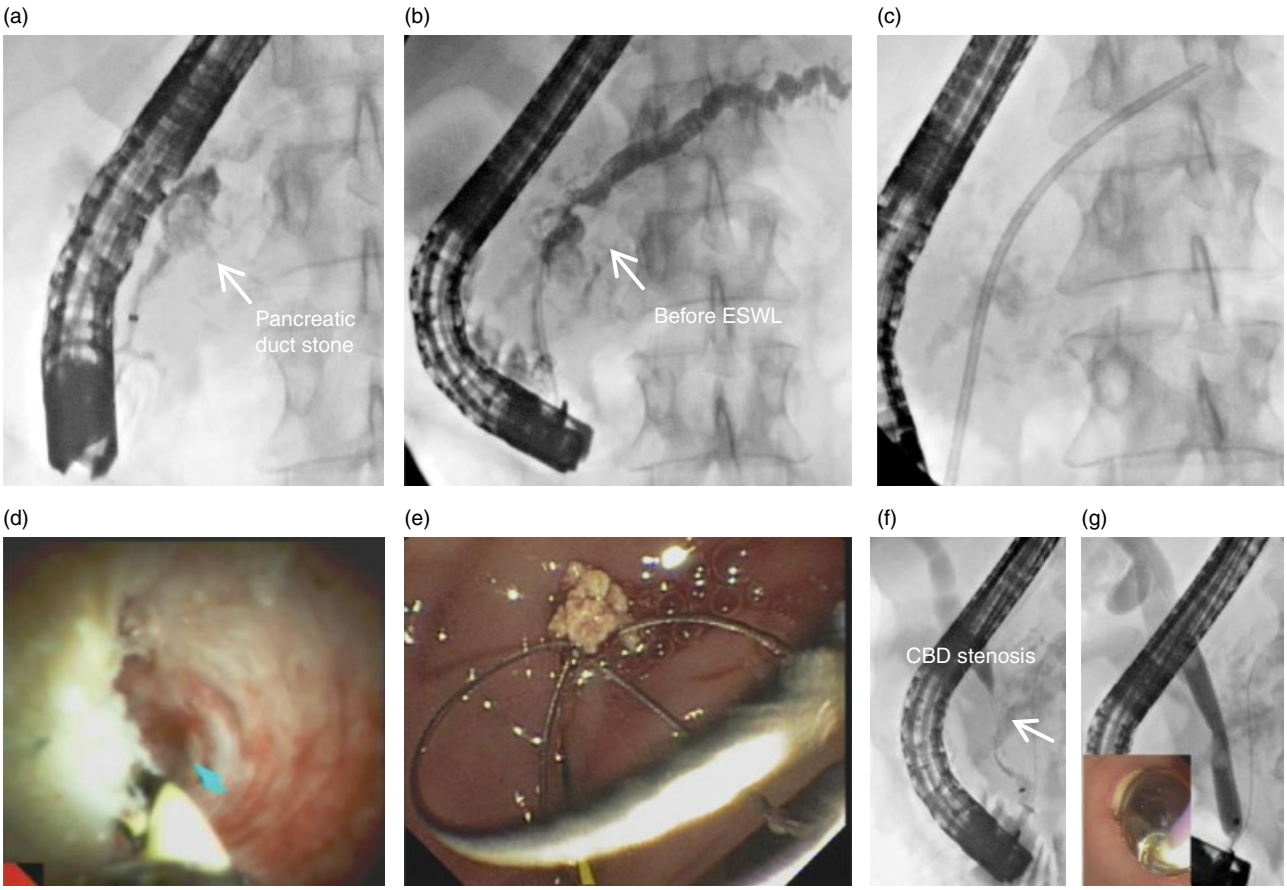

**Figure 55.1** A 48-year-old patient with symptomatic calcifying chronic pancreatitis. (a) Pancreatic duct with prepapillary stricture and a stone with a size of 8 × 10 mm behind the stricture. (b) Dilatation of the stricture and stent insertion (7F 12 cm). (c) Stent for extracorporeal shock wave lithotripsy. (f) Common bile duct (CBD) stricture and balloon dilatation of the stricture before stent insertion (g).

recurring symptoms. This is a question that should be solved in a randomized trial. Improved pain management, however, was achieved by a pancreatojejunostomy in two randomized controlled studies [4–6]. Endoscopic therapy led to pain reduction or complete pain relief in 32% [5] and 61% [4], respectively, whereas this was achieved in 75% [5] and 86% [4], respectively, by pancreatojejunostomy. However, endoscopic drainage can achieve a long-lasting complete or partial pain relief in a substantial proportion of patients, and does not impede surgery as a second-line therapy.

## Endoscopic Treatment of Bile Duct Obstruction

Obstruction of the CBD will develop in 3–46% of patients with chronic pancreatitis [75]. Indications for endoscopic intervention include significant cholestasis, cholangitis, prevention of secondary biliary cirrhosis, and differentiation of the cause of pain (obstruction of the CBD vs. chronic pancreatitis). Long-term success rates can be achieved in one- to two-thirds of the patients, dependent on the endoscopic drainage modality [3]. Thus endoscopic therapy is indicated as an interim procedure until definitive surgery (e.g., as an acute intervention in septic patients, or in patients unfit for surgery or in those unwilling to undergo surgery). Complications include stent occlusion and cholangitis. Prophylactic antibiotic therapy together with ursodeoxycholic acid has not been proven to be effective [76–78]. Endoscopic drainage should be, therefore, of limited duration.

Immediate endoscopic drainage should be performed in the case of obstructive cholangitis. Although no published studies have compared endoscopic therapy to observation without drainage, treatment of mechanical cholestasis as part of the therapy for cholangitis is important and well substantiated by clinical experience. If chronic pancreatitis causes distal obstruction of the bile duct with cholestasis or obstructive jaundice, then either surgical treatment or endoscopic stent therapy can be performed. A retrospective analysis of all patients treated with an average observation period of 45 months demonstrated that stent therapy for the obstruction of the CBD in patients with chronic pancreatitis has no additional effect beyond 1 year [11]. Surgical treatment should therefore be pursued for recurrence of CBD obstruction after 1 year of stent therapy. A prospective study showed an even worse long-term effect of stent management of distal bile duct obstruction in patients with calcifying pancreatitis (long-term effect 9%) [12]. In these cases surgical treatment is clearly preferred.

The placement of multiple plastic stents into the biliary stricture of patients with chronic pancreatitis is superior to insertion of single plastic stents. In prospective, nonrandomized, and retrospective studies the success rate after insertion of up to five plastic stents into the CBD was higher than after a single stent, with long-term success rates of up to 92% of patients during a period of 12–48 months after stent removal [79–81]. The insertion of coated metal stents has demonstrated impressive results in case series [82,83]. A prospective nonrandomized study at 13 centers in 11 countries treated 187 patients with benign biliary strictures by fcSEMS [84]. Removal was scheduled at 10–12 months. On an intention-to-treat basis the stricture resolution rate was 76%, and the rate of stricture recurrence was 14.8% (95% CI: 8.2–20.9) during follow-up for 20 months. Thus, effective long-term success was achieved in 62.7% of patients.

A recent randomized controlled study compared insertion of multiple plastic stents with a single fcSEMS in 112 patients for treatment of benign biliary strictures over 1 year [85]. The resolution rate of biliary strictures was 85.4% with plastic stents and 92.6% with fcSEMS ($P < 0.001$). The mean number of ERCP to achieve resolution was significantly lower for fcSEMS as for plastic stents. The recurrence rate within 1 year of follow-up did not differ significantly between groups (14% with fcSEMS vs. 5% with plastic stents). Thus, fcSEMS placement appears to be an advantageous alternative to plastic stents in the management of benign biliary strictures. Exchange of single plastic stents should be undertaken at least every 3 months because otherwise occlusion of the stent may cause cholangitis. The exchange interval is less critical with the insertion of multiple stents and is unnecessary if fully coated metal stents are used. Those are patent for up to 9 months [86]. Currently, a high spontaneous migration rate of fcSEMS in approximately 30% of cases [84,85] will often require an earlier exchange.

The management of chronic bile duct obstruction after unsuccessful attempts at endoscopic treatment should be surgical. If there is an indication to treat cholestasis by surgery, a preoperative endoscopic insertion of a stent into the bile duct should only be undertaken if (i) surgery cannot be done promptly or (ii) cholangitis is present. A multicenter prospective randomized study examined the effect of preoperative endoscopic stent insertion into the CBD for mechanical cholestasis secondary to carcinoma of the head of the pancreas before pancreas resection. Preoperative drainage significantly increased the rate of complications [87]. A patient with a short individual life expectancy, high comorbidity, and the difficult, foreseeable technical feasibility of an operation (e.g., marked collateral circulation secondary to portal hypertension) are all factors in favor of endoscopic treatment for bile duct obstruction.

## Introduction

Chronic pancreatitis requires a multidisciplinary management strategy. Gastroenterologists, advanced endoscopists, radiologists, and pancreatic surgeons should collaborate to establish a plan of care. Accurate delineation of each patient's pancreatic anatomy is the first step in workup, and employs the sequential use of computed tomography (CT), magnetic resonance imaging (MRI) and cholangiopancreatography (MRCP), endoscopic ultrasound (EUS), and endoscopic retrograde cholangiopancreatography (ERCP). Randomized studies performed more than a decade ago [1,2] demonstrated an advantage of surgery over endoscopic therapy for long-term control of pain associated with chronic pancreatitis. As endoscopic techniques have matured, however, more present-day patients are achieving an acceptable outcome without the need for surgical intervention [3]. Aside from cases of suspected cancer, most surgery for chronic pancreatitis is limited to cases where endoscopic treatment either is anatomically not feasible or has failed.

Indications for surgery typically include the following, either alone or in combination: intractable pain refractory to endoscopic stenting, suspected malignancy, or symptomatic local complications (such as bile duct or bowel obstruction, portal vein compression, splenic vein thrombosis, fistula, or pseudocyst).

When surgery of the pancreas itself is planned, the following factors are considered:

- When cancer is suspected or confirmed, oncologic resection is performed.
- When an inflammatory mass is present in the head of the gland, the head should be resected.
- Any dilated pancreatic duct (≥7 mm) which would not otherwise be resected should be drained.
- When splenic vein thrombosis exists, splenectomy should be performed.

Table 56.1 summarizes the commonly considered operative options based on the most common morphologic considerations. There are a host of less common clinical scenarios that would dictate other surgical options, and these are highlighted both in the text of this chapter, and expanded upon in subsequent chapters.

## Surgical Drainage of the Pancreatic Duct

Indications for a pure drainage operation include patients with the phenotype of a significantly dilated pancreatic duct (≥7 mm) *without* an associated inflammatory mass in the head of the pancreas. Main pancreatic ductal stones should be removed at the time of laterolateral pancreaticojejunostomy. If pancreaticolithiasis is extensive in side-branches within the head of the gland, consideration should be given to either "coring out" or resecting the pancreatic head.

Although the eponym "Puestow" is still commonly used to describe laterolateral pancreatojejunostomy, most modern pancreatic surgeons perform the operation as modified by Partington and Rochelle (Fig. 56.1) [4]. In this modification, the pancreatic tail resection advocated by Puestow is abandoned, which leaves more pancreatic parenchyma and lowers morbidity and mortality. Although operative safety was improved, these patients frequently experienced either immediate failure of pain control or delayed recurrence years later, often

**Table 56.1** Authors' choice of operation for chronic pancreatitis based on pancreatic morphology typically present.

| Pancreatic morphology and clinical indications | Incidence | Operation |
|---|---|---|
| Main duct dilation without inflammatory head mass | Uncommon | Frey procedure |
| Main duct dilation with inflammatory head mass | Common | |
| + any concern for malignancy | | Pancreatoduodenectomy |
| – no concern for malignancy | | Frey procedure |
| Main duct dilation and very high stone burden in head of pancreas | Uncommon | Pancreatoduodenectomy with lateral pancreaticojejunostomy |
| Left-sided pancreatitis with main duct disruption ("disconnected duct syndrome") | Common | Distal pancreatectomy |
| Duodenal obstruction | Uncommon | Pancreatoduodenectomy |
| Common bile duct obstruction | Common | Pancreatoduodenectomy |
| Hemosuccus pancreaticus | Rare | Pancreatoduodenectomy or distal pancreatectomy[a] |

[a] In the acute bleeding phase, angiographic embolization is preferred; if embolization is definitive, surgery may not be required.

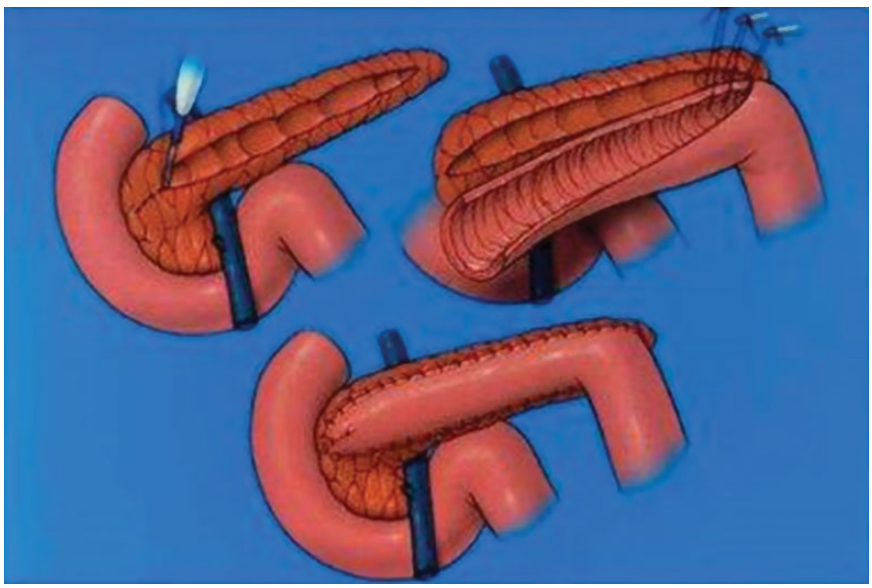

**Figure 56.1** Laterolateral pancreaticojejunostomy, as described by Partington and Rochelle. The pancreatic parenchyma is incised anteriorly to expose the duct. Pancreaticoliths should be thoroughly removed. A roux limb of small bowel is sutured to the open pancreatic parenchyma in a running fashion. *Source*: By permission of Mayo Foundation for Medical Education and Research. All rights reserved.

due to an inflammatory mass in the head of the pancreas [5]. This realization has led to the current belief that the pancreatic head is the "pacemaker" of pain in patients with chronic pancreatitis, and pure ductal drainage procedures are now infrequently performed. The senior author now performs local resection of the pancreatic head and lateral pancreaticojejunostomy (LR–LPJ) in those patients with intractable pain and "large duct" (≥7 mm) chronic pancreatitis (Fig. 56.2).

## Surgical Resection of the Pancreas

When a mass exists in the pancreatic head and surgery is entertained, the pancreatic head should be resected. This can either involve a coring of the pancreatic head alone (Beger or Bern procedures), a combination of coring the pancreatic head and incising the lateral pancreatic duct (Frey procedure or LR–LPJ), or a pancreaticoduodenectomy. The Beger, Bern, and Frey procedures are detailed in Chapter 58. Although perioperative safety may be slightly better with duodenum-preserving procedures with coring of the pancreatic head, in randomized trials compared to pancreaticoduodenectomy, long-term follow-up reveals that both are highly effective in controlling pain [6–11]. Patients treated with pancreaticoduodenectomy at the Mayo Clinic for pain related to chronic pancreatitis ($n = 166$, median follow-up of 15 years) showed lower mean pain scores (scale 1 to 10) after surgery (1.6) as compared to before surgery (7.9, $P < 0.001$) [12]. There appears to be regional variation worldwide with respect to the morphologic phenotype of chronic

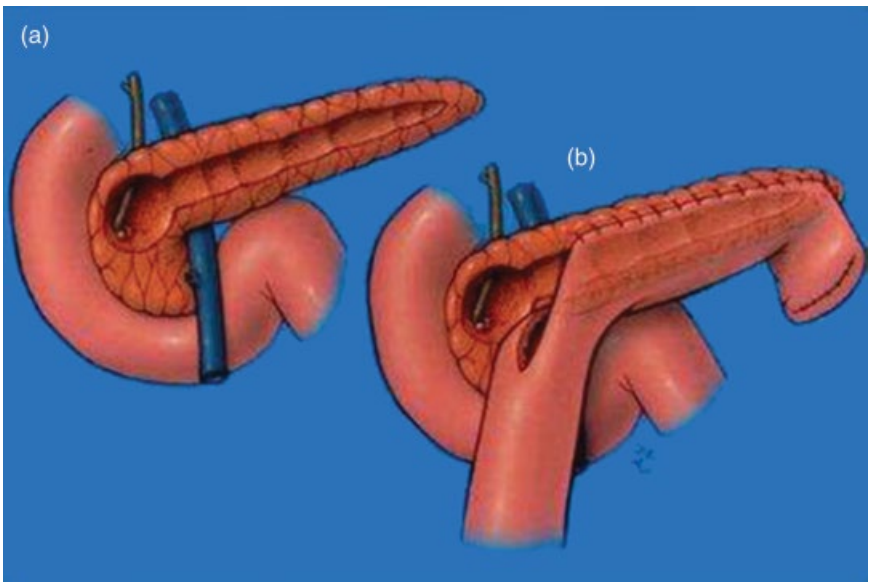

**Figure 56.2** Frey procedure, which combines local coring of the pancreatic head with an anterior pancreatotomy (a). Pancreatoliths should be thoroughly removed, and this is drained by a roux limb sutured to the open pancreatic edges (b). *Source*: By permission of Mayo Foundation for Medical Education and Research. pancreatitis, which may clarify apparent differences in the preferred surgical approach in various countries. In Germany, inflammatory pancreatic head masses associated with chronic pancreatitis are nearly twice the size on average of those from a cohort from the United States (4.5 vs. 2.6 cm) [13].

Patients with chronic pancreatitis have an increased risk for pancreatic ductal adenocarcinoma, and differentiating cancer from a benign inflammatory mass can be difficult with imaging alone. Duct dilation distal to a mass and distal gland atrophy may signify cancer. Subtle extension of increased soft tissue density along arteries can sometimes be a clue to the presence of cancer on CT or MRI. In uncertain cases, CA 19-9 elevation raises the suspicion of malignancy. EUS can be used to identify and biopsy masses, although there is known poor interobserver agreement with this method in the setting of chronic pancreatitis [14]. When clinical suspicion is raised for cancer, oncologic resection is required, and a head-coring operation or a pure drainage procedure should be avoided.

Isolated left-sided pancreatectomy is reserved for focal disease in the distal gland. Indications for concurrent splenectomy in this setting include a perisplenic pseudocyst, splenic vein thrombosis, fibrotic encasement of the splenic vessels, and suspected malignancy. Hemosuccus pancreaticus from peripancreatic pseudoaneurysm formation is a very rare complication of pancreatitis [15]. In such patients, angiographic embolization is preferred in the setting of acute bleeding; when resective surgery is necessary, we recommend pancreaticoduodenectomy. Pancreatic ascites is a rare complication which can generally be managed using endoscopic techniques.

Total pancreatectomy (ideally with islet cell autotransplantation) is also rarely indicated, and usually used in the setting of severe whole-gland disease. This strategy results in 73% of patients free of narcotics at 5 years; when islet cells are autotransplanted, 40% of patients achieve independence from insulin [16]. Patients with hereditary pancreatitis syndromes (*PRSS1*, *SPINK1*, *CTFR*, etc.) should not undergo *prophylactic* resection. However, the young age at which many develop intractable pain coupled with severe whole-gland disease makes them among the best candidates for consideration of total pancreatectomy with islet cell autotransplantation.

## Surgical Management of Biliary Obstruction

Bile duct stricture with or without obstruction is unusual in the setting of chronic pancreatitis unless significant involvement of the pancreatic head is present. For this reason, most patients being considered for surgery will already be in consideration for a head-coring procedure or pancreaticoduodenectomy. Before surgical intervention, many patients will have undergone endoscopic efforts to relieve biliary obstruction, and indwelling stents may be present. A careful review of cholangiograms that pre-date endoscopic interventions is mandatory.

The level(s) of radiographic stricture in the biliary tree are important considerations in the operative plan. Patients with strictures at the level of the ampulla with a dilated bile duct into the pancreatic parenchyma will be adequately treated with either pancreaticoduodenectomy or a head-coring procedure; however, a head-coring procedure must include intrapancreatic bile ductotomy to ensure bile drainage into the roux limb. Patients with extrapancreatic biliary strictures will not

be helped by a head-coring procedure, and pancreaticoduodenectomy is recommended. An ongoing French multicenter randomized clinical trial (PASTEC) is comparing surgery and endoscopic stenting in the treatment of biliary obstruction related to chronic pancreatitis. This trial is expected to run through 2019.

# Pancreatic Duct Drainage Procedure

*Dirk Bausch and Tobias Keck*

*Department of Surgery, University of Schleswig-Holstein, Campus Lübeck, Lübeck, Germany*

## Introduction

Compared to the general population, patients with chronic pancreatitis have a fourfold increase in mortality [1] and a tenfold increased risk of pancreatic malignancy [2]. Progressive inflammatory destruction of the pancreatic parenchyma in chronic pancreatitis is usually accompanied by intractable pain and a loss of exocrine and endocrine pancreatic function, clinically evident as malabsorption and pancreatogenic diabetes.

The pathogenesis of pain in chronic pancreatitis is likely multifactorial. One potential mechanism may be increased intraductal pressure and obstruction of the pancreatic ductal system. The inflammation itself, together with alterations in pancreatic nerve fibers, including an increase in nerve fibers and neurogenic inflammation, may also contribute to the typical pain commonly associated with chronic pancreatitis. Changes in the central nervous system and alterations in central pain processing may also lead to pain. The characteristic abdominal pain often leads to impaired social and work life due to frequent hospitalization [3].

Currently, endoscopic or interventional treatment is considered the first step in the treatment of patients with chronic pancreatitis. Endoscopic treatment that relieves the pancreatic ductal system (endoprothesis, stone extraction, extracorporeal shock wave lithotripsy, or ductal dilatation) improves pain for up to 1 year [4]. Multiple interventions improve pain in about 65% of cases and reduce the number of patients requiring surgical intervention [5].

However, stent replacement often has to be performed 3-monthly and may require multiple hospital admissions [6,7]. After unsuccessful endoscopic treatment, about 49% of the patients still require surgery within 1 year [8] (Fig. 57.1). Although endoscopic duct drainage may provide long-term success in the presence of isolated proximal duct stenosis and in the absence of an inflammatory mass of the pancreatic head and calcifications, surgery is superior to endoscopic therapy in the latter case [9] and may also be more cost-effective [10]. Moreover, early surgical intervention may also prevent disease progression, preserve pancreatic function, and improve long-term pain control [9,11–13].

## Indication for Surgery

The most common indication for surgery for chronic pancreatitis is intractable pain despite endoscopic intervention. Other indications for surgery are local complications, such as duodenal or biliary stenosis, symptomatic pseudocysts, pancreaticopleural fistula, a disconnected pancreatic duct, pancreatogenic ascites or suspicion of neoplasm. All procedures attempt to reduce pain and resolve organ complications while preserving exocrine and endocrine function. Their long-term efficacy is commonly evaluated by the restoration of quality of life and successful rehabilitation. Three distinct groups of procedures can be employed to treat chronic pancreatitis: drainage procedures, procedures combining drainage and resection, and resecting procedures. The choice of procedure depends on the morphological features of the pancreatitis. Drainage combined with resection of the pancreatic head (Beger procedure [14], Frey procedure [15]) is commonly chosen if an inflammatory mass of the pancreatic head is present, resecting procedures (pylorus-preserving pancreaticoduodenectomy, Whipple procedure) are used if malignancy is suspected. The majority of patients with chronic pancreatitis (85%) have an inflammatory mass of the pancreatic head and thus require drainage combined with resection or

*The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery*, Third Edition. Edited by Hans G. Beger, Andrew L. Warshaw, Ralph H. Hruban, Markus W. Büchler, Markus M. Lerch, John P. Neoptolemos, Tooru Shimosegawa, and David C. Whitcomb.

Companion website: www.wiley.com/go/beger/thepancreas

resection of the pancreatic head [16] (Fig. 57.2a). However, drainage procedures are the procedure of choice in patients with a dilated pancreatic duct (≥5 mm) without an inflammatory mass [17] (Fig. 57.2b). Another indication for surgical drainage may be malignant transformation of the portal vein with collaterals in the case of long segment portal vein stenosis. However, short segmental portal vein or mesenterico-portal vein stenosis with portal hypertension may also be alleviated during pancreatic head resection by decompressing the stenosis [18]. Resection of the pancreatic head is even possible after interventional recanalization of the portal vein for nonfixated portal vein thrombosis. Drainage procedures are thus not mandatory in this situation [19].

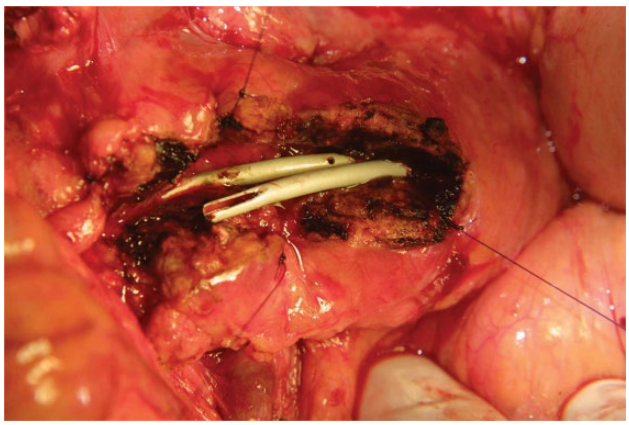

**Figure 57.1** "Lost stents" after endoscopic therapy of an inflammatory stenosis due to chronic pancreatitis. Intraoperative view during a Frey procedure.

## Drainage Procedures

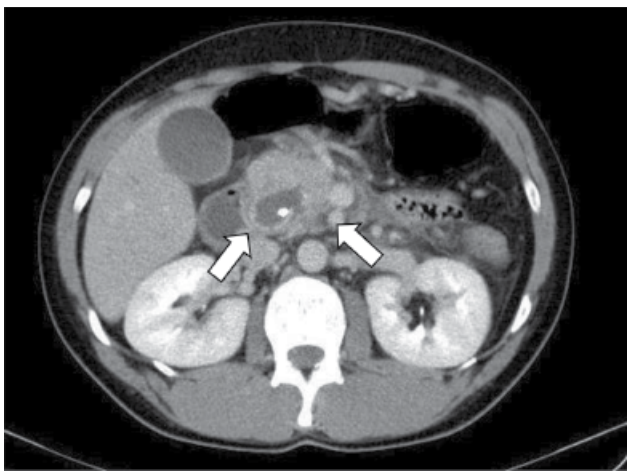
The first drainage procedure of the pancreas in humans was performed in 1911 through transcutaneous catheter placed in the pancreatic duct [20]. The procedure provided pain relief and the patient survived for 30 years. More than 50 years later, the procedure was modified and a distal pancreatectomy, splenectomy, and pancreaticojejunostomy were performed [21]. The procedure was further refined as a distal pancreatectomy and side-to-side pancreaticojejunostomy [22]. The latero-lateral panceaticojejunostomy still in use today was first described in 1960 [23].

A Partington–Rochelle procedure comprises an incision of the pancreatic duct at the anterior surface of the pancreas from the tail to the head of the pancreas. Calculi in the pancreatic ducts can then be removed and segmental stenosis can be relieved. The procedure is completed by a Roux-en-Y jejunal limb sutured side-to-side to the pancreatic duct [23].

Drainage procedures are associated with low morbidity and mortality rates (about 1%). However, drainage is inferior to resection with regard to pain management and complication management [24–36] (Fig. 57.3).

As a hybrid procedure with partial resection of the pancreatic head, the Frey procedure is often also considered a drainage procedure. It comprises excoriation of the pancreatic head combined with an incision of the pancreatic duct at the anterior surface of the pancreas to the tail of the pancreas. The procedure is completed by a Roux-en-Y jejunal limb sutured side-to-side to the excoriated pancreatic head and pancreatic duct [15]. Compared to the Partington–Rochelle procedure, the

(a)



(b)

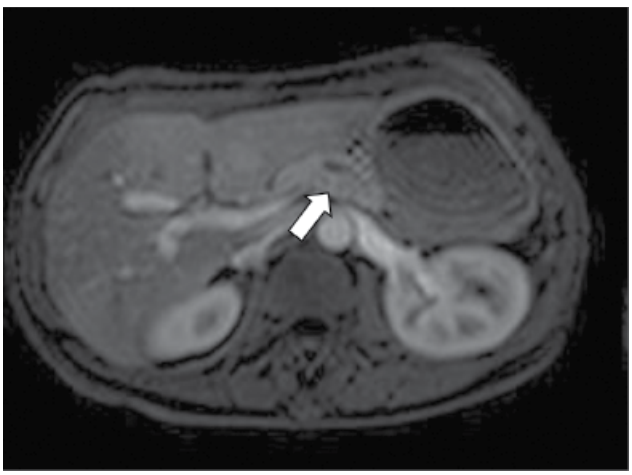


**Figure 57.2** CT scan of chronic pancreatitis. (a) The majority of patients with chronic pancreatitis have an inflammatory mass of the pancreatic head (arrow) and thus require drainage combined with resection or resection of the pancreatic head. (b) Drainage is the procedure of choice in patients with a dilated pancreatic duct (≥5 mm) without an inflammatory mass (arrow).

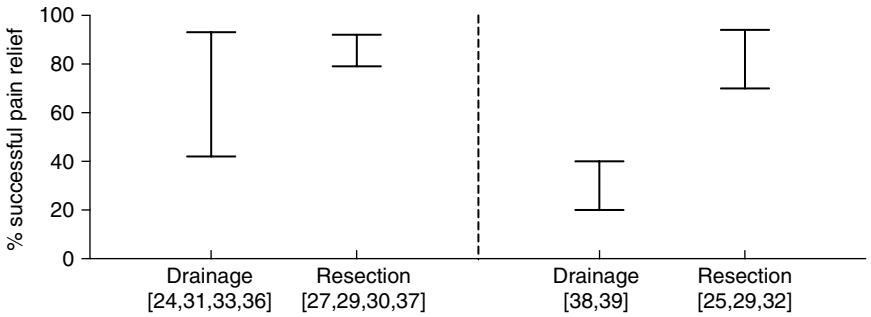

**Figure 57.3** Drainage procedures are inferior to resection with regard to pain management. The figure shows short-term (left) and long-term (right) pain relief after drainage or resection procedures [24,25,27,29,30–33,36–39].

Frey procedure improves the long-term outcome. Compared to other resection procedures, the outcome achieved by the Frey procedure is equivalent with regard to pain control, quality of life, and exocrine and endocrine organ function [32,40–43].

A rare form of chronic pancreatitis termed "small duct disease" affects the whole organ. It is not associated with a dilated pancreatic ductal system and may easily be misdiagnosed as autoimmune pancreatitis. Treatment of choice for this small duct disease is longitudinal V-shaped excision of the ventral pancreas. The procedure combines extensive drainage with a limited resection [44]. This drainage procedure may provide long-term pain relief and an improved quality of life in the majority of patients [45]. Compared to V-shaped excision, resection may not be as effective in the treatment of small duct disease [46].

## Conclusion

In summary, drainage procedures such as the Partington–Rochelle are often not sufficient to provide acceptable pain and complication control because of the frequently observed inflammatory mass of the pancreatic head. In the absence of this, they provide good results with low morbidity and mortality. In the presence of an inflammatory mass, hybrid procedures such as the Frey procedure or V-shaped excision are as effective as resection.

## Introduction

Chronic pancreatitis is a pathologic fibroinflammatory syndrome of the pancreas in individuals with genetic, environmental, and/or other risk factors, which results in persistent pathologic responses to parenchymal injury and stress [1]. Common features of chronic pancreatitis include pancreatic atrophy, tissue fibrosis, upper abdominal pain, duct distortion, and strictures, and in the late course of the disease, inflammatory head mass, calcifications and pancreatic duct stones, duodenal dystrophy, functional exocrine insufficiency, diabetes mellitus, and cellular dysplasia.

The mechanistic definition of chronic pancreatitis, recently published as the result of an international proposal, reflects the complex nature of this disease. Alcohol abuse and cigarette smoking are the most frequent causes of chronic pancreatitis. After a preclinical period of up to 12 years, the majority of patients develop abdominal complaints and upper abdominal pain as first signs of the disease. In the late stages, local complications are caused by the progressive inflammatory process, and are enhanced by alcohol consumption and cigarette smoking. Patients referred for surgical treatment suffer severe abdominal pain; 30–50% show alcoholic chronic pancreatitis exhibiting an inflammatory mass in the head of the pancreas, frequently causing common bile duct (CBD) obstruction [2,3]. Infrequently, severe obstruction of the duodenum, portal vein compression or thrombosis, and splenic vein occlusion are clinically relevant. Pathomorphologically, main-duct stenosis with prestenotic duct dilation and side-branch duct stenoses are observed (Table 58.1). For discussion of the natural history of chronic pancreatitis, see Chapter 42; for early stage chronic pancreatitis, see Chapter 44; for epidemiology and pathophysiology of alcoholic chronic pancreatitis, see Chapter 40; for strategies for surgical treatment, see Chapter 56.

## Are Duct Stenting and Endoscopic Interventions an Alternative to Surgery?

Duct stenting, endoscopic dilatation of pancreatic main-duct stenosis, and endoscopic stone extraction for obstructive chronic pancreatitis have been reported by a number of recent studies with good results. However, sphincterotomy and stenting of the pancreatic main duct is considered a temporary treatment. The risk of stent occlusion and migration and the need for long-term control of upper abdominal pain are the limitations of the interventional endoscopic treatment modalities. Data from prospective, randomized, single-institute trials comparing endoscopic therapy with surgical treatment have been published [9,10]. Short-term pain relief was similar in both groups. The long-term outcome after a 1- to 3-year follow-up revealed major advantages for surgical treatment with regard to pain control and frequency of rehospitalization compared to interventional stenting.

## Who Benefits from Surgical Treatment?

Surgery for chronic pancreatitis is essentially a palliative treatment. The primary goals of surgery are (i) long-term pain control and (ii) control of chronic pancreatitis-associated complications of adherent tissues. Upper abdominal pain refractory to medical treatment in combination with local complications is the most frequent setting for surgical treatment (Box 58.1). Preservation of exocrine and endocrine pancreatic functions are secondary but equally important goals of surgical treatment. Most patients with chronic pancreatitis are under 55 years and professionally active. Social and occupational rehabilitation and improvement of quality of life are additional primary goals for the long-term outcome.

## Kausch–Whipple Resection or Hemipancreatectomy—Still Standard Treatment for Chronic Pancreatitis?

Currently, pancreatoduodenectomy, left or distal hemipancreatectomy, and total pancreatectomy are still applied for chronic pancreatitis. The disadvantages of these major pancreatic resections are (i) the unnecessary sacrifice of pancreatic and peripancreatic biliary and gastroduodenal tissues and (ii) the surgery-inherent loss of duodenal and pancreatic tissue, which leads to impairment of endocrine and exocrine functions in the long-term outcome. New onset of diabetes mellitus and exocrine insufficiency after pancreatoduodenectomy and hemipancreatectomy have been extensively documented [11–24]. Long-term observations showed that patient survival was shorter after duodenopancreatectomy for chronic pancreatitis compared to after an organ-preserving surgical procedure [25].

**Box 58.1 Indications for duodenum-preserving pancreatic head resection for chronic pancreatitis**

- Upper abdominal pain refractory to medication
- Inflammatory mass of pancreatic head
- Biliary stenosis
- Single/multiple narrowing of pancreatic main duct
- Compression of portal vein/superior mesenteric vein
- Severe stenosis of peripapillary duodenum
- Clinical symptomatic pseudocyst / persisting
- Pseudocyst after failure of endoscopic treatment
- Pancreas divisum after failure of endoscopic treatment

## Indications and Rationale for Duodenum-Preserving Pancreatic Head Resection

Surgical treatment of chronic pancreatitis is presently dominated by organ-preserving surgical procedures. Introduced by Partington and Rochelle [26], intestinal drainage of the pancreatic main duct and duodenum-preserving subtotal pancreatic head resection and their modifications have the advantages of tissue sparing and maintenance of pancreatic function [27]. Based on contrast-enhanced computed tomography, magnetic resonance imaging, and magnetic resonance cholangiopancreatography, the majority of pathomorphologic changes of chronic pancreatitis are observed predominantly in the pancreatic head, frequently associated with an inflammatory mass and obstruction of the CBD. Infrequently, the inflammatory tumor in the pancreatic head causes portal vein and superior mesenteric vein compression and obstruction of the duodenum. To resolve these complications, resection of the pancreatic head is recommended. Duct drainage procedures in chronic pancreatitis are only indicated in the subgroup of patients with pancreatic main-duct stenosis and dilatation extending into the duct of the body and tail.

With regard to long-term pain control, duct drainage procedures without resection of the pancreatic head are associated with a re-appearance of abdominal pain in about one-third of patients observed after a >5-year follow-up (HG Beger, unpublished data). A duct drainage procedure in chronic pancreatitis is considered unnecessary in patients with a dilated body–tail duct without

duct obstructions when the pancreatic head is resected. Long-term follow-up observations after pancreatoduodenectomy and duodenum-preserving pancreatic head resection (DPPHR) have shown long-lasting pain control after head resection without an additional duct drainage procedure [28,29]. The effectiveness of DPPHR has been proved through randomized controlled trials (RCT) and long-term observations over 5–10 years which showed completely pain-free patients in 80–90% of cases. For patients with an inflammatory head mass who were treated with a duct drainage procedure without subtotal pancreatic head resection, a risk persists for the development of biliary stenosis in the long term, with the need for biliary stenting and/or re-surgery.

## Surgical Technique of DPPHR for Chronic Pancreatitis

DPPHR comprises three different surgical steps:

1) exposition of the pancreatic head with identification of the portal vein, respective inferior mesenteric vein and the supraduodenal CBD; tunneling of the pancreatic neck in front of the portal vein;
2) subtotal resection of the pancreatic head to conserve the intrapancreatic CBD;
3) reconstruction with an excluded jejunal loop, executing two pancreatic anastomoses.

Steps 1 and 3 are almost identical to the surgical steps performed in the Kausch–Whipple procedure.

An extensive Kocher maneuver should be avoided to preserve the vessels on the dorsal side of the pancreatic head. The anterior gastroduodenal artery is identified and ligated near the common hepatic arteries. The posterior superior branch of the pancreaticoduodenal artery and the inferior anterior pancreaticoduodenal artery should be carefully preserved. Subtotal resection of the pancreatic head is performed from the ligamentum hepatoduodenale along the intrapancreatic segment of the CBD, including the uncinate process (Figs 58.1, 58.2, and 58.3). Bleeding vessels arising in the transected tissue are immediately sutured (Fig. 58.4). Preservation of the dorsal capsule of the pancreatic head and the dorsal branch of the gastroduodenal and pancreaticoduodenal vessels is recommended to maintain sufficient perfusion of the wall of the duodenum and papilla. Reconstruction of the gastrointestinal tract is performed with an excluded jejunal loop (Fig. 58.5).

Two modifications of the DPPHR procedure are presently in use. In patients displaying a prepapillary CBD stenosis, which persists due to an inflammatory process in the wall of the CBD, after subtotal head resection, an additional biliary anastomosis by an incision of the CBD is executed [30] (Fig. 58.6). In patients who show multiple stenosis and dilations of the main duct in the body and tail, the pancreatic main duct is opened longitudinally on its ventral surface, extending towards the tail of the pancreas. A side-to-side anastomosis is executed in addition to the head resection [31].

## Early Postoperative Course

Early severe postoperative complications are infrequent (Table 58.2). Severe, surgery-related complications are <10% according to Clavien–Dindo III. Local bleeding,

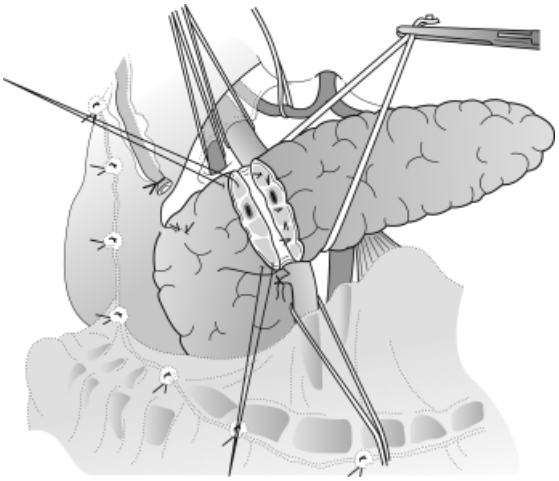

**Figure 58.1** Duodenum-preserving pancreatic head resection after tunneling of the portal vein behind the pancreas. The resection line is the duodenal side of the portal vein.

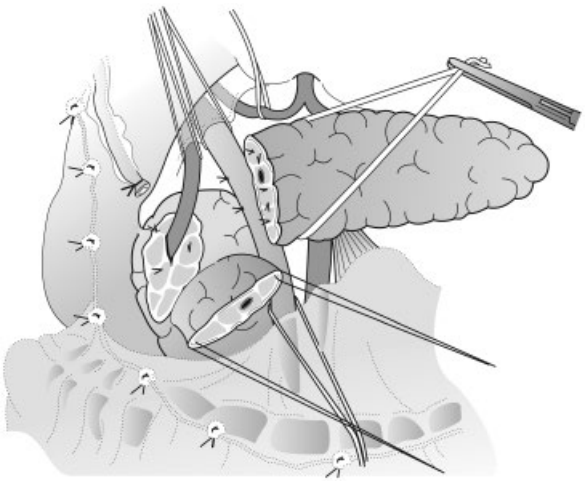

**Figure 58.2** Subtotal resection of the pancreatic head after ventral rotation. The common bile duct is identified at the level of the hepatoduodenal ligament and decompressed by resection of periductal pancreatic tissue, except for a small rim between common bile duct and duodenal wall.

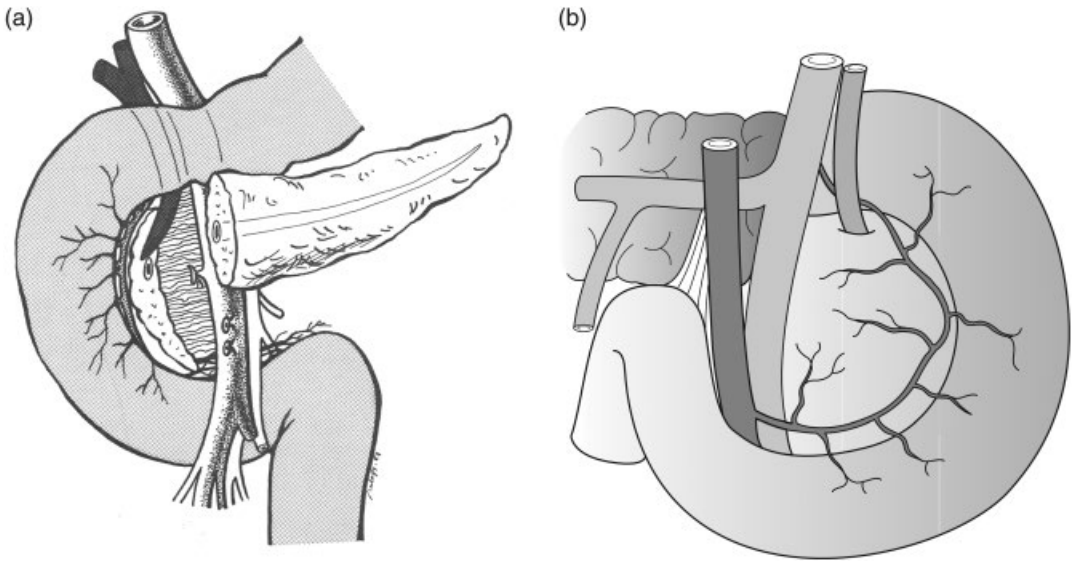

**Figure 58.3** (a) After finishing the subtotal pancreatic head resection, a shell-like remnant of the pancreatic head remains along the duodenal wall. Bleeding vessels are frequently closed by single stitches using 5-0 sutures. (b) The dorsal capsule of the pancreatic head is preserved to maintain blood flow to and from the duodenal wall. The dorsal pancreaticoduodenal arcades and inferior pancreaticoduodenal artery are preserved.

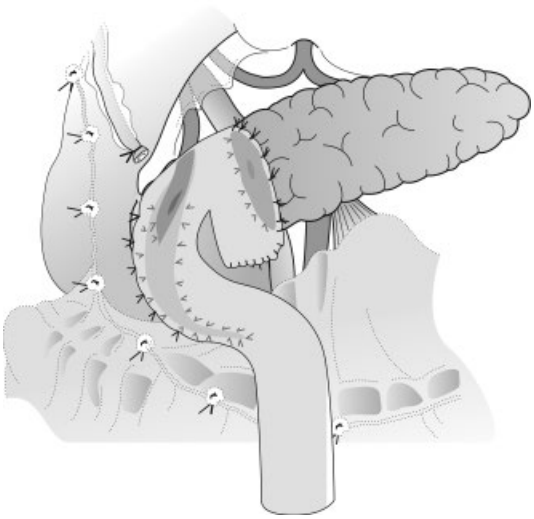

**Figure 58.4** Reconstruction of the upper jejunal loop after subtotal resection of the pancreatic head requires exclusion of the first jejunal loop and creation of an end-to-side duct-to-mucosa anastomosis between the pancreatic neck and the jejunum (two-layer anastomosis). Anastomosis between the shell-like remnant of the pancreatic head and the excluded jejunal loop (end-to-side anastomosis) is also performed. A Y-en-Roux anastomosis between the excluded jejunal loop and the first jejunal as side-to-end anastomosis is included.

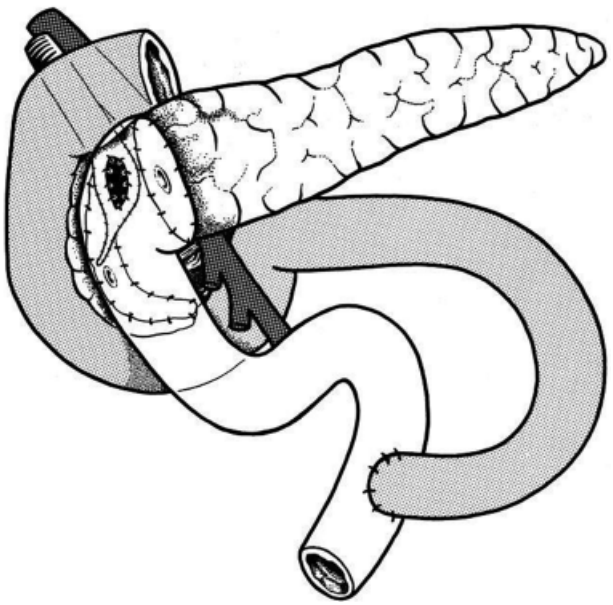

**Figure 58.5** In the case of extended narrowing of the intrapancreatic segment of the common bile duct caused by an inflammatory process in the wall of the common bile duct an internal biliary anastomosis is additionally executed by incision of the prepapillary common bile duct of 10–12 mm.

which appears as intestinal blood loss, caused by arterial leakage from the shell-like remnant of the pancreatic head and anastomotic leakage, which appears as evacuation of intestinal content into the drainage bag, is observed in <2% of cases. Severe intestinal bleeding, leakage of the pancreaticojejunostomy and surgical-side infection around the pancreatic head are reasons for reintervention [25]. Between the 2nd and 5th postoperative days, patients are on regular oral nutrition (Table 58.3). Glucose metabolism is maintained at preoperative levels up to the 5th postoperative year (Table 58.3). When C-peptide and insulin responses are measured 3–36 months postoperatively after intravenous and oral glucose load, they were

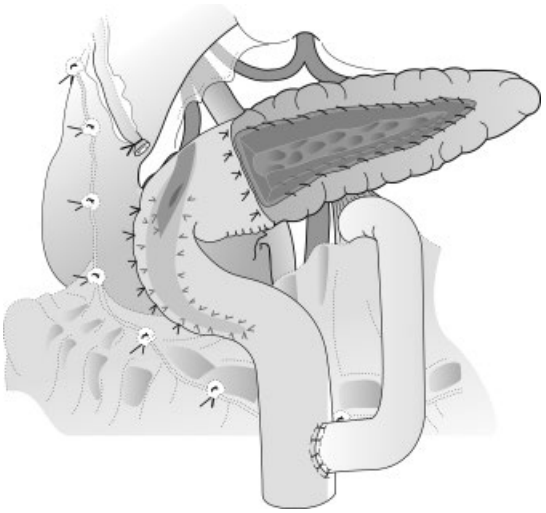

**Figure 58.6** Where the pancreatic main duct shows multiple duct stenosis and dilatations, duct drainage of the pancreatic main duct from the head to the tail is additionally applied by a side-to-side anastomosis with the excluded jejunal loop.

**Table 58.2** Early postoperative results after duodenum-preserving subtotal pancreatic head resection in 603 patients.

| Hospital mortality | 5 | 0.81% |

Data from [2].

found to be at preoperative levels. However, the concentrations of glucagon and pancreatic polypeptide (PP) displayed a highly significant decrease after stimulation [32–34]. The loss of glucagon and PP delivery into the blood explains the observation that up to 10–12 % of patients experienced postoperative improvement of the disrupted glucose metabolism, because both hormones are produced predominantly in the endocrine tissue of the pancreatic head.

## Long-Term Outcome After DPPHR

After a median observation period of 5.7 years and a follow-up rate of 94%, control of pancreatic pain is complete and long-lasting in approximately 90% of cases (Table 58.4). In terms of pain and attacks of pancreatitis, DPPHR changes the natural course to a silent disease. In our experience, preoperatively, each patient had 2.7 hospitalization periods, whereas after a median follow-up of 5.7 years, only 9% of the patients experienced a rehospitalization. Due to the persistent destruction of the functional parenchyma of the pancreas inherent in chronic pancreatitis, the frequency of diabetes mellitus increases as well as the level of exocrine insufficiency [35–37]. The major advantages of duodenum-preserving subtotal pancreatic head resection for chronic pancreatitis are conservation of the duodenum and the CBD and temporary maintenance of endocrine pancreatic functions. Several RCT have been published comparing DPPHR with Kausch–Whipple duodenopancreatectomy, with DPPHR found to be superior in terms of postoperative morbidity, maintenance of glucose metabolism, an absence of delayed gastric emptying, and a low frequency of rehospitalization [38–42] (Table 58.5). With regard to the Frey procedure, as performed in the majority of patients, the level of maintenance of glucose metabolism, frequency of postoperative morbidity, and quality of life in the long term are almost the same as the results after DPPHR [44].

## The Frey Procedure—an Alternative Surgical Approach for all Patients with Chronic Pancreatitis?

In 1987, Frey et al. published a technique for chronic pancreatitis in six patients; the authors recommended a coring-out technique of ventral pancreatic head tissue combined with longitudinal pancreaticojejunostomy [45]. In 1994, Frey propagated a variation of the local resection–lateral pancreaticojejunostomy (LR–LPJ) procedure, extending the coring-out to the dorsal part of the pancreatic head, which results in a partial head resection, but leaves the intrapancreatic segment of the CBD predominantly embedded in pancreatic tissue. The Frey procedure, taking out some tissue ventrally from the pancreatic head, is a modification of the Partington–Rochelle duct drainage procedure.

When the Frey procedure is performed as a subtotal pancreatic head resection in chronic pancreatitis, the long-term outcome is similar to that for DPPHR [44]. However, in many institutions that perform a tissue-sparing resection in chronic pancreatitis, coring out the pancreatic head is performed as a partial ventral pancreatic head resection. With regard to the long-term outcome in pain control, ventral coring-out of pancreatic head tissue is found to result in the re-establishment of upper abdominal pain in approximately one-third of patients (HG Beger, unpublished data). An additional

risk of the Frey procedure is incomplete decompression of the CBD due to partial ventral coring-out of the pancreatic head tissue, leading to postoperative cholestasis, with attacks of cholangitis due to persistence or reappearance of duct compression by pancreatic tissue mass. Re-surgery after the Frey procedure is a well-documented indication for redo-surgery because of the persistence of biliary stenosis [46,47].

## Summary

Duodenum-preserving resection of the head of the pancreas is a low-risk procedure for patients with chronic pancreatitis, particularly for those who have developed an inflammatory mass in the pancreatic head. Subtotal resection of the pancreatic head does not result in a significant reduction of the exocrine and endocrine functions of the pancreas. Because of the limited nature of the intervention, hospital and late mortality rates are low. More than 80% of patients with chronic pancreatitis experience long-lasting relief of pain after duodenum-preserving head resection. For patients with stenosis of the intrapancreatic CBD, an internal biliary anastomosis establishes long-lasting normal bile flow. For patients with multiple duct stenosis in the left pancreas, duct stones, calcifications, and duct dilations, pancreaticojejunostomy, in addition to subtotal pancreatic head resection, relieves recurrent attacks of pancreatitis and restores pain-free survival and quality of life.

## Overview

Chronic pancreatitis is a debilitating disease characterized by pain, local mechanical complications such as biliary or duodenal obstruction, and pancreatic endocrine/exocrine insufficiency that may lead to a poor quality of life in many patients [1]. Significant developments in the management of chronic pancreatitis have occurred over the past few decades, driven by advances in cross-sectional imaging, endoscopy, and innovative surgical approaches to this complex problem [2]. Surgical approaches may be broadly categorized into drainage, resective, and hybrid procedures, with the latter preserving the duodenum and biliary tree [3]. The focus of this chapter will be major resective procedures that include pancreatoduodenectomy, distal pancreatectomy, and total pancreatectomy with or without islet cell autotransplantation. In this chapter, we aim to: (i) define indications for major pancreatic resection for chronic pancreatitis, (ii) describe major resective procedures, and (iii) summarize short- and long-term expected outcomes from these procedures.

## Major Pancreatic Resection

### Indications and Contraindications

While surgical options to manage chronic pancreatitis have expanded, the indications for major pancreatic resection remain relatively constant, except for hemosuccus pancreaticus and pancreatic ascites, which may now be managed by interventional radiologic and endoscopic techniques, respectively (Table 59.1). Chronic, intractable pain, either intermittent or constant, is the most common indication for surgical intervention. Mechanical complications such as pseudocysts, pancreatic duct disruption (chronic fistula/leak, disconnection, stricture/obstruction), obstructive jaundice, intestinal obstruction (duodenal or colonic), hemorrhage, and portal venous obstruction are well-recognized sequelae of chronic pancreatitis that may be amenable to surgical, endoscopic, and/or radiologic intervention. Inability to distinguish an inflammatory mass from a neoplasm on cross-sectional imaging, especially in a patient population at greater risk than the average population for developing pancreatic malignancy, calls for a resective approach to surgical management in order to exclude and treat possible malignancy [4].

Contraindications to resective procedures include the inability for the patient to tolerate major pancreatic surgery, anatomic restraints, and degree of peripancreatic inflammation that would preclude safe resection (Table 59.1). Anatomic issues related to congenital or acquired vascular anomalies such as mesenteric arterial vascular disease or portal venous hypertension with extensive collateralization would be important to address preoperatively. The degree of peripancreatic inflammation should also be assessed, as chronic pancreatitis patients may present with cases of acute-on-chronic pancreatitis. Although narcotic dependence is not a contraindication to pancreatic resection at our institution, we insist patients be abstinent from toxic exposures known to contribute to the pathophysiology of chronic pancreatitis such as ongoing nicotine use or alcohol abuse [2,4].

In the case of any proximal pancreatectomy, celiac artery stenosis secondary to either atherosclerosis or median arcuate ligament syndrome may result in hepatic ischemia and resultant necrosis following division of the gastroduodenal artery, which interrupts retrograde arterial flow from the superior mesenteric artery (SMA) to the liver [5,6]. Although celiac axis stenosis may be

[b] If failed endoscopic management.

diagnosed from its typical triad of postprandial abdominal pain, weight loss, and abdominal bruit on auscultation, due to collateral formation, the vast majority of patients with this condition are asymptomatic [5,7]. Cross-sectional images in the arterial phase, particularly sagittal views, reliably demonstrate celiac artery stenosis, as evidenced by focal narrowing of the proximal celiac artery with post-stenotic dilation and prominent arterial collaterals around the pancreatic head [5]. Celiac axis stenosis may be addressed preoperatively by endovascular revascularization through balloon angioplasty with or without stenting or intraoperative decompression in the form of median arcuate ligament release, aorto-celiac bypass, or patch angioplasty [5,6,8].

Extrahepatic portal venous hypertension may be associated with chronic pancreatitis when there is mechanical entrapment, obstruction, or thrombosis of the portomesenteric vein [9,10]. Patients with such complications are often compensated without evidence of liver cirrhosis and are not clinically apparent [10]. However, preoperative imaging demonstrates portal/superior mesenteric vein (SMV) stenosis (from extrinsic compression) or chronic thrombosis (from intimal changes in veins secondary to surrounding fibrosis), usually with formation of multiple venous collaterals around the pancreas and other foregut structures [9]. Pancreatic resection in this setting may be complicated with massive intraoperative hemorrhage (due to inadvertent injury to parasitizing venous collaterals under relatively high pressure), postoperative hepatic portal venous ischemia (due to loss of mesenteric venous inflow to the liver), or mesenteric venous congestion (due to loss of venous outflow from collateral vessels) [9–11]. Operating time, intraoperative blood loss, blood transfusions, and overall complications are increased in patients with extrahepatic portal venous hypertension undergoing surgery for chronic pancreatitis compared to patients without portal venous hypertension [9,10].

Anatomic planes may be distorted or obliterated as a result of peripancreatic chronic inflammation with resultant fibrosis. Development of safe dissection planes between the pancreas and surrounding vascular structures may result in significant intraoperative hemorrhage. As with the evaluation of pancreatic neoplasms, planes between the pancreatic head and the SMV/SMA should be carefully evaluated with inflammatory encasement of surrounding visceral arteries precluding safe resection. Such situations may be better approached with hybrid procedures such as the Frey procedure or Beger procedure, which would involve resecting pancreatic parenchyma without extensive peripancreatic dissection of surrounding vasculature (see Chapter 58) [4]. Although such procedures may be performed with acceptable perioperative morbidity and mortality without significant derangements in pancreatic function, our institutional preference is for pancreatoduodenectomy when possible over duodenal-preserving pancreatic head resections, as this has been shown to provide durable pain relief in our experience [1,12–14].

We do not believe narcotic dependence to be a contraindication to major pancreatic resection, as neuropathic pain is often severe and progressive in patients

with chronic pancreatitis [15]. However, we insist chronic pancreatitis patients abstain from alcohol and smoking, known contributing factors to the pathogenesis of chronic pancreatitis [2]. Chronic pancreatitis patients referred for surgical management have generally exhausted all nonoperative management strategies for their pain management, including multimodal analgesia, pancreatic enzyme supplementation with nutritional support, or celiac plexus neurolysis. Pain management in the postoperative period should therefore include a dedicated pain consult service to assist with management of acute-on-chronic postoperative pain as well as a long-term strategy to wean patients off narcotics.

### Preoperative Investigations

High-quality cross-sectional imaging is critical in the surgical planning of pancreatic resection for chronic pancreatitis. Our preference is a pancreas protocol triple-phase (noncontrast, arterial, and venous phases), thin-slice (2 mm cuts) helical abdominal computed tomography (CT). This is used to evaluate the arterial and venous anatomy, the presence of vascular collaterals, and their relationship to any inflammatory process extending beyond the pancreas. As with pancreatic head resections for other indications, vascular anomalies such as a replaced or accessory right hepatic artery would be important to note to avoid inadvertent injury during hilar and uncinate process dissections. Additionally, abdominal CT allows for evaluation of the morphology of the pancreas with respect to irregularity of pancreatic contour, ductal dilation with or without pancreatolithiasis, gland atrophy or enlargement, parenchymal calcification, and the presence of any cystic or solid lesions. Mechanical complications such as biliary or gastrointestinal obstruction may be determined as well, which could prompt preoperative optimization with biliary drainage (endoscopic or percutaneous) and/or provisions for nutritional supplementation (such as a nasojejunal feeding tube preoperatively) [4].

Important adjuncts to CT include endoscopic retrograde cholangiopancreatography (ERCP), magnetic resonance cholangiopancreatography (MRCP), and endoscopic ultrasound (EUS). ERCP is considered the gold standard in diagnosing and staging chronic pancreatitis with a reported sensitivity of 90% and specificity of 100%. Disadvantages of ERCP include cost and invasiveness with a 3–7% risk of post ERCP pancreatitis. MRCP has emerged as a noninvasive alternative to ERCP for mapping ductal anatomy as well as visualizing pancreatic parenchymal changes associated with chronic pancreatitis. Disadvantages of MRCP include inability to perform therapeutic maneuvers that could be done with ERCP, decreased accuracy in visualizing side-branches of the pancreatic duct compared to ERCP, and decreased sensitivity in detecting early stages of chronic pancreatitis compared to ERCP. EUS may be particularly useful in cases of chronic pancreatitis with suspected malignancy where fine-needle aspiration or core-needle biopsy may be performed. Autoimmune pancreatitis may be detected in rare circumstances, which is treated medically. With this said, a negative biopsy in the context of a pancreatic mass with underlying chronic pancreatitis does not exclude malignancy and pancreatic resection should still be pursued [2,16].

### Types of Pancreatic Resections

Pancreatic resections may be proximal, distal, or total and the choice of operation for patients with chronic pancreatitis should be tailored to location and extent of disease as well as morphologic characteristics of the pancreatic parenchyma (e.g., calcifications) and duct (e.g., dilation, stones, stricture/disconnection). Proximal resections include pancreatoduodenectomy with or without pylorus preservation. Concomitant splenectomy is typically performed for distal resections (distal and subtotal pancreatectomy) as splenic preservation in the setting of chronic pancreatitis is often difficult due to chronic inflammation around the tail of the pancreas. Moreover, sinistral hypertension secondary to splenic vein thrombosis from pancreatitis may be associated with upper gastrointestinal bleeding from gastric varices, the definitive treatment of which is splenectomy. Total pancreatectomy combines technical aspects of both proximal and distal resections and may be performed in conjunction with islet cell autotransplantation to avoid implications of managing brittle diabetes. The perioperative outcomes following such procedures for all indications are summarized in Table 59.2 [3,4].

## Pancreatoduodenectomy

### Patient Selection

Candidates for pancreatoduodenectomy include chronic pancreatitis patients with intractable pain, small-duct (<7 mm), head-dominant disease where perivascular tissue planes are relatively preserved and portal hypertension is absent. Pancreatoduodenectomy will address intractable pain with resection of the pancreatic head, mechanical complications such as biliary or intestinal obstruction, and suspicion of malignancy. Although improvements in cross-sectional imaging have enhanced diagnostic discrimination, the distinction between benign and malignant disease remains a dilemma in 6–8% of patients [24]. Modifications of pancreatoduodenectomy include reconstruction with a lateral side-to-side pancreaticojejunostomy rather than the standard

end-to-side pancreaticojejunostomy. A circumstance for which a lateral side-to-side pancreaticojejunostomy may be considered is in the patient with large-duct, head-dominant disease with a pancreatic stone burden in the head that exceeds the ability to "core out" such parenchyma effectively in duodenal sparing pancreatic head resections [4].

## Technique

A midline incision is used unless patients are of obese body habitus or with a broad costal arch. In the latter, a bilateral subcostal is our preference. A fixed, upper abdominal retractor is placed to allow secure retraction of both costal margins in the cephalad direction for optimal exposure. The operation begins with abdominal exploration, freeing the omentum from the transverse colon in its avascular plane, take down of the hepatic flexure, and Kocher maneuver for pancreatic exposure and mobilization. Adhesions to the posterior stomach are taken down to completely open the lesser sac. The SMV is identified between the uncinate process and mesocolon at the level of the transverse duodenum and inferior border of the pancreas. The gastrocolic venous trunk is identified and divided. Blunt dissection is performed to develop a retropancreatic tunnel under the neck of the pancreas to the level of the SMV–portal vein confluence. This plane may be difficult to develop and attempts at creating a retropancreatic tunnel should be abandoned if persisting will lead to tearing or delamination of vein walls (Fig. 59.1).

The gastrohepatic ligament beneath the left lobe of the liver is incised avascularly, taking care to preserve the nerves that supply the pylorus. The common hepatic artery is traced distally. The gastroduodenal artery is divided as well as the right gastric artery. Prior to division of the gastroduodenal artery, a noncrushing clamp is placed temporarily to ensure adequate arterial flow to the liver, the absence of which would indicate celiac axis stenosis for which celiac revascularization would be necessary. After ligation and division of the gastroduodenal artery, a plane is developed between the superior border of the pancreas and the common hepatic artery to identify the portal vein. Blunt dissection is carried out underneath the neck of the pancreas to complete mobilization of the pancreatic neck from the portomesenteric vein, which is encircled with umbilical tape (Fig. 59.2).

Cholecystectomy is performed and the cystic duct is kept in continuity with its junction to the bile duct. The common bile duct is palpated posterior laterally to identify the presence of a replaced or accessory right hepatic artery. The bile duct is mobilized from surrounding hepatoduodenal ligament structures and isolated with umbilical tape. The right gastroepiploic and retroduodenal vessels are divided off the duodenum distal to the pylorus for approximately 3–4 cm (Fig. 59.3). Attention is then directed to the inframesocolic compartment. The ligament of Treitz is mobilized and the tissues to the right of the inferior mesenteric vein are incised, thereby communicating the inframesocolic dissection with the previously performed Kocher maneuver. The bowel is transilluminated approximately 20 cm beyond the ligament of Treitz and a mesenteric window is created. The proximal jejunum is stapled and transected. Mesenteric branches to the proximal jejunum are divided up to the fourth portion of the duodenum and uncinate process. The mobilized proximal jejunum is then passed beneath the SMA back into the supramesocolic compartment (Fig. 59.4).

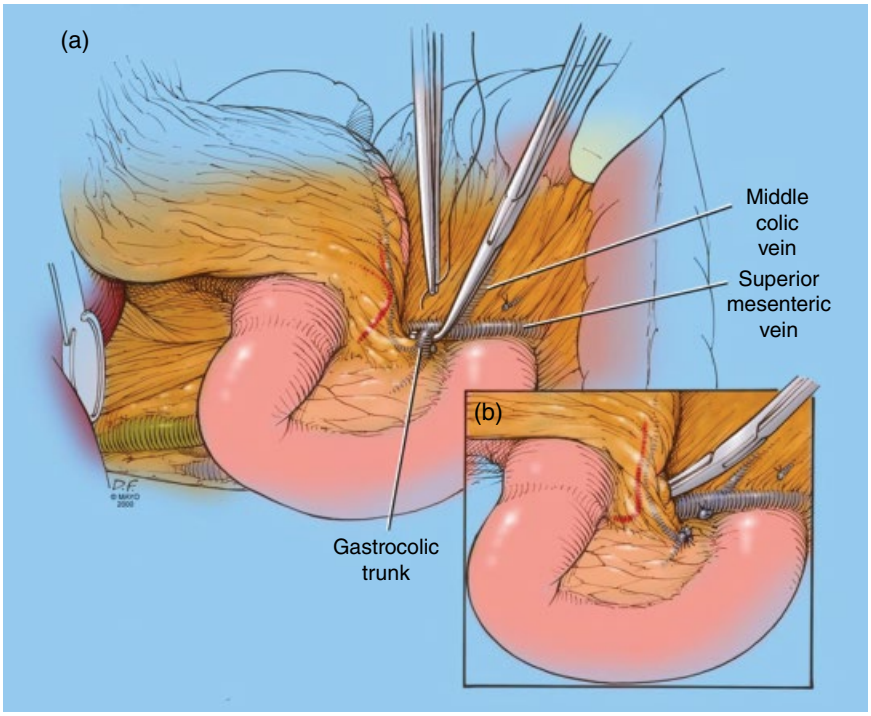

**Figure 59.1** (a) The superior mesenteric vein is identified beneath the neck of the pancreas and the gastrocolic venous trunk is divided. (b) A plane is gently developed between the neck of the pancreas anteriorly and the superior mesenteric vein/portal vein posteriorly using a blunt dissector. *Source:* By permission of Mayo Foundation for Medical Education and Research. All rights reserved.

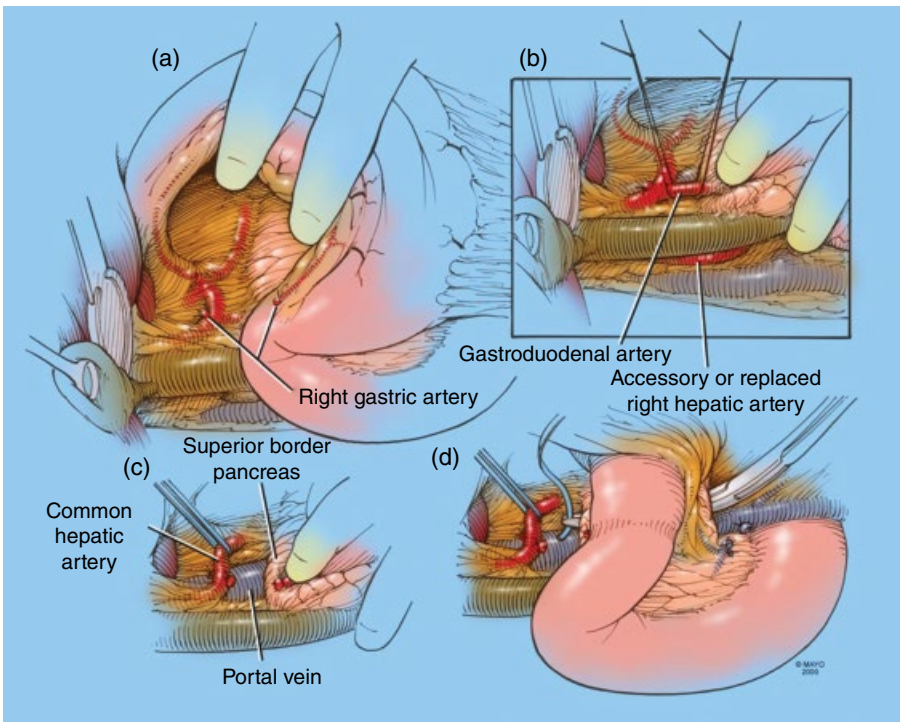

**Figure 59.2** (a) The right gastric artery is divided. (b) The common hepatic artery is identified and the gastroduodenal artery is divided; arterial pulsation posterior to the bile duct may represent a replaced or accessory right hepatic artery. (c) The portal vein is identified underneath the common hepatic artery at the superior border of the pancreas. (d) A retropancreatic tunnel is created at the neck of the pancreas from the superior mesenteric vein to portal vein and isolated with umbilical tape. *Source:* By permission of Mayo Foundation for Medical Education and Research. **Figure 59.3** (a) The right gastroepiploic artery and vein are divided. (b) Retroduodenal arteries are divided to mobilize the duodenum approximately 3 cm from the pylorus. *Source:* By permission of Mayo Foundation for Medical Education and Research. All rights reserved.

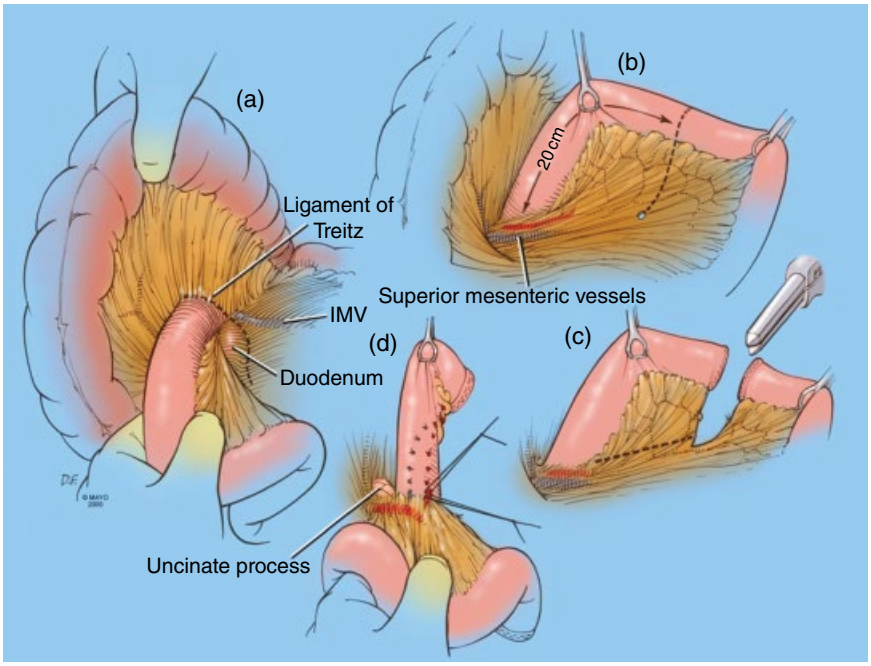

**Figure 59.4** (a) The ligament of Treitz is mobilized in the infracolic compartment with care taken to avoid injury to the inferior mesenteric vein (IMV). (b) The jejunum is divided approximately 20 cm from the ligament of Treitz. (c) The bowel is transected with a GIA stapler. (d) Mesenteric vessels are divided with either silk ties or an energy device until the uncinate process is visible. *Source:* By permission of Mayo Foundation for Medical Education and Research. All rights reserved.

The duodenum is then transected approximately 3 cm beyond the pylorus. In preparation for division of the pancreas, hemostatic sutures are placed at the inferior and superior borders of the pancreas. The pancreas is divided with a scalpel to the left of the portomesenteric vein; this allows for centering of the pancreatic duct as it courses quite posteriorly more proximally. A bulldog clamp is placed on the common hepatic duct to minimize bile spillage and the bile duct is transected sharply. The uncinate process is then dissected off the surrounding mesenteric vessels. Vein retractors are placed and the portomesenteric confluence retracted to the patient's left. Venous tributaries are divided, which allows access to the anterior aspect of the SMA. Occasionally, the first jejunal vein will need to be ligated and divided if it courses to the right of the SMA to facilitate peri-adventitial dissection. Dissection is carried posteriorly on the right side of the SMA and pancreatoduodenal tributaries are controlled and divided. Posterolaterally, the inferior pancreatoduodenal artery will arise from the SMA and should be ligated and divided. The specimen is now removed from the operative field (Fig. 59.5).

Reconstruction is undertaken (Fig. 59.6). An opening is made in the mesocolon to the right of the middle colic vessels. The jejunum is passed through this opening. A two-layered, interrupted, duct-to-mucosa end-to-side pancreaticojejunostomy is fashioned over a temporarily placed silastic stent. We prefer using 4-0 silk for our

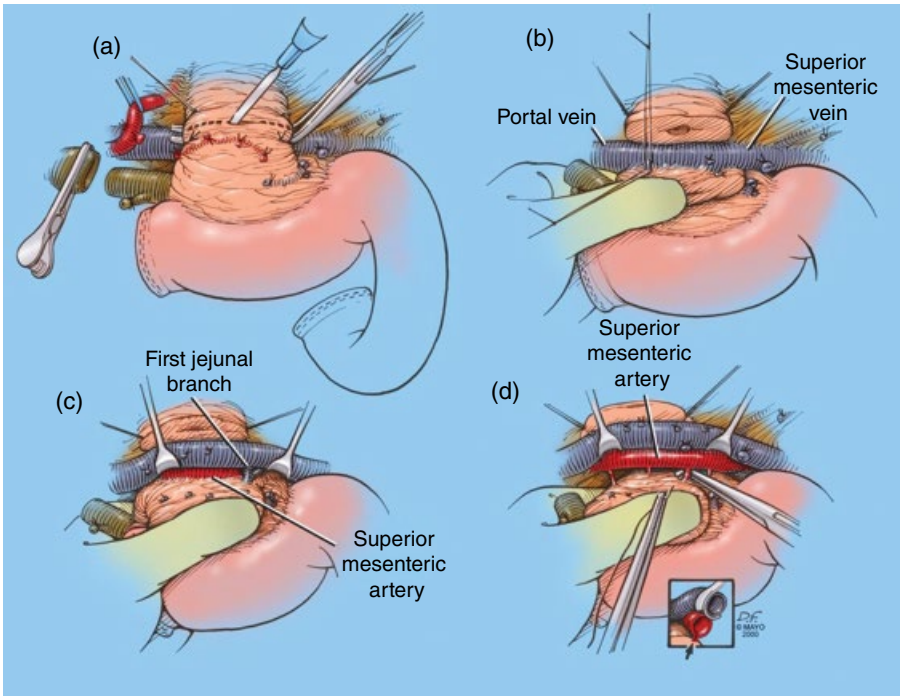

**Figure 59.5** (a) The common hepatic duct is divided sharply and a bulldog clamp placed to minimize bile spillage. The neck of the pancreas is divided sharply with electrocautery. (b) Venous tributaries from the portal vein are divided to free the portal vein. (c) The first jejunal branch is divided. (d) Periadventitial dissection of the superior mesenteric artery is performed. An energy device may be utilized; however, the inferior pancreaticoduodenal artery should be ligated and divided with silk ties. *Source:* By permission of Mayo Foundation for Medical Education and Research. outer layer and 6-0 Vicryl suture for the inner layer. Approximately 8–10 cm distal to the pancreaticojejunostomy, an end-to-side hepaticojejunostomy is fashioned with technique dependent upon bile duct size. We prefer a running biliary enteric anastomosis in a single layer with two 5-0 polydiaxone sutures (PDS), one placed anteriorly and the other posteriorly to prevent purse-stringing of the anastomosis. Patients with small, thin-walled bile ducts are reconstructed with interrupted 6-0 PDS. The traversing jejunal limb is secured to the mesocolon with interrupted 3-0 silk. Distal to this biliary enteric anastomosis (by approximately 20–30 cm), an antecolic, end-to-side, two-layer duodenojejunostomy is constructed. The outer layer is formed with interrupted 3-0 silk sutures and the inner layer is formed with a running 3-0 Vicryl suture. Mesenteric defects are closed and hemostasis is attained. A closed suction drain is placed in the peritoneal cavity in Morison's pouch and the tip just beyond the underlying pancreaticojejunostomy. Closure is performed in layers in the usual fashion.

## Perioperative Outcomes

Our institutional experience at Mayo Clinic was recently reviewed to include 166 patients undergoing pancreatoduodenectomy for treatment of chronic pancreatitis from 1976 to 2013 (Tables 59.3 and 59.4). This was a longitudinal follow-up study to determine long-term outcomes following pancreatoduodenectomy and differences in practice with respect to chronic pancreatitis management [1]. This study suggested that alcohol was the most common underlying etiology (51%), while the most common clinical manifestation was abdominal pain (88%). Uncertainty or suspicion of malignancy prior to surgery was identified in 48% of patients. A low operative mortality (1.8%) was observed with no operative mortality reported since 1997. Rates of delayed gastric emptying (11%), postoperative pancreatic fistula (8%), and postpancreatectomy hemorrhage (5%) were low. Median length of hospital stay was 12 days. Trends in management of chronic pancreatitis were also evaluated and increasing nonsurgical management options such as endoscopic stenting as well as celiac plexus neurolysis increased over time ($P < 0.001$). This resulted in a doubling of time from presentation of chronic pancreatitis to surgery from 1 year to 2 years ($P = 0.017$).

## Long-Term Results

Long-term results following pancreatoduodenectomy for chronic pancreatitis were assessed with a short form (SF-12) questionnaire administered to all patients still

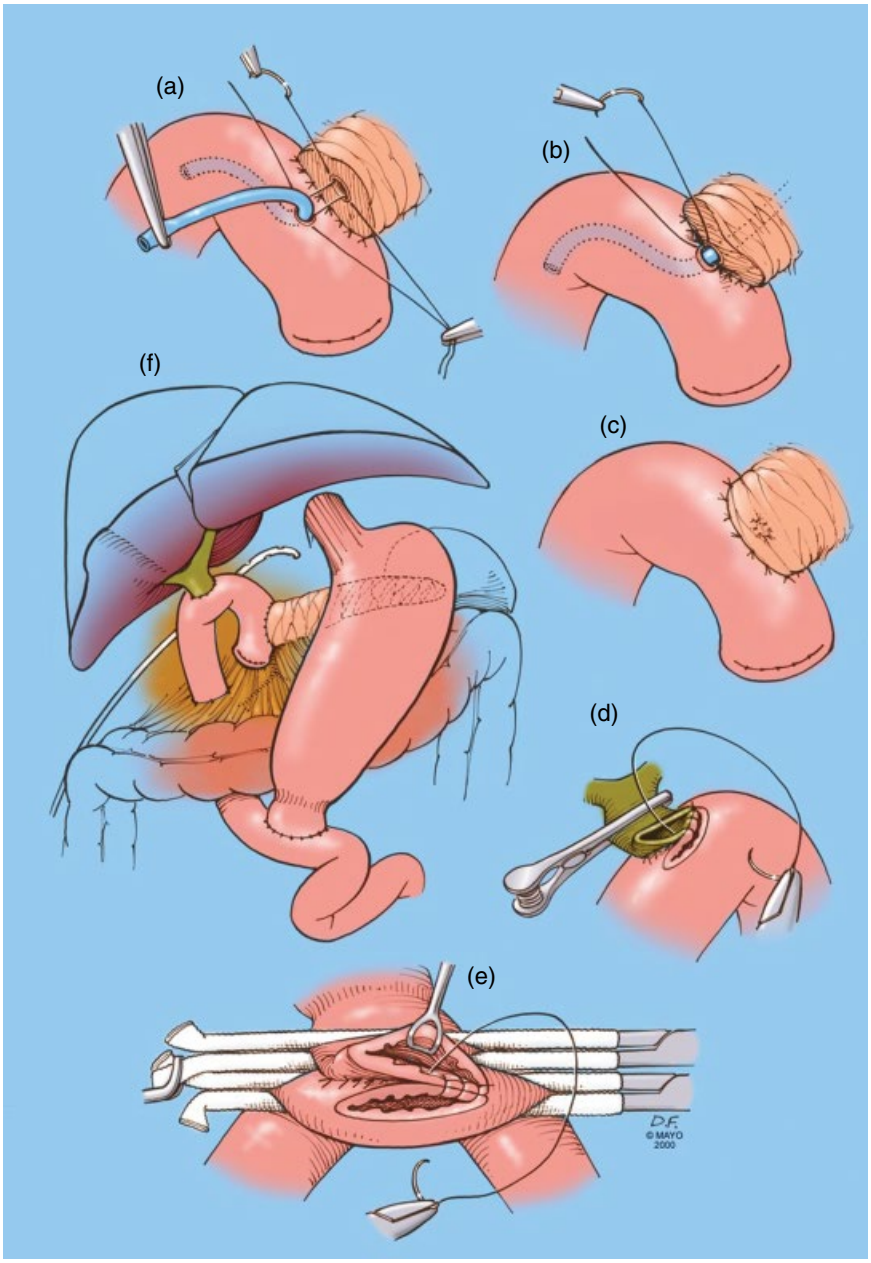

**Figure 59.6** (a) Duct-to-mucosa pancreaticojejunostomy is fashioned. (b) Silastic catheter is used as a temporary stent while completing the inner layer. alive and eligible for study. Results from the SF-12 survey demonstrated that the mean physical component score (PCS) was 43.8 ± 11.8 and mental component score (MCS) was 54.4 ± 7.9. Patients were significantly lower on the PCS ($P < 0.001$) and significantly better on the MCS ($P = 0.001$) than the general US population. Mean pain score out of 10 was significantly lower after surgery at 1.6 ± 2.6 than before surgery at 7.9 ± 3.5 ($P < 0.001$). In long-term follow-up, no pain medication was required in 66% of the cohort. With respect to long-term pancreatic function, new onset of diabetes since the time of surgery was present in 28% of patients and pancreatic enzyme supplementation was utilized by 43% of patients, with 15% of patients reporting frequent diarrhea (Table 59.5).

Long-term survival was also examined (Fig. 59.7). Compared to an age-matched US population, inferior

| Intensive care unit days (median, range) | 0 (0–15) | 1 (0–15) | 0 (0–11) | <0.001 |

survival was noted in patients undergoing pancreatoduodenectomy for chronic pancreatitis. This observation is consistent with other studies and we speculate this phenomenon is due to the underlying chronic pancreatitis as well as comorbidities inherent in this population [21,25]. This is underscored by the large proportion of alcoholic pancreatitis observed and the deaths secondary to causes such as alcoholic cirrhosis seen in the follow-up period. Previous epidemiologic studies in patients with chronic pancreatitis have demonstrated frequent alcohol abuse and cigarette smoking with related deaths due to liver cirrhosis, cardiovascular disease, and malignancies of the mouth, esophagus, and lungs [25]. It should be noted, however, that survival curves become parallel between chronic pancreatitis patients and matched general population subjects beyond 10 years of follow-up. Thus, survival beyond 10 years in patients with chronic pancreatitis who undergo pancreatoduodenectomy approaches that of age-matched general population controls.

## Distal Pancreatectomy

Distal pancreatectomy is rarely indicated in patients with chronic pancreatitis. That said, patients experiencing intractable pain following acute necrotizing pancreatitis with associated "disconnected duct syndrome" secondary to critical stenoses or complete obliteration of the pancreatic duct may be candidates for distal pancreatectomy. In such patients, the pancreas to the right of the ductal stenosis may be uninvolved and distal resection may afford complete relief of symptoms. As with proximal pancreatectomies for chronic pancreatitis, these operations may be complicated by chronic inflammation with resultant fibrosis. Collateral damage to surrounding organs, such as the posterior wall of the stomach, left transverse colon, fourth portion of duodenum, left kidney, and adrenal gland, may occur during dissection away from these structures. With a similar operative incision, set-up, and exposure to proximal pancreatectomy, we begin our operation by dissecting the omentum from the colonic splenic flexure to enter the lesser sac. The omentum is divided at the transverse colon. Short gastric vessels are then serially divided up to the level of the gastroesophageal junction in order to mobilize the stomach. The splenocolic and splenorenal ligaments are divided. A plane is developed between the spleen and tail of the pancreas anteriorly and the left kidney and adrenal gland posteriorly. Dissection is then carried out medially where the splenic artery and vein are divided. The pancreas is then transected at the level of the disconnection. The stump is oversewn if there is

incomplete disconnection, as shown by preoperative ERCP; if complete, the stump is not disturbed.

## Total Pancreatectomy

Total pancreatectomy with islet cell autotransplantation may be indicated in patients with intractable pain due to hereditary or idiopathic pancreatitis [26–28]. However, we would not recommend prophylactic total pancreatectomy in patients with hereditary pancreatitis in the absence of intractable pain. The operative exposure for total pancreatectomy is also similar to that of pancreatoduodenectomy. Spleen preservation may be attempted, but like distal pancreatectomy, may be difficult due to the degree of peripancreatic inflammation and fibrosis. Some technical points will be highlighted in this procedure that combines key steps of proximal and distal pancreatectomy. For total pancreatectomy with islet cell autotransplantation, preserving blood supply to the pancreas until

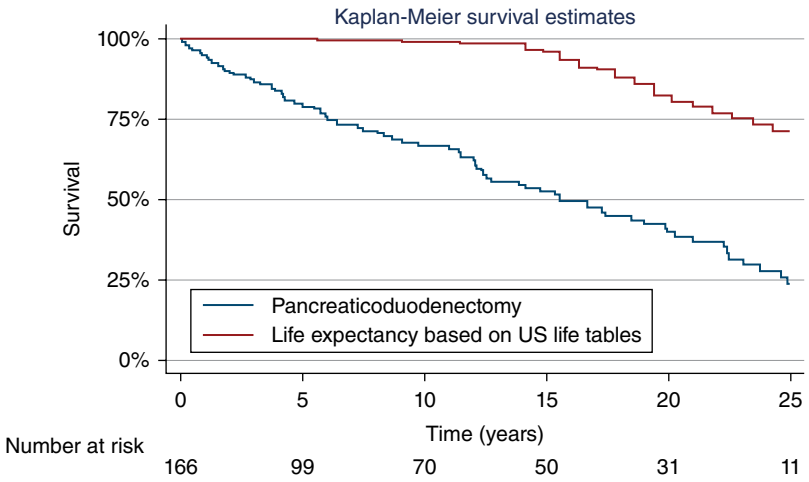

**Figure 59.7** Survival of patients with chronic pancreatitis treated by pancreatoduodenectomy compared to expected survival based on life tables.

terminal stages is advised by mobilizing the entire pancreas before taking its vascular supply. Venous drainage of the stomach deserves special mention, particularly in cases of total pancreatectomy with splenectomy. With the splenic vein, short gastric veins, right gastric and gastroepiploic veins taken during a total pancreatectomy with splenectomy, venous drainage of the stomach is dependent upon the left gastric (coronary) vein. To prevent venous congestion of the stomach, preservation of the left gastric vein is important. Should venous congestion of the stomach occur despite these preventative efforts, distal gastrectomy may be considered.

## Introduction

The introduction of laparoscopy into abdominal surgical practice has revolutionized the approach to complex surgical conditions. The first laparoscopic procedure for chronic pancreatitis was reported in 1994 by Gagner and Pomp who successfully performed a pylorus-preserving pancreaticoduodenectomy on a 30-year-old woman [1]. In 1996, Cuschieri et al. described a series of five laparoscopic distal pancreatectomies (LDP) with splenectomy in patients with chronic pancreatitis, with good perioperative outcomes [2]. Due to concerns of excessive morbidity, the expansion of laparoscopic pancreatic surgery was initially met with resistance. However, over the past 10 years this approach has slowly been integrated into the repertoire of high-volume centers, with rates of mortality and morbidity equivalent to those of open procedures [3]. In addition, with the advent of robotic assistance, surgeons can now benefit from binocular three-dimensional vision, scaling, stabilization of tremor, reduced operator fatigue and improved ergonomics from the console–surgeon interface.

As the majority of surgical interventions for chronic pancreatitis are typically performed through an open approach, data on outcomes following minimally invasive procedures are scarce. Although there are many reports on laparoscopic versus open pancreas surgery in general, these data tend to combine both benign and malignant indications. Since only a few studies have focused solely on benign indications, it may be reasonable to infer that outcomes of larger laparoscopic and/or robotic series can be used to provide insight into the applicability of minimally invasive approaches to chronic pancreatitis. This chapter, therefore, will summarize the limited available data on the safety, feasibility, and efficacy of laparoscopic procedures for chronic pancreatitis, but also draw on the larger available existing reports of minimally invasive pancreatic surgery performed for other indications.

Broadly, surgical strategies for chronic pancreatitis can be categorized into resection type procedures, drainage type procedures, and combination type procedures involving resection and drainage (Table 60.1). In addition, laparoscopic surgery can be broadly defined as pure or robotic assisted.

## Resection Procedures

### Total Pancreatectomy with Islet Autotransplantation

Total pancreatectomy with islet autotransplantation (TPIAT) is a rare procedure that is performed in only a few specialized centers across the United States, with mortality and morbidity up to 16% and 70%, respectively [5]. As expected, the majority of such procedures are completed through an open approach, with laparoscopic or robotic-assisted approaches infrequently reported (Fig. 60.1). A single-center retrospective review of six patients with chronic pancreatitis who underwent fully robotic-assisted TPIAT reported a mean operative time of 712 minutes and mean estimated blood loss (EBL) of 630 mL and no mortality [4]. At 1 month follow-up, all five patients who initially presented with intractable chronic pain syndrome were in the process of weaning off narcotics.

The largest reported case series of robotic-assisted laparoscopic total pancreatectomy includes 10 patients with both benign and malignant pathology [5]. One of three
